COMMENT AND CRITICISM.

THE thoughts and actions of young men of intellectual strength, in whom is vested the future fate of scientific progress in this country, are worth attention, and are of the deepest interest to those who are, or soon will be, no longer explorers of new fields. The meeting last week in New York, of the new society of naturalists, composed almost wholly of young men, was remarkable for the force and directness of the discussions, and the absence of pointless and wearisome talk. It became plain that we have men capable of the best work, and that we are preparing for a brilliant future of investigation, whenever the instrumentalities necessary for fullest success are sufficient. The spirit of independence, and the disregard of purely personal influence, were as great as could be desired. All propositions, from whatever source, met with an equal and critical treatment; and no clique or locality had the slightest claim for consideration. Philadelphia was best represented; while there was a striking absence of delegates from Washington, New Haven, and Cambridge.

THE International conference for fixing upon a universal prime meridian and a universal system of time has at length been called by the State department to meet in Washington, Oct. 1, 1884. Diplomatic proceedings are always expected to go on with a certain dignified leisure; but the arrangements for the meeting of this conference have been delayed far beyond any thing customary, even in diplomacy. The act authorizing the conference became a law in August, 1882. As there was some doubt whether there would be a sufficiently general response to the invitation to insure the success of the conference, a preliminary circular requesting the views of the various governments interested, and an expression of their willingness to enter the conference, was issued from the State department toward the end of 1882. The responses were in some cases favorable, and in others negative or undecided. A desire was felt by the Europeans to have a preliminary discussion of the subject at the International geodetic conference at Rome in October, 1883. The feeling at this conference having shown that there would be little difficulty in the universal adoption of the Greenwich meridian, the final step of calling the conference was taken. Why so late a date was chosen we are not informed.

IN our issue of Dec. 14 we published an article under the title of 'The signal-service and standard time,' criticising the action of the chief signal-officer in not adopting the new standards of time at signal-service stations. We have since learned that our criticism was not well founded, as the information upon which it was based gave an incomplete idea of the position of the service in this matter. It is true that the observers of the service are still governed by the local times of their respective stations; but this is only a temporary arrangement, and will be changed as soon as possible. The reason of the delay is this: the international observation, which is taken at many stations of observation throughout the whole world, is made at seven A.M., Washington time. It is proposed to make this observation eight minutes earlier, or at seven A.M. of the time of the 75th meridian, which is exactly Greenwich noon; but, before this change can be made, the co-operating weather-services and numer-

ous independent observers must first be notified, and their consent obtained. Correspondence has already been begun, and a circular letter sent to all who co-operate in the international work, asking consent to the proposed change. Favorable replies are being received; and there is little doubt that the change will be made, probably Jan. 1, 1885. It should be remembered that the international observation is made largely by observers who kindly co-operate with the chief signal-officer, but who are not under his orders: a change of this kind cannot, therefore, be summarily ordered, but must be made by mutual consent.

It would, of course, be easy to make the change in this country without waiting for the action of observers elsewhere; but this was thought inadvisable. It is a mistake, however, to suppose that the observers are really governed by local times. All observations are made at seven A.M., three P.M., eleven P.M., or other hours of Washington time, and have been so made ever since the establishment of the weather-service. Under Gen. Myers's management, it was thought that it would save confusion at the several stations if the observers kept their clocks at local times instead of Washington time, and observed at the proper corresponding times. This arrangement continues at the present day, though the observations are in reality all made on Washington time. Now, in view of the proposed change in the time of the international observation, it was thought inadvisable to make any change in existing arrangements until the whole change required could be made at one time. The chief signal-officer is in full accord with the reforms in standard time now being introduced, as he has shown in many ways; and he proposes to bring the whole work of the service into conformity with the new system as soon as this can be done without introducing confusion in the different departments of the service.

For more than three hundred years, access to the sacred city of Villa Rica, in Araucania, has been prevented by the Indians. Its name indicates its importance and wealth in the days of Indian supremacy. Now it is a mere collection of ruins, overgrown with herbage and shrubbery; though the forms of antique monuments and buildings are still traceable, and invaluable for archeological study. Very recently, Chile has taken possession of the territory; and its treasures of antiquity are, or will soon be, accessible to ethnologists.

A scheme for conveying brine by pipes from the Cheshire salt-fields to the Mersey, for manufacture there, was started two years ago. The pumping-works are erected, but so far with no results. The scheme was floated on the London exchange; but no 'salt man' joined therein, the general opinion being, that in flowing through pipes for so long a distance the salt would cake, and the stopping-up and corrosion of the pipes would necessitate repairs sufficient to swallow up profits. This would apply to the western New York and Lehigh valley scheme.

It is to be hoped that the state weather-services, of which several are now established, will give attention to questions apart from the ordinary statistical side of meteorological observation, which at present takes so much of their time. Thunder-storms especially need detailed examination from many closely placed observers, such as the state services may possess; for these storms are commonly so small that they often slip, unobserved, through the necessarily coarse meshes of the general signal-service network of stations.

There are as yet, in this country, no observations — at least, none published — of duration or detail sufficient to determine how many hours before its arrival a thunder-storm can be foretold. The antecedent conditions, the area, the average and abnormal tracks, and the duration of these small storms, have yet to be carefully studied. The blowing of the winds about them is imperfectly known. There are no data for determining the relation of the fre-

quency and violence of lightning to the different parts of the storm-area, or for discovering its possible preference for one or another topographical or geological district when it 'strikes.' Some of these points have been studied in Europe, but much remains to be done even there. Indeed, there is no department of meteorology in which local and closely placed observers can attain an end so distinctly original, and so far out of reach of the government service, as in this; and ten years' observations from stations near one another, and numerous enough, would yield results of the greatest practical and theoretical interest.

LETTERS TO THE EDITOR.

**** Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Mr. Francis Galton's proposed 'family registers.'

MANY obliging letters reach me from America, offering family information for my use, of the kind described by my friend, Mr. Henry F. Osborn, in your issue No. 39, as that which I want.

The scheme there described is one that I circulated to gather opinions and to obtain guidance before determining its precise form. This is now done, and with your permission I will say a few words upon it.

The information wanted applies to so many different individuals in the same family group, and differs so much in minuteness, according to the degree of kinship, and it has to be arranged in so special a manner, that a copious explanatory description and numerous tables are requisite. There is no real complexity; nevertheless, I feel assured, that, without considerable guidance, endless mistakes will arise. Correspondents will send pages of useless matter; and, on the other hand, they will be silent about simple facts, the absence of which will seriously diminish the value of otherwise copious returns. I therefore found it necessary to prepare a book containing a full account and explanation of what was wanted, in order to exhibit the varous hereditary tendencies that converge upon any given person, and containing at the same time all the necessary schedules. This I have done: it is in the press, and will be published about Christmas by Macmillan, and will be procurable in America.

As regards the prize scheme, I found it inadvisable to restrict it to medical men, and I have thrown it open to 'British subjects resident in the United Kingdom.' I could not extend it farther, owing to the extreme difficulty of verifying statements of facts alleged to have occurred abroad. My self-imposed task will be hard enough as it is. The conditions of the prizes are fully explained in a fly-leaf to the English edition.

Let me take this opportunity of saying a few words about another book to which my name is attached as editor, and which will appear at the same time. It is called the 'Life-history album,' and was prepared by a sub-committee, of which I was asked to be chairman, who acted by direction of the Collective investigation committee of the British medical association. This book gives explanations and schedules for the registration of *personal* data as life advances, just as the *Record* gives for a comprehensive account once for all of *family* data; the details, however, being very different in the two books: they are much more medical in the 'Album.' It is believed by the Life-history sub-committee that the medical value to the possessor, of his own life-history up to date, would be considerable, and of great service to the children. They also feel, that, if these albums are commonly kept, it will be possible hereafter to obtain extracts of a great many of them for purely statistical purposes, which would be of high scientific value. The albums will contain a vast amount of information which is now left to perish, and the lack of which is a great hinderance to obtaining that complete and comprehensive knowledge of the family antecedents of numerous persons, which is at present the paramount desideratum to inquirers into heredity.

I shall be very grateful to any of your readers who may see my forthcoming 'Record of family faculties,' and may make themselves acquainted with what I want, who will send me information concerning their own families. But I cannot explain my wants with sufficient brevity either here or by letter, and must, perforce, refer those who care to know them to the book itself. FRANCIS GALTON.

42 Rutland Gate, London, December, 1883.

The red sunsets.

I have recently noticed several articles upon the gorgeous sunsets lately seen in this country, and desire to put down a few notes on the same.

The red glare was so brilliant the evening of Nov. 27, that the fire-alarm was sounded in New Haven, Conn., calling out the engines. On the succeeding night the deep red glow was magnificent, appearing far above blocks in the busiest part of the city. Careful observation has shown the phenomenon very nearly as brilliant at sunrise as at sunset. The deep red has appeared the last of all the *colors* in the sky at sunset, and invariably the first in the morning. There has been, in addition to this, a grayish afterglow at night, and in the morning a slight effulgence betokening the rising sun. This afterglow, or effulgence, has made it possible to observe the sky directly at the region where the deep red had just appeared, or was soon to appear; and this invariably showed fine fleecy clouds at a great height, generally stratified horizontally, and extending with slightly increasing density to the south-west or south-east horizon. These light stratified cloud-appearances were visible, even though the sky appeared absolutely cloudless a few minutes before and after the effulgence. The stars the past month have shown, night after night, most extraordinary twinkling, and the air has been saturated with moisture. Again and again, with a high barometer and a perfectly clear sky, sometimes even with a cold north-west wind, I have been astonished to find the relative humidity a hundred per cent.

As to a probable explanation, the wildest theories have been advanced: meteors, cosmical dust, zodiacal light, comets, electricity, volcanic gases and ashes, etc., have each had their adherents. Of these, the last is the only one worthy of consideration. The recent (?) eruptions at Java, 11,000 miles distant, are advanced as a sufficient cause for the presence of the ashes.

That volcanic ashes may be carried great distances is well known. Loomis's 'Meteorology,' p. 77, gives an instance in which ashes were carried 700 miles to the north-east and 1,200 miles to the west of the volcano Coseguina. Notwithstanding this evidence, it

would seem well-nigh incredible that the upper currents and the power of suspension of the ashes could have combined in carrying the particles 11,000 miles.

Common cloud-coloring is caused by diffraction from particles of dust or water-droplets. Light of different wave-lengths has a greater or less power of passing through dust, smoke, water-droplets, ice-spiculae, etc. It is stated that the light at the blue end of the spectrum has less power of penetration than at the red end: hence the light is sifted out, as it were; and the blue disappears first, then the orange, and, last of all, the red (Scott's 'Meteorology,' p. 205). Why may it not be possible that the blue, having the greater refrangibility, is refracted to such an extent as to be intercepted by the earth long before the red has disappeared? Taking into account the great abundance of moisture, the appearance of ice-spiculae (which, however, may have been volcanic ashes), and the fact of the appearance being precisely similar to that ordinarily seen upon clouds, there is no necessity of resorting to the at best doubtful theory of the volcanic origin of the phenomenon.

The similarity between the ordinary sunset and this phenomenon was finely illustrated one evening by a magnificent red-cloud sunset, manifestly caused by clouds comparatively near the observer. These clouds, gradually fading away, were followed by the deeper red so prominently noticed recently, and evidently produced by ice-spiculae at a great distance.

G. A. N.

ON the evening of Dec. 22 a red glow was noticed upon the clouds which overspread the whole heaven. On the 23d the cloudiness was complete, and even denser than on the previous evening; but the glow tinged the whole visible vault down to the eastern horizon, and continued for at least an hour after sunset, fading first in the east. On the 24th the clouds were slightly broken. Before 5 P.M. (standard time) a yellowish tinge began to be apparent. At 5.10 the color was reddish, and reached the horizon on all sides. At 5.20 the color was a deeper red, with clouds more broken. At 5.30 the clouds were thin, and showed faint but distinct blood-red color on the eastern horizon, though a little brighter in the west. At 5.40 the cloudiness was reduced to a partial thin film, but a dusky redness was still perceptible in all parts of the sky. At 5.55 the sky was everywhere thinly veiled, but a dark ruddy tint could still be faintly seen all around the horizon. At 6.10 the sky was mostly cloudless, though few stars were visible. A dark-red glow could be discerned in all parts of the heavens, and in the west it rose in broad, ill-defined bands from the position of the sun. At 6.20 no clouds, but only stars of first three or four magnitudes were visible. At first no ruddiness was seen, but shortly it became unmistakably apparent. It was a faint dusky red still obscurely barred in the west. This glow lasted two hours and eight minutes after sunset: atmosphere calm; thermometer sinking from 28° to 25° F. The observations possess interest in connection with similar ones recently made in various parts of the world. ALEXANDER WINCHELL.

Ann Arbor, Dec. 25, 1883.

Plant distribution in Lower California.

I would call attention to the fact, that many Arizonian, New Mexican, and Mexican species of plants, together with more northern species, are found on the narrow strip of tablelands in northern Lower California. Among them I may mention Quercus Emoryi and Q. pungens, Astragalus Sonorae, Fouquiera splendens, and many others, with Geranium caespitosum of the Rocky Mountains, Ivesia Baileyi of Nevada, Galium pubens, Quercus agrifolia, the common Pteris, Aquilegia truncata, and a number of introduced (?) species well known throughout the United States. CHARLES R. ORCUTT.

San Diego, Cal., Dec. 15.

Kames near Lansing, Mich.

A few years since, I spent one or two days at Mason, some ten miles south of Lansing, Mich. I had hoped to return at some future time, and complete my observations upon some peculiar ridges of sand, gravel, and bowlders in the vicinity of that village; but, as it may be some years before I shall be able to do so, I would like to lay the observations before the readers of *Science*, hoping that some of the Michigan readers may have time to investigate the subject fully.

The surface is here nearly plane. The front moraine of the Saginaw glacier lobe lies some thirty-five miles to the south-south-east, beyond Jackson. These ridges trend towards this moraine from some unknown point north of Mason to another unknown point ten or more miles south-south-east. I was informed that some of these ridges were six and eight miles in length, and are sometimes used as a highway. The drainage is to the northward at present, parallel with the course of the ridges, though I noticed one or two instances where creeks had intersected the ridges instead of being guided by them. The ridges seemed to persist in a northerly course, though with many local exceptions. I noticed one instance in which the main ridge turned nearly at an angle of 100°; but the main course was continued farther north in the heavier ridge, and at the elbow by a much lighter one. The ridges are quite variable in elevation. Perhaps the mean lies between twenty and thirty feet. The slope was not measured, but is, as a rule, too great to permit their being crossed by teams at the natural grade. The component material is all water-worn, and evidently deposited through the agency of water. The bowlders are of all sizes, up to twelve inches. Perhaps forty per cent were sandstone, similar in lithological characters to the subjacent rock strata. The remainder were metamorphic or igneous species, except some limestone pebbles.

Whether these ridges were formed in the longitudinal crevasses and river-channels of the ancient glacier, or not, must be determined by a more careful survey of the region than the writer was able to make in the few days spent at Mason. L. C. WOOSTER.

Eureka, Kan., Dec. 17, 1883.

Longevity in a fasting spider.

On the fifteenth day of October, 1881, I enclosed a spider in a small paper box. From that day to the seventh day of May, 1882 (204 days), I carefully watched and daily inspected the prisoner, and can positively affirm that he partook of no food or water. The box in which he was confined was as clean and white as white paper could make it, and remained so while he continued to occupy it, except for the appearance of a few dark specks which I suppose to be the droppings of the prisoner. I carefully observed him every day, and sometimes two or three times in a day; and I was unable to detect any emaciation or symptoms of weakness, or even irritability of temper, while he lived. He always appeared as active, and looked as plump and healthy, as he did the day I dropped him into the box, until within three days of his death, when I first observed that when the box was tipped he would fall from his position.

WILLIAM JONES, M.D.

Newburgh, N.Y.

The pedunculated lateral-line organs of Gastrostomus.

The recent discovery of a form of deep-sea fishes closely allied to the Eurypharynx described by M. Vaillant, by the U. S. fish-commission steamer Albatross, has afforded excellent opportunities for a more thorough examination of the external characters presented by the skin of these forms. This species of eurypharyngoid fishes, — the one studied by Professor Theodore Gill and myself, and named by us Gastrostomus Bairdii, — upon closer examination of the region of the lateral line, discloses features which appear to be somewhat remarkable, if not unique, amongst organs of the kind hitherto known.

The lateral line is in its usual position, and begins just behind the head. There is no mucous canal covering the end-organs; but these are isolated in groups of from two to five, standing on the skin in an oblique row at the hind margin of each muscular somite. The groups consist, in fact, of from two to five stalked organs, as shown in fig. 1 in the cut. The stalks are not pigmented at all, except at the tips, where they support a discoidal cup-shaped organ, which is more or less completely pigmented internally. In some instances these end-organs are very distinctly cup-shaped; in others that form is less clearly apparent. The base from which the stalks arise is not so deeply pigmented as the surrounding skin, which is very densely loaded with pigment, and very black. The pigment on the basal disks is, in fact, arranged in a slightly reticular manner: the pigmented layer is continuous with the outer clear sheaths of the stalks; and the medullary portion of the stalk can be seen in some cases to consist mainly of nerve-fibrils, which pass outwards to the cup-like organs at the tip. In a few cases there appears to be a clear space in the centre of the cup-like end-organ, as shown in fig. 2, surrounded by a dense circle of pigmented tissue.

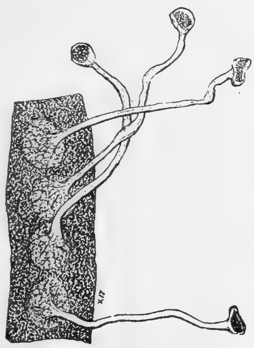

FIG. 1.

The function of these side-organs of Gastrostomus is apparently tactile, or may serve a special purpose at the great depth in which this fish lives. They remind one very forcibly of the rows of comb-like end-organs which have recently been described by F. Leydig on the head of the cave-fish (Amblyopsis spelaeus DeK.); but in this case the stalks are not so robust, and are much more slender, and relatively longer. It may even be that these lateral bands of side-organs of Gastrostomus are phosphorescent at their tips, like the side-organs of scopelids, steroptychids, etc. The lateral bands made up of short oblique rows of these organs, as the fish moves through the water at a depth of five to fifteen hundred fathoms, may possibly become luminous.

Fig. 2.

That they are also sensory in function there can be no doubt, being found in the usual position of the lateral line, as in common fishes, and, like it, probably innervated from the vagus. The stalks are fully a sixteenth of an inch long, and are apparent on the side when the fish is immersed in alcohol or water, and project outwards quite freely, so as to be visible along the sides when the fish is viewed from above. These naked side-organs remind one also somewhat of the naked nerve-hills on the sides of the body of young fishes, such as those of Gadus and Gambusia. In the former the stiff sensory hairs of the nerve-hills project immediately from the surface of the hill into the surrounding water, but in no embryo fishes am I aware that the side-organs are ever pedunculated. In fact, the side-organs of Gastrostomus Bairdii, like the whole of the rest of the organization of the animal, particularly its skull and branchial apparatus, present an extreme phase of specialization. J. A. RYDER.

RETROSPECT AND PROSPECT.

WITH the present number *Science* enters upon the second year of its existence. The time is an appropriate one, while extending a cordial greeting to its readers, to call their attention to its work and its purposes. That a journal of popular science, with the varied and informal contents appropriate to a weekly publication, would, if judiciously conducted, prove a welcome addition to the list of American periodicals, has long been felt by those most interested in scientific progress; but, when the numberless difficulties in the way of success had to be considered in detail, they were found to be numerous and perplexing. The general scope of the journal was the only feature about which little doubt could be felt. Two quite distinct yet inseparable objects of existence presented themselves: one was to keep the readers of the journal informed of the progress of science in all its branches; the other, to give expression to the well-matured views of scientific men upon all public questions connected with the increase of knowledge, and thus to become, so far as possible, an organ of public opinion upon scientific affairs.

In pursuing the latter object the path of duty was too plain to require discussion. The journal must be the organ of no individual, clique, or party, but must, while preserving entire impartiality, give plain and fearless expression to its convictions upon any question in which the interests of science at large were involved. How far it has fulfilled this requirement is a question to be decided by its readers and patrons, without argument from ourselves.

The question of the contents of the journal in detail was a far more intricate one. Shall its articles be designed exclusively for the specialist, or shall the results it makes known be popularized by the omission of all purely technical nomenclature? Shall they be long and elaborate, or short at the risk of incompleteness? Shall they be strictly and purely scien-

tific, or shall the speculative, sentimental, and poetic sides of things be allowed to appear? Shall its chronicles of progress consist of the briefest possible memoranda of all important current researches, each duly labelled for reference, or shall a selection be so made that each account shall be prepared with a statement of the origin, place, and object of the research, with a view of making its true significance known? In the case of scientific articles, where shall we draw the line between what belongs to this journal and what to those intended for the publication of original researches? These are merely a few of the more important questions which the projectors were obliged to meet, and which they have endeavored to decide in the way best fitted to give general satisfaction. The result is seen to a certain extent in the present number; but some aspects of the subject may be profitably considered from a broader field of view.

The difficulty arising from the technical nature of scientific researches admits of being partially resolved, so far at least as the general principle is concerned, by a very obvious consideration. Science must be almost as much popularized, to be made accessible to all scientific readers, as to be readable by the educated public who were never in a laboratory. A new formula in thermodynamics is as incomprehensible to a botanist as to a member of Congress. The average physicist knows as little about a brachiopod as the average merchant. What the most modest well-read clergyman may fairly think he knows about Darwinism far exceeds all that the common run of chemists really do know. The obvious conclusion is, that, should we seek to make discussions of current scientific researches accessible to all scientific readers, we cannot avoid being somewhat popular in style.

On the other hand, if the journal should present to its readers only that class of reading-matter which they get for nothing in the daily papers, its very existence would be a superfluity. To justify the publication of any periodical devoted to a specialty, it must present its readers with a kind of matter which they cannot find in the public prints.

The term 'popular science' is often made to include a class of discussions quite different from the presentation of scientific truths in common language. Science at the present day is the ideal of democracy. Its work and its honors, from the highest to the lowest, are thrown open, without restriction, to all men. There is no authority which can say to the humblest worker, "I know this, and you do not: I am therefore above your criticism, and you must accept my statements without essaying to inquire into the validity of their foundation or the soundness of their application." There is no tribunal in the scientific world which has the power to proclaim what is and what is not proved; what problems are and what are not solved. To one who has never considered this state of things, the first impression felt is, that it must imply universal anarchy; that in a community where every one has equal authority — that is, no authority at all — there can be no such thing as permanent and widely received opinions. But the very opposite is the truth. A system which requires every doctrine to stand on its own merits, and to maintain itself only by being proof against every assault, is the very one under which truth stands the best chance of showing its permanency. A long-established scientific doctrine stands like the Matterhorn, not through being protected from assault, but by being able to resist the storms of ages.

Now, there is in every civilized country a class of writers who avail themselves of this principle of equality to discuss subjects of which they have no accurate knowledge, to propound new theories, and to attack old ones. A voluminous literature thus arises which is the work of the lay element in the scientific community, and which is therefore sometimes called popular science. Such productions must stand on their merits as much as the propositions of the professional scientific man, and are entitled to consideration only according to their merit. The policy of *Science* is to admit nothing to its pages which does not belong to the domain of knowledge, excluding with especial care speculations upon subjects like the nebular hypothesis in which many active minds are so fond of indulging.

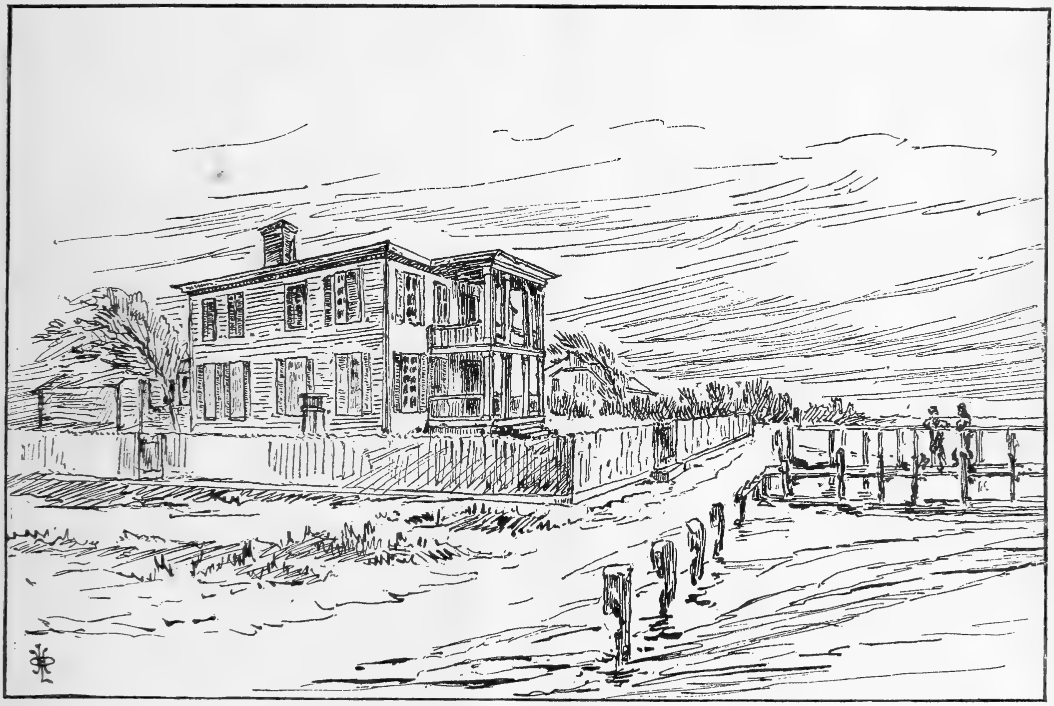
After a careful consideration of the form in which the results of current researches should be presented, it has been decided to substitute for the weekly summary heretofore presented brief discussions of current work which shall be of more interest to the general reader. To combine brevity with perspicuity in such cases is often a very difficult problem, in which the golden mean affords the only solution.

The form in which *Science* is now presented has been to a large extent the result of careful inquiry among its accessible friends and patrons. Manifestly, the plan in view cannot be developed in a single number; but we hope that a few weeks will show our purpose to make *Science* of greater value than heretofore to our widening circle of readers.

THE MARINE LABORATORY OF THE JOHNS HOPKINS UNIVERSITY.

THE Chesapeake zoölogical laboratory was instituted by the trustees of the Johns Hopkins university as part of the biological department of that university in 1878, and Dr. W. K. Brooks was appointed director. Its purpose is twofold, — to furnish complete facilities for original studies in marine zoölogy, and a place for more elementary instruction. The fauna of the southern waters of the United States was selected for study. In providing thus a place for advanced work, this university has taken the initiative among American colleges; the various summer schools held along our coast being more particularly concerned in instruction than in investigation of new problems. The first and second sessions in 1878 and 1879 were held in the lower parts of the Chesapeake Bay. In 1880 the laboratory was moved to Beaufort, N.C.

Beaufort has been a favorite haunt of naturalists ever since 1860, when it was visited by Drs. Stimpson and Gill. No better place could be selected for the study of the forms of life in southern waters. It lies at the mouth of Old Topsail Inlet, ten miles west from Cape Lookout, protected from the ocean, except in its worst moods, by a broad sand-bar, and yet so near that an hour's sail carries one out upon the high seas. Owing to the configuration of the coast-line, the warm Florida current flows by and almost bathes the shore. This warm current, setting up from the shores of the Gulf, sweeps along with it many pelagic animals which belong to a hotter climate. Yet, while the ocean-life is decidedly southern, the climate of Beaufort is not oppressive : indeed, the place and its neighbor, Morehead City, are summer resorts. The town, standing almost in the ocean, is swept by nearly constant breezes, which temper the heats of July and August.



MARINE LABORATORY AT BEAUFORT.

The place is quite accessible, being only two miles from Morehead City, the eastern terminus of the North Carolina midland railway, and may be reached by steamer from Norfolk *viâ* Newberne, and by rail from points north and west *viâ* Goldsboro.

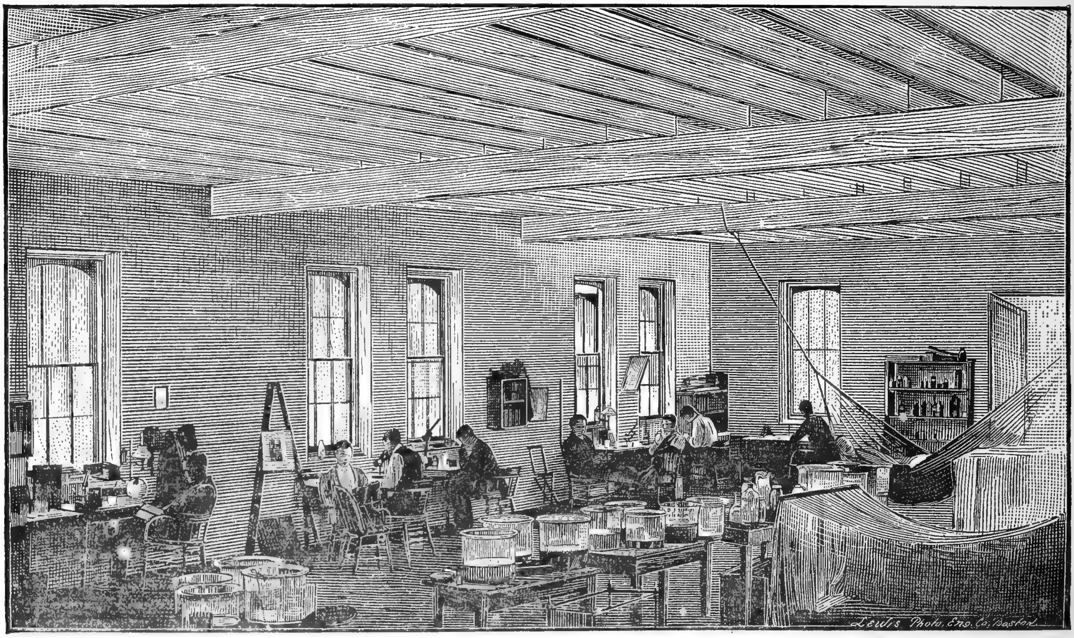
The site of the laboratory at Beaufort is most convenient, being at the very water's edge. A pier built out from the front gate to the deep water crosses a flat of black soft mud, bare at every low tide, and a place where the

specimen hunter is richly rewarded. A search here obtains for one crabs and hermits, Porcellana in tubes with Chaetoptorus, Alpheus, annelids, mollusks, echinoderms, ascidians, and barnacles upon the wharf-piles. The general student can here find material to illustrate his study of almost any of the larger groups literally within a stone's throw of his work-room. From the end of the wharf at high water the dip-net secures not only quantities of things to interest the general student, but crustacea, medusae, Sagitta, and larvae of the greatest interest to the specialist.

Across the channel which runs along the water-front is a large sand-shoal, uncovered during several hours every day; and here are the favorite haunts of myriads of interesting creatures. I say myriads advisedly, for one of the most striking features of the Beaufort fauna is the extreme abundance of almost all the forms which occur there at all. The inner side of this shoal is literally honeycombed by a colossal species of Balanoglossus often three feet long; and on the outer edge are to be found Mellita in great numbers, and dead shells of Mellita inhabited by Thallasema, as many as one has the patience to collect. All over the shoal creep Limulus. In the deeper water just off the shoal are Renillas without limit and the beautiful nudibranch Pleurophyllidia.

Trawling in the sound procures starfish, echinoids and ophiurans, Chiton, Fissurella, Leptogorgia, Astrangia, often with large masses of coral. High tides sweep in pteropods, Sagitta, Leucifer, Siphonophora, pelagic larvae, and medusae of great interest, such as Liriope and Cunina. The rocks upon the artificial breakwater furnish Penophora, tubularian hydroids, and several species of actinians. On shells inshore are found the known genera of entoproctan Bryozoa.

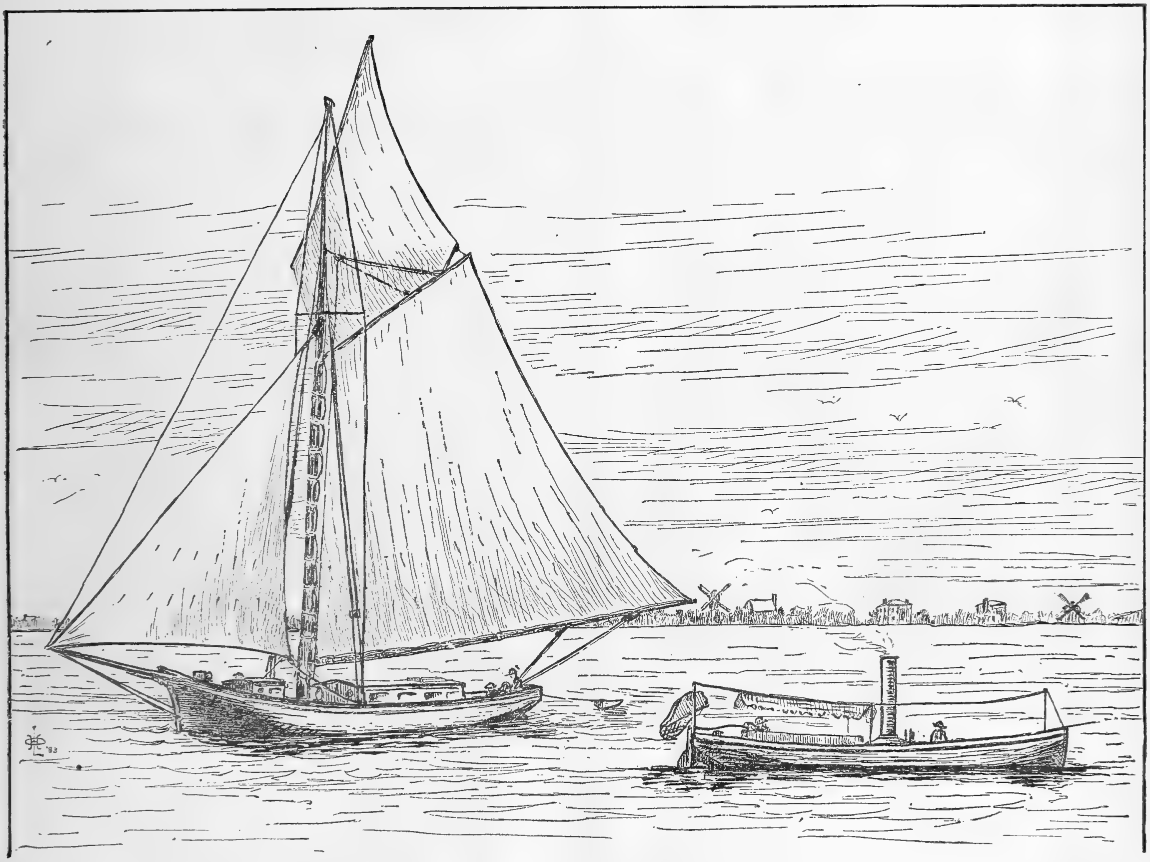
But I cannot give a complete list of the fauna here, nor even mention all the attractions. I have not tried to do so, but merely to intimate the exceeding variety and abundance of forms of the greatest interest. Though Beaufort has been the resort of naturalists for the last twenty-five years, it has not yet been to any degree exhausted.



INTERIOR OF MARINE LABORATORY AT BEAUFORT.

Since Beaufort was felt to be a somewhat transient location for the laboratory, a permanent building, with all the modern conveniences for work, was not erected. A two-storied double house, with eight rooms, was rented for work-room; and houses adjoining were secured as living-quarters for the party. Thus, both in their work and in the life out of the shop, the party was kept pretty well together; and the members had that opportunity of forming personal acquaintance with one another, the

value of which does not require comment. The furnishing of the building was simple, — tiled tables, with lights only; and other luxuries were dispensed with. Not even were pumps erected to maintain a constantly renewed stream of salt water circulating through the aquaria. In their place was used the cheaper and very effective device of aeration by means of a stream of fresh air constantly forced through the aquaria by a Sprengel pump.



YACHT AND STEAM-LAUNCH OF JOHNS HOPKINS MARINE LABORATORY.

Facilities for work were not, however, in the least curtailed; and all the apparatus for capture and means for getting about were provided. The dredge and trawl, spade and sieves for bottom fauna, towing and dipping nets of silk bolting-cloth for surface forms, and many special traps devised for the capture of particular animals, formed a complete array of appliances. Besides its small boats, the laboratory has for several years possessed a steam-launch of Herreschoff pattern, twenty-seven feet long, and with a draught of about thirty inches, capable of taking us to any points about the sounds and rivers, or even of venturing out to sea when Old Prob did not menace with danger-signals. The launch was most useful, and was in service almost every day for dredging, trawling, or carrying parties out to tow in the open ocean. She is, however, but a passing stage, as her name Nauplius implies; and we hope some day to possess a full-grown steam-vessel, in which we can with safety explore the deeper waters offshore, which are as yet almost entirely unstudied.

During the past summer the navy has received an important addition in the form of a yacht, to be called the Zoea, though at present otherwise registered. She is a full-rigged sloop, forty-seven feet long, fifteen feet beam. She won a silver cup in a regatta upon the Potomac while in her former service, and her speed was a pleasant feature of collecting-trips

in her. Her sailing qualities do not at all unfit her for our work. Her cabin has ample accommodations for four persons, and could stow eight; and the cuddy forward has room and all the utensils for the cook: so that cruises to a distant dredging-ground can be undertaken without inconvenience, by a fair-sized party.

Of the usefulness of the Chesapeake zoölogical laboratory we may feel assured, though it is still in its infancy. It has held six sessions. During that time there has been a total attendance of fifty, of whom fourteen have been in attendance at least two sessions. These fifty men have been gathered from more than twelve different colleges, and are at present located in fourteen different states, besides two who came from Canada, one from Cambridge, Eng., and one from Japan.

In 1879 the laboratory was in co-operation with the Maryland fish-commission; and Dr. Brooks devoted most of his own time during the season to a study of the oyster, with especial reference to its embryology and its artificial propagation. The theoretical results of his work are of the greatest significance; but he succeeded in artificially fertilizing the oyster's eggs, and shedding such light upon the habits of reproduction that the greatest interest was aroused, and zeal in the search for some practicable method of oyster-culture, to replenish the waning oyster-beds. This interest has resulted in the discovery of a practicable method.

I will not recapitulate all the scientific papers published as resulting from work done in the laboratory: suffice it to say, that important memoirs have been published upon Lingula, Squilla, Leucifer, Renilla (the last two being published in the *Philosophical transactions* of the Royal society), Thallasema, and a monograph, not yet complete, of the Hydromedusae of the south coast. Beside these memoirs, the various members of the laboratory have written numerous shorter papers, which have been published in the *Quarterly journal of microscopical science*, the university *Studies*, and Carus's *Zoologischer anzeiger*. These articles, embodying the results of the laboratory's work, number, in all, fifty-nine separate titles.

For the most part, the laboratory has been morphological in the aspect of its work; not exclusively so, however, for both in 1881 and 1883 Dr. Sewall worked there upon selachians with reference to the equilibrium-sense function of the semicircular canals.

Last summer (1883), after three years at Beaufort, the laboratory was moved back to the Chesapeake Bay, and located in a building rented from the Hampton normal school. The location was in many respects not a good one, for it was far away from the best collecting-grounds and supplies of pure salt water; but it was selected to permit the laboratory to co-operate with the Maryland state oyster commission in experiments upon artificial propagation, and other expedients for a rapid and reliable method of restocking the oyster-beds in Chesapeake Bay. Lieut. Winslow, U.S.N., detailed for special service, was with us during most of the summer; and in the early part of the season the oyster-police boat, Gov. Hamilton, was stationed at the lower end of the bay.

The results of the season's work are not yet so far worked up as to permit one to speak about them. We had among us Mr. William Bateson of Cambridge, Eng., who came over to work upon Balanoglossus. His work includes a more thorough knowledge of the larval history of Balanoglossus than has been hitherto attained, and promises much that will be of greatest interest in respect to that most problematical creature. Henry L. Osborn.

THE DETERMINATION OF THE OHM.

The importance of having a uniform standard of electrical resistance is so apparent, that the establishment of a unit which shall be suitable for practical work, and will also satisfy the demands of electrical science, has for a number of years been regarded by all electricians as of the first importance.

The requirements of such a standard are, that it shall be easily reproduced or verified; that it shall have a simple relation to the units of work, heat, etc., and therefore be based on the fundamental units of length and time; and, finally, that it shall be of so great resistance as to be suitable for all ordinary practical work.

In the year 1862 the British association decided that a unit of resistance based simply on the earth quadrant, or ten million metres, as the unit of length, and the second as the unit of time, would be of such a magnitude as to best satisfy the requirements of the case. Experiments were then undertaken by a committee of the British association with a view to the construction of standards which should accurately represent this unit of resistance, or *ohm* as it was called. Owing to some minor defects in experimentation, and to an unaccountable error in the determination of the coefficient of self-induction of the revolving coil, their result was in error. This standard British association unit, as it is now called, is confessedly too small; but it is the basis of the

so-called ohm-coils that are in current use. The latest experiments indicate that the value of the British association unit is .9867 ohms; this result having been obtained by Lord Rayleigh by two distinct methods, and by Mr. Glazebrook by still another method. But different observers still differ quite widely in their results.

The International committee on electrical units, which met in November, 1882, in Paris, in view of the present unsettled state of the case, and the necessity for the speedy adoption of a suitable standard, decided that when the length of a column of pure mercury of one square millimetre section, and having a resistance of one ohm, shall have been determined to within one part in a thousand, the ohm shall then be defined as the resistance of such a column of pure mercury of the determined length; and the different governments represented were urged to prosecute experiments for the accurate determination of this length. For this purpose, among others, an appropriation of twelve thousand five hundred dollars was made by the last Congress of the United States. The work on the unit of resistance is under the charge of Professor Rowland of the Johns Hopkins university; and the experiments are being carried on in Baltimore, both at the university and at Clifton Park, two miles from the city. Owing to some unexpected delays in the construction of necessary apparatus, the work that has been undertaken first is the determination of the specific resistance of mercury in British association units. This has been experimented upon by measuring the resistance of columns of pure mercury contained in glass tubes of various calibers and lengths, so that the resistances of the columns experimented upon range from one to ten British association units. The remaining part of the work is the determination in ohms of the resistance of the British association standard used in this determination of the specific resistance of mercury. Two principal methods will be employed for this purpose.

First, the resistance will be found by means of the mechanical equivalent of heat. The apparatus used by Professor Rowland, in his well-known work on that subject, has been set up for this purpose. It is proposed to heat some non-conducting liquid, such as alcohol or turpentine, by means of the heat developed by the passage of the current of electricity in a conductor whose extremities are kept at a known difference of potential. The same heating will then be produced, under the same circumstances, by purely mechanical means; and the resistance of the conductor will thus be determined directly from the work-equivalent of the heat developed in the conductor.

The second method to be used is that of Kirchoff, as modified by Rowland in his determination of the ohm in 1876. The instruments will, however, be in large part new, and constructed expressly for this research; so that a new set of instrumental constants will be involved. A third method, the earth-inductor method of Weber, will also be used if time permits.

For these experiments it is proposed to use, as a source of electricity in the calorimetric method, fifty Planté cells charged by a small dynamo machine. For measuring large currents of electricity an electrodynamometer has been constructed, with the Helmholtz arrangement of two large coils and a single small suspended coil. The diameter of the large coils is about one metre: that of the small suspended coil is about twenty-five centimetres. There are two sets of large coils, — one wound with large wire, about no. 8; and the other with much smaller, about no. 15. There are also two small suspended coils wound to correspond. This arrangement gives the instrument great power and range. The divided circle was made by Fauth & Co. expressly for this instrument. Four induction-coils are to be wound in four parallel equidistant grooves, turned on the outside of a brass cylinder about one metre in diameter. These coils will each consist of about two hundred turns of no. 15 copper wire. This arrangement will afford great variety in the manner in which the several coils may be combined; for the inductive action of each coil upon each of the others may be taken, giving three simple combinations for each coil.

The trustees of the Johns Hopkins university have kindly placed the Clifton House at Professor Rowland's disposal for the conduct of these experiments; and, as it stands in extensive grounds at a considerable distance from the road, it will be peculiarly suitable for delicate electrical experiments. Piers have been built for the different instruments, and a small steam-engine set up for supplying the power necessary for running the dynamo machine and the mechanical equivalent of heat apparatus. The actual experimentation will be carried on, under Professor Rowland's direction, by A. L. Kimball, assisted by H. R. Goodnow and Ensign Louis Duncan, U.S.N.; the latter having been specially detailed for the work by the Navy department.

It is hoped that a satisfactory conclusion will be reached by September, 1884.

PECULIARITIES OF WEATHERING IN THE POTTSVILLE CONGLOMERATE.

THE striking characteristics of the Pottsville conglomerate in eastern Pennsylvania are its highly siliceous composition and its solidity. Owing to a consequent great durability, it stands out prominently along the different mountain ridges which surround the anthracite coal-basins; but though, as compared with the associated rocks, its resistance to weathering is very great, the effects of this action are everywhere revealed on examination.

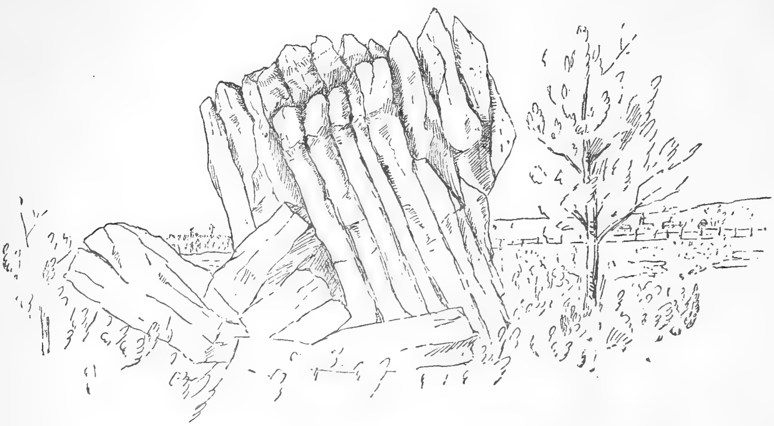


FIG. 1.—Outcrop showing weathering along the plane of stratification.

The surfaces of the finer and more compact varieties are frequently seen to be covered with numerous small holes, or pit-marks, resulting from the removal of separate grains. Blocks of the coarse pudding-stone have generally a very rough surface, the pebbles projecting half their thicknesses above the surrounding matrix; and fragments of this rock are sometimes so thoroughly permeated and softened by percolating water that they can be crushed to grains by the hand.

Along the planes of stratification the subaerial decay of this rock is particularly well marked. Deep clefts and gashes are found along these planes, which frequently cut entirely across large masses, dividing them into separate slabs. This action is best developed along the upturned edges of steeply inclined dips, where water has the best opportunity to accumulate and to prolong its action in incipient grooves; and, with isolated blocks only slightly inclined, the increased decay along the upturned edges, due to this same cause, is often noticeable. A somewhat remarkable fact about such weathering is, that clefts parallel to the stratification are found in an apparently homogeneous rock. In such cases a difference or deficiency of cementing-material must be the directing cause.

Weathering action across the plane of stratification is exhibited in its first stages by shallow and narrow grooves, which run sinuously across the rock. These have their origin in little streams of rain-water which flow from the surface down the sides of the rock. Once started, such a groove forms a channel whose drainage capacity constantly increases as the depression enlarges; and by degrees the fine groove grows to a decided fissure, half a foot or more across, which the continued action of rain-water cuts deeper and deeper into the rock. This fissure is generally of approximately uniform breadth; but, as it enters farther into the rock, the water drains into it from all sides, and an enlargement is sometimes formed at the end, which I have seen to result in an almost circular hole, completely penetrating the rock.

The most peculiar and remarkable of all the results of this weathering action are, however, those produced by a superficial action in the plane of stratification. Over flat surfaces of the rock, white, washed-looking patches occur; but where a slight depression exists, the water

FIG. 2.—Isolated conglomerate mass showing increase of weathering along the planes of stratification on the upturned edge.

accumulates and stands, and as a consequence the grains of the rock in immediate contact are loosened, and, on the evaporation of the water, blown away. Thus the depressions which were at first, perhaps, only a fraction of an inch, are deepened, and, by degrees, basins of as much as a foot in depth are eaten out. These are often so regular in outline, and with such smooth sides, that they might readily be mistaken for pot-holes; and, indeed, it was such that I first considered them, and was puzzled to account for the peculiar channel in which the waters producing them must have flown. A distinguishing feature of these depressions, however, is that each one has an outlet cut down to near the bottom of the cavity; and this is easily accounted for, on the theory of their subaerial origin, by considering, that, once such a basin started, the overflow would always pass off over the lowest edge, and as the basin increased in depth, by continued dissolving action, so would the outlet also. A further confirmation of this is furnished by the facts, that in inclined rocks the outlet is always towards the lower rim, and the bottom of these cavities is either horizontal or sloping towards the outlet. In the bottom is also generally accumulated a small amount of gravel and sand recently loosened from the bed. These basins are of all sizes, up to three feet

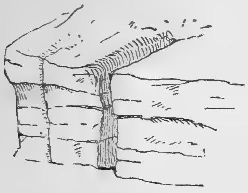

FIG. 3. — Weathering across the plane of stratification.

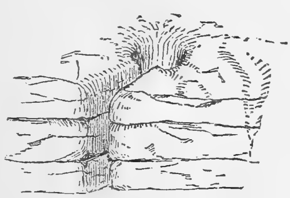

FIG. 4. — Enlargement at end of fissure.

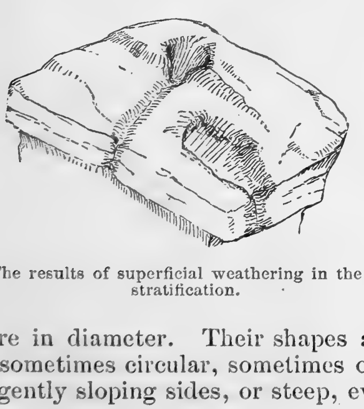

FIG. 5. — The results of superficial weathering in the plane of stratification.

and more in diameter. Their shapes are varied, — sometimes circular, sometimes oblong, — with gently sloping sides, or steep, even recurving ones, according to the character of the rock. They are frequently connected in strings by narrow channels, like a miniature lake system; and, with the enlargement of these channels, a simple, deep groove across the rock results, all this action combining to give the rock a very rugged appearance.

The very preponderance of silica grains in this rock, to the exclusion of any good cementing-material, is probably one of the chief reasons for its decay. Rain-water is, without doubt, one of the most active agents; but the secretions from the thick growth of moss and lichens, which frequently covers the surface and penetrates into the cavities of the rock, have probably also their effects. The deep gashes produced by the action of the rain-water offer excellent opportunities for frost to continue the work of destruction; the ice forming in these clefts, and, by its prying action, completing the separation of the already partially divided mass.

As a consequence of this wide-spread weathering process, large continuous outcrops are rarely found. Collections of huge blocks generally mark their site; and the thick accumulations of smaller fragments, which are so frequently found over conglomerate areas,

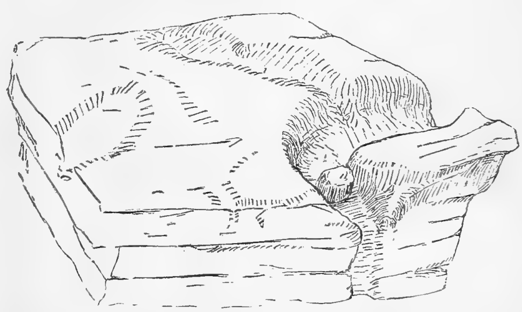

FIG. 6. — Large basin in conglomerate, with a double outlet.

result, without doubt, from the further subdivision of these larger blocks.

The products of decay either accumulate in place, are washed down by streams, or blown away by the wind. On the top of Broad Mountain, and elsewhere, the disintegration *in situ*, I am informed, is so great that the loose rock is dug out as gravel; and, in valleys watered by streams flowing down from conglomerate ridges, deep deposits of siliceous sand are found, valuable for building-purposes.

The decay of the sandstones and shales, associated with or underlying the conglomerate, is even more pronounced than in that rock. Changes of color, especially from the greenish tints to red, brown, and yellow, are the most

frequent results; and this is often accompanied by a softening to a barely coherent sand or clay. Erroneous conclusions are thus frequently drawn from surface indications, as to the nature of the underlying rock.

The subject of the decay of rocks has recently been admirably treated by Dr. T. Sterry Hunt,[1] chiefly with regard to the crystalline rocks; and it deserves to be further studied, in the case of these more recent rocks, from its evident importance in chemical geology, its interesting and well-known relation to topography, and its economic bearing. ARTHUR WINSLOW.

Pennsylvania geological survey.

ELECTRIC LIGHT TESTS AT THE LOUISVILLE EXPOSITION.

THE display of electric lights at the Louisville exposition, as to number, was the greatest ever made in and around one building. The number of lights used varied somewhat, but the average was about as follows: —

	Incandescent lights.	Arc-lights.
Edison isolated lighting company . .	4,600	–
U. S. electric light company	210	29
Fort Wayne Jenney electric light company	–	100
Thomson Houston electric light company	–	36

The jury — consisting of Benjamin Rankin, Louisville; W. W. Weaver, Chicago; Charles Smith, J. A. Tanner, M.D., and H. W. Eaton, Ph.D., Louisville — was not appointed till about three weeks before the close of the exposition: hence thorough tests were impossible.

As the U. S. company did not enter into the contest, there was no competition on the incandescent lights. However, the following tests were made: connection was made with a circuit containing 315 lights at what was considered an average point in the circuit; and fifteen lamps, five of them new and the balance selected systematically from the circuit while lighted, were tested in a specially constructed photometer-room while indicator-cards were being taken from the engine.

A Bunsen photometer with a twelve-foot bar was used, and the horizontal intensity determined with the carbon at an angle of 45°. The intensity of the (nominally) 16-candle lights varied from 12 to 19.66 candles, averaging 13.77 candles; and the average horse-power was 32.50. These figures give 9.70 lights, or 133.57 candles, per mechanical horse-power.

The action of the automatic regulator was then tested with a light in the photometer, first 50 and then 100 lights being thrown off and on. In one of the six cases the variation was 1.23 candles, but in all the others it was less than .66 of a candle. Only a momentary flicker was noticed as the lights were thrown off and on.

The jury reported as follows: "The tests of the Edison system are most satisfactory as to the efficiency of the various appliances, the steadiness of the light produced, and the general results. It is a matter worthy of note, that

[1] The decay of rocks geologically considered. By T. Sterry Hunt, LL.D., F.R.S. *American journal of science*, September, 1883.

during the 100 days of the exposition, with over 4,000 lights burning, there was not at any time a suspension of light from failure of the appliances of the Edison electric lighting company."

Of the arc-lights, lamps were chosen, one at a time, from the circuits, and inserted in the same circuit in the photometer-room, care being taken that no change was made in the circuit adjustments. Indicator-cards were taken from the engine used, during the testing of each lamp. The strength of current, and fall in electromotive force, were also determined with an amperemeter and voltmeter; but, as only relative results were desired, these instruments were not graduated.

The photometer-bar was fifty feet long; and tests showed that there was no reflection vitiating the results, from the dead-black surface of the walls of the room. The photometric tests were made with an Edison incandescent light as a standard. Fifteen tests from candle to incandescent, and ten from incandescent to arc lights, were made for each lamp, five arc-light tests being between the same number of tests of the standard.

The arc-light was cut out during the tests of the standard, and a new cup was allowed to form before the next set of tests was made.

The dynamos were worked to their full advertised capacity in regard to the number of lights in the circuits; and four lights were tested in each case, with the following results: —

	Jenney.	Thomson Houston.
Total number of lights in circuit	16	12
Total mechanical horse-power	26.92	11.79
Average horizontal intensity in candles .	496.5	291.8
Average intensity per horse-power . . .	306.5	296.9
Relative efficiency of lamps from light, current, and fall in electromotive force .	1.055	1

From these tests, and an examination of the dynamos, lamps, regulators, etc., the awards were made as follows: to the Edison company, for isolated lighting, medals for the best incandescent system and light, and for the best dynamo and lamp for the incandescent light; to the Fort Wayne Jenney electric lighting company, medals for the best system and dynamo for arc-lighting; but, to the Thomson Houston electric lighting company, a medal for the best arc-light, because, "while the light of the Jenney was slightly stronger per horse-power of electrical energy used in the lamp, it was not quite so steady as the Thomson Houston."

H. W. EATON.

THE LATE MR. DARWIN ON INSTINCT.[1]

AT the meeting of the Linnean society this evening (Dec. 6) a highly interesting posthumous paper on Instinct, by Charles Darwin, will be read and discussed. We have been favored with an early abstract of the same, which we here present to our readers.

After detailing sundry facts with reference to the migratory instincts of different animals, Mr. Darwin proceeds to suggest a theory to account for them. This theory is precisely the same as that which was subsequently and independently enunciated by Mr. Wallace in *Nature*, vol. x. p. 459. Thus, to quote from the essay: "During the long course of ages, let valleys become converted into estuaries, and then into wider and wider arms of the sea; and still I can well believe that the impulse [originally due to seeking food] which leads the pinioned goose to scramble northward would lead our bird over the trackless waters; and that, by the aid of the unknown power by which many animals (and savage men) can retain a true course, it would safely cross the sea now covering the submerged path of its ancient journey."

The next topic considered is that of instinctive fear. Many facts are given showing the gradual acquisition of such instinctive fear, or hereditary dread, of man, during the period of human observation. These facts led Mr. Darwin to consider the instinct of feigning death, as shown by sundry species of animals, when in the presence of danger. Seeing that 'death is an unknown state to each living creature,' this seemed to him 'a remarkable instinct:' and accordingly he tried a number of experiments upon the subject with insects, which proved that in no one case did the attitude in which the animal 'feigned death' resemble that in which the animal really died; so that the instinct really amounts to nothing else, in the case of insects at all events, than an instinct to remain motionless, and therefore inconspicuous, in the presence of danger. From the facts given with regard to certain vertebrated animals, however, it is doubtful how far this explanation can be applied to them.

A large part of the essay is devoted to 'Nidification and habitation,' with the object of showing, by an accumulation of facts, that the complex instincts of nest-building in birds and of constructing various kinds of habitations by mammals, all probably arose by gradual stages under the directing influence of natural selection.

The essay concludes with a number of 'miscellaneous remarks' on instincts in general. First the variability of instinct is proved by sundry examples; next the fact of double instincts occurring in the same species; after which, "as there is often much difficulty in imagining how an instinct could first have arisen," it is thought "worth while to give a few out of many cases of occasional and curious habits, which cannot be considered as regular instincts, but which might, according to our views, give rise to

[1] From *Nature* of Dec. 6.

such." Finally, cases of special difficulty are dealt with. These may be classified under the following heads: 1. Similar instincts in unallied animals; 2. Dissimilar instincts in allied animals; 3. Instincts apparently detrimental to the species which exhibit them; 4. Instincts performed only once during the lifetime of an animal; 5. Instincts of a trifling or useless character; 6. Special difficulties connected with the instinct of migration; 7. Sundry other instincts presenting more or less difficulty to the theory of natural selection.

The 'conclusion' gives a summary of the general principles which have been set forth by the whole essay. This, therefore, we shall quote *in extenso*: —

"We have in this chapter chiefly considered the instincts of animals under the point of view whether it is possible that they could have been acquired through the means indicated on our theory, or whether, even if the simpler ones could have been thus acquired, others are so complex and wonderful that they must have been specially endowed, and thus overthrow the theory. Bearing in mind the facts given on the acquirement, through the selection of self-originating tricks or modification of instinct, or through training and habit aided in some slight degree by imitation, of hereditary actions and dispositions in our domesticated animals, and their parallelism (subject to having less time) to the instincts of animals in a state of nature; bearing in mind that in a state of nature instincts do certainly vary in some slight degree; bearing in mind how very generally we find in allied but distinct animals a gradation in the more complex instincts, which shows that it is at least possible that a complex instinct might have been acquired by successive steps, and which, moreover, generally indicates, according to our theory, the actual steps by which the instinct has been acquired, inasmuch as we suppose allied instincts to have branched off at different stages of descent from a common ancestor, and therefore to have retained, more or less unaltered, the instincts of the several lineal ancestral forms of any one species, — bearing all this in mind, together with the certainty that instincts are as important to an animal as their generally correlated structures, and that in the struggle for life under changing conditions slight modifications of instinct could hardly fail occasionally to be profitable to individuals, I can see no overwhelming difficulty on our theory. Even in the most marvellous instinct known, that of the cells of the hive-bee, we have seen how a simple instinctive action may lead to results which fill the mind with astonishment.

"Moreover, it seems to me that the very general fact of the gradation of complexity of instincts within the limits of the same group of animals, and likewise the fact of two allied species placed in two distant parts of the world and surrounded by wholly different conditions of life, still having very much in common in their instincts, support our theory of descent, for they are explained by it; whereas, if we look at each instinct as specially endowed, we can only say that it is so. The imperfections and mistakes of instinct on our theory cease to be surprising: indeed, it would be wonderful that far more numerous and flagrant cases could not be detected, if it were not that a species which has failed to become modified and so far perfected in its instincts that it could continue struggling with the co-inhabitants of the same region, would simply add one more to the myriads which have become extinct.

"It may not be logical, but to my imagination it is far more satisfactory, to look at the young cuckoo ejecting its foster-brothers, ants making slaves, the larvae of the Ichneumonidae feeding within the live bodies of their prey, cats playing with mice, otters and cormorants with living fish, not as instincts specially given by the Creator, but as very small parts of one general law leading to the advancement of all organic bodies, — Multiply, vary; let the strongest live and the weakest die."

DR. GRINEWETZKY'S CROSSING OF NOVAIA ZEMLIA.

On the $\frac{1}{14}$ November, Dr. Grinewetzky described, before the Geographical society of St. Petersburg, his travels on this island. He first started on foot on the $\frac{5}{17}$ August, with Kriwoskeya and a Samoyede (a few of whom are found near Karmakuly). The weather was beautiful, the thermometer 5° C.; but soon after reaching a mountain with a very extensive view, where they passed the night, they were overtaken by a violent snow-storm, and compelled to return. In April, 1883, the Samoyede Hametz crossed the island to the south-east coast, and found Samoyede *chums* (tents). Hearing of this, Grinewetzky, accompanied by Hametz and another Samoyede, set out in sleds drawn by dogs. They had scarcely any food for the dogs, but were assured they would find plenty, as wild reindeer were abundant. This proved not to be the case; and on the fifth day the poor dogs were near starving, when a large herd of reindeer was met. Many shots were fired without effect, due to the difficulty of seeing distinctly, as the men's eyes were much affected by the reflected sunlight, and, in addition, their hands were benumbed by the cold (— 20° to — 25° C.). At last two were killed, and the dogs saved. At first a number of very steep parallel ridges, principally of black slate, were encountered. At some places, hard and exceedingly steep snowdrifts had to be avoided by ascending the surrounding hills. Excepting these drifts, there was but little snow, as, if loose, it was swept away by the strong east-south-east wind prevailing. After the watershed between the west and east coasts is passed, the country becomes a low plateau, and the snow softer and rather deep and regular. On the $\frac{30\text{ April}}{12\text{ May}}$, with the temperature at — 27° C., they prepared to return, as they had already proceeded two days farther than was intended, and no chums were in sight; and, although one of the Samoyedes said the chums were only three miles distant, they began the return.

This expedition is important as the first crossing of Novaia Zemlia by civilized man. According to information collected by Tjagin (1878–79), Pakhtus-

sow, Ziwolka, and Moisseew (1832–39), and a few notes by Höfer and Nordenskiöld, and from his own observations, Grinewetzky gives the following sketch of the south island of Novaia Zemlia. It may be divided into three parts. The northern lies between Matotschkin Shar on the north and the Pukowaja River on the south: this part has the highest mountains (four thousand feet), forming isolated groups rather than ranges. The central part, extending to the Karelka and Belushia Rivers, has five or six parallel ridges, running generally north and south; black slate is common; and the watershed is about seventeen miles from the west coast. The southern part is a rather low plateau: the Goose Land (Gusiwaya Zemlia) is included in this part, which is free from snow by the end of June, and in July has a rather rich vegetation, especially on the gently sloping ground.

Dr. Grinewetzky also expressed the opinion that the wild reindeer of the northern island belong to a totally distinct sub-species from those of the southern island.

LOSS OF NITROGEN FROM ARABLE SOILS.

The renewed attention of agriculturists has of late been drawn to the question of the nitrogen supply of cultivated soils. On the one hand, Schulz, in Germany, claims to have brought about a gain of nitrogen on a sandy soil by means of the cultivation of lupines, and manuring with kainit. On the other hand, Lawes, Gilbert, and Warington,[1] in England, have published results which show that a very considerable annual loss of nitrogen occurs in the drain-water of cultivated fields; and experiments by Dehérain,[2] in France, show, according to his interpretation of them, an alarming decrease in the total nitrogen of the soil in the course of a few years, and in spite of abundant manuring.

Schulz's experiments have added nothing to our knowledge of the natural supply of nitrogen to the soil, and it is not proposed to consider that topic here. The results of Lawes, Gilbert, and Warington, and of Dehérain, however, have attracted much attention. If they are to be accepted without reserve, they lead to the conclusion that the fertility of our cultivated fields, so far as it depends upon their nitrogen, is being removed in the drainage-water, or in other ways, at a comparatively rapid rate.

The instigation to Lawes, Gilbert, and Warington's experiments was given by the observation, that, in the field-experiments carried on for a series of years at Rothamsted, scarcely a third of the nitrogen of the manure was found in the crop under the most favorable conditions, while, in those cases in which no mineral manures were applied, the deficit was much greater. The most obvious conclusion was, that there must be a great loss of nitrogen in the drainage; and experiments were instituted to test this idea. Their earlier experiments were with three lysimeters. Excavations were made under and around an area of a thousandth of an acre. The mass of soil thus isolated was supported by perforated iron plates, and surrounded by masonry, thus leaving the soil with its natural structure. The quantity of water percolating through this soil has been determined since 1870; and since May, 1877, its content of nitrates has been also determined. The soil was uncultivated and free from vegetation. Numerous interesting facts are disclosed by these determinations, but that which now interests us chiefly is the quantity of nitrogen found in the drain-water. This amounted, in the average of four years, to 46, 36, and 44 pounds per acre, at depths respectively of 20, 40, and 60 inches.

Subsequently the same experimenters have determined the nitrates in the drainage-waters from their experimental wheat-field, each plot of which is drained by a single lateral at a depth of 24 to 30 inches. Having no means of measuring the drainage, the authors take, as the basis of their calculation of the loss of nitrogen, the amount of drainage-water yielded by the 60-inch deep lysimeter at the same time. On this assumption, the annual loss of nitrogen varied from 15 and 16 pounds per acre, on unmanured plots, to as high as 74 pounds per acre.

It is greatly to be regretted that the authors were not able to measure the drain-water in these experiments; for the method which was adopted to supply the deficiency leaves much to be desired. The soil in the lysimeter was uncultivated and bare of vegetation: that of the wheat-field was cultivated, and bore crops of wheat varying considerably in amount. Both these circumstances affect the amount of drainage-water. Cultivation, especially of a clay soil such as that at Rothamsted, may affect very markedly the ease with which water passes downward through it, the amount of water which it can retain in its interstices, and the rapidity of evaporation from its surface. The growth of vegetation exerts a still greater effect on the movements of water in the soil. It has been shown by numerous observers, that much more water evaporates from a soil covered with vegetation than from a bare soil, and that consequently much less of the rainfall percolates through the soil. The diminution of the drainage-water in this way has also been directly proved by Wollny. Furthermore, the various plots in these experiments carried unequal quantities of vegetation, so that the amount of evaporation due to this source must have been unequal also. It appears, then, in the highest degree improbable, that the quantity of drainage-water actually was the same for each plot as was assumed, and unlikely that it was as great as was assumed. When we add to these considerations the fact, that it is uncertain whether the soil of the lysimeter represented an average of the soil of the field, and, further, that all errors of the lysimeter are multiplied a thousandfold when the results are expressed per acre, we are forced to the conclusion that the figures given for the total amount of drain-water, and consequently those also for the total loss of nitrogen in this way, can be, at best, only approximations, and are most likely too large.

[1] *Journ. roy. agric. soc.*, xvii. and xviii.

[2] *Annales agronomique*, viii. 321.

Even if we allow them their full value, however, they do not in all cases cover the entire loss of nitrogen. On the basis of the results just described, the authors have calculated the average annual amount of nitrogen in the manure, crop, and drainage of fourteen experimental wheat-plots for a period of thirty years. In seven cases the nitrogen found in crop and drainage is from 14 to 40 pounds per acre less than the amount applied as manure. Analyses of the soil of one plot in 1865, and again in 1881, showed that about a third of this amount was still present in the soil, the latter having gained nitrogen. The authors believe the remainder either to have escaped the drain-tiles, and been carried into the lower strata of the soil, or to have been set free in the gaseous state in the soil.

Dehérain's experiments were intended to determine the total loss of nitrogen by the soil. Three series, of four plots each, were laid out, each plot having an area of one are (equal to about four square rods). The first series bore fodder-maize; the second, potatoes; the third, beets, fodder-maize, and esparcette successively. During the first three years, one plot in each series was unmanured; one received, per hectare, 80,000 kilograms of stable-manure; one, 1,200 kilograms of nitrate of soda; and one, 1,200 kilograms of sulphate of ammonia. During the following four years none of the plots received any manure. At the beginning of the experiments, and at the end of three and seven years respectively, the percentage of nitrogen in the soil was determined. With the aid of these determinations, a balance was struck for each plot between the nitrogen originally present and that added in the manure, on the one hand, and that removed in the crops and remaining in the soil at the close of the experiments, on the other hand. In every case except that of the esparcette, a very great loss of nitrogen was found to have occurred. The following table contains the annual loss of nitrogen from a portion of the plots, reduced to pounds per acre to compare with Lawes, Gilbert, and Warington's results: —

Maize plots.

Manuring.	First period.	Second period.
Stable-manure	− 257	− 118
Nitrate of soda	− 358	− 183
Sulphate of ammonia	− 320	− 132
Nothing	− 338	− 93

Esparcette plots.

Manuring.	First period (roots and maize).	Second period (esparcette).
Stable-manure	− 808	+ 327
Nitrate of soda	− 663	+ 134
Sulphate of ammonia	− 732	+ 135
Nothing	− 567	+ 149

Compared with the losses observed in Rothamsted, some of these figures are enormous, being over nine times as great as the highest obtained there. When we consider that the soil was calculated to contain, to a depth of 14 inches, only about 7,000 pounds of nitrogen per acre, they seem to show that but a comparatively short time would be required to reduce the supply of nitrogen to the point at which culture ceases to be profitable.

In order to be able to judge of the force of these results, it is desirable, in the first place, to consider somewhat more in detail the method by which they were obtained. At the beginning of the experiments the soil was found to contain .204% of nitrogen; and this was made the basis of the calculation for all the plots. It is highly improbable that this assumption of uniformity among all the plots, as regards nitrogen, is correct; and, when we consider that a difference of .001% corresponds to a difference of about 34 pounds of nitrogen per acre, we are led to question, not only the accuracy of Dehérain's results, but the possibility of discovering small losses of nitrogen by means of soil-analysis. The absolute quantity of nitrogen was calculated on the further assumption that one hectare of soil to a depth of 35 centimetres weighed 3,850,000 kilograms, which, again, involves a possibility of error. Finally, the determination of the quantity of nitrogen removed in the weighed crops rests on assumptions as to the percentage of nitrogen they contained, while it is a well-established fact that considerable variations in this respect occur. Especially does heavy manuring with nitrogenous fertilizers, such as some of these plots received, tend to increase the percentage of nitrogen in the crop.

To recapitulate: Dehérain's conclusions involve three improbable assumptions; viz., pertect uniformity of soil as regards nitrogen, equal weight of soil over equal areas, and a uniform and average percentage of nitrogen in the crops.

On the other hand, all but a few of the plots show a loss of nitrogen; and while, for the reasons just stated, the accuracy of the reults is very questionable, it would appear that we must admit some loss of nitrogen to be probable in most of the experiments.

Aside from these considerations, however, there are others which should be borne in mind. During the first three years the manured plots were very heavily manured. Sulphate of ammonia and nitrate of soda were applied at the rate of 1,070 pounds per acre, and stable-manure at the rate of over 35½ tons per acre, — quantities much greater than would be used under any ordinary conditions. Moreover, from the fact that the unmanured plots yielded nearly as large crops at the close of the experiments as at their beginning, we may conclude that the soil was naturally of good quality.

Dehérain's calculations show that but a very small proportion of the nitrogen of the manures was utilized by the crops; and, though the exactitude of his figures may be questioned, the general result is what we should expect. A large excess of available nitrogen was evidently present in the soil. The latter was occupied by crops for only four or five months of the year, at most (except the esparcette plots); and, during the remaining two-thirds of the year, leaching, and other

natural agencies which tend to remove nitrogen from the soil, had undisputed possession of the field. When the manuring was discontinued, the losses of nitrogen, according to Dehérain's results, sank very materially, though still remaining considerable.

From the combined results of both these investigations, it would appear that we may fairly conclude, that, under ordinary conditions of tillage, there is considerable loss of nitrogen from the soil. Lawes, Gilbert, and Warington's experiments show that much nitrogen may escape in the drainage; and, according to their calculations, more nitrogen was removed from six out of thirteen of their experimental plots in crop and drainage, during thirty years, than was supplied in the manure. From Dehérain's experiments we learn that a soil under constant tillage may grow poorer in nitrogen in spite of heavy manuring. In fact, of all the elements of the soil which are required for plant-growth, nitrogen is one of the most mobile. The soil, it is true, has the power of fixing ammonia in insoluble combinations; but both ammonia and organic nitrogen are constantly being converted into nitric acid in every fertile soil, and this compound the soil has no power to retain. Under natural conditions, when the soil is thickly covered with vegetation, this nitric acid is assimilated by the roots as rapidly as it is formed, while the compact state of the soil hinders access of oxygen to the deeper layers, and thus moderates nitrification. This action of plant-roots in arresting nitrates on their way to the lower strata of the soil is shown very plainly in Lawes, Gilbert, and Warington's experiments already cited. While the land carried a crop of wheat, the drain-water contained little or no nitrates, except when an excess of nitrogen had been given in the manure; but as soon as the crop was removed, nitrates made their appearance in the drain-water.

But an untilled soil is not only protected against losses of nitrogen: it is also in condition to retain the nitrogen brought to it in rain, snow, etc. This comes partly in the form of ammonia, which is fixed by the soil, and partly in the form of nitric acid, which is fixed by the vegetation. In this way a soil carrying permanent vegetation may be continually gaining nitrogen. This is indicated by Dehérain's results on the esparcette plots, and, aside from them, is sufficiently evident from the facts, that at some period of the world's history all its nitrogen must have existed in the free state, and that, so far as we know, the combined nitrogen of atmospheric precipitates is the sole natural source of nitrogen to the soil.

Tillage alters this state of things very materially. By breaking up and mellowing the soil, it facilitates the access of oxygen, and increases the rapidity of nitrification. At the same time, the natural vegetation is replaced by one occupying in many cases but a part of the ground, and occupying it for but a portion of the year. Add to this that by diminishing the amount of vegetation we diminish the evaporation of water, and thus leave the soil moister, and at the same time expose it more fully to the sun's rays, thus rendering it warmer, both of which conditions favor nitrification, and we see that cultivation both increases the flux of nitrogen in the soil, and decreases the means of utilizing it.

The clear recognition of this state of things brings with it the suggestion of at least a partial remedy, which is to keep the soil occupied as fully and as long as possible with growing vegetation. The roots of the living plant lend to the soil an absorptive power for nitrogen compounds, similar to that which it has of itself for other elements of plant-food, and enable it to store up these compounds against future needs. To prevent a loss of nitrogen, we must make use of this power as fully as possible, both in the system of cultivation adopted, and in other ways. After taking off a crop in the early fall, instead of leaving the land bare, let it be sown with some quick-growing crop, e.g., rye, which shall serve solely to store up the nitrogen which would otherwise be lost. In the spring this crop is ploughed under, and furnishes nourishment for the succeeding crop. Such a plan has been adopted here and there with advantage. Its general use would turn largely, of course, on the question of expense. On a virgin soil containing already large reserves of nitrogen, no appreciable benefit might result from it, though even there the *preservation* of the present fertility is worth striving for. But between this condition and the state of relative exhaustion to which the soil of our older states has been reduced, there must be a point where saving nitrogen in this way would be of immediate as well as prospective benefit. The exact methods of applying the principle involved to particular cases it is not the province of this article to discuss. The principle itself, however, is very simple. Keep growing roots present in the soil as long and as extensively as possible to seize upon the nitrogen (and other elements as well) which will otherwise be washed out of the soil, and to store it up in insoluble forms, ready for the needs of future crops.

H. P. ARMSBY.

THE LIFE OF HAMILTON.

Life of Sir William Rowan Hamilton, Knt., LL.D., D.C.L., M.R.I.A., Andrews professor of astronomy in the University of Dublin, and royal astronomer of Ireland, etc.: including selections from his poems, correspondence, and miscellaneous writings. By ROBERT PERCEVAL GRAVES, M.A., sub-dean of the Chapel royal, Dublin. Vol. i. London, *Longmans, Green, & Co.*, 1882. 20+698 p. 8°.

THIS volume, which forms one of the latest issues of the Dublin university press series, has been prepared partly through the assistance furnished by the Board of Trinity college, and published by the provost and senior fellows. Mr. Graves had at first, however, undertaken the biography of Hamilton on his own responsibility, and unassisted in the labor which it involved; and we ought not to pass unremarked his especial fitness for the performance of this arduous task. In the first place, he was unconnected with Hamilton by

any tie of kindred. Both had experienced unbroken friendship from early youth. Hamilton, in his will, had nominated Mr. Graves as his literary executor; and the sons of Hamilton asked him to undertake the task, seconded by the approval of several of the most influential friends of the great mathematician. And, while Mr. Graves has to confess himself to be no mathematician, he combined — what was of greater import — the requisite amount of personal knowledge with the appropriate scientific attainments and freedom from incompatible engagements. In his preface, the author very gracefully says, by way of allusion to his self-distrust in assuming the control of Hamilton's voluminous papers and correspondence, "I gave a reluctant consent, wishing that the memory of my friend had been more fortunate, but at the same time conscious that by me would be devoted to it the warmth of honest affection and admiration, and the desire to be just and truthful."

In recording the successive mathematical discoveries of Hamilton, Mr. Graves does not attempt accurately to appreciate their importance, or to give them their exact place in connection with precedent or subsequent discovery. He has taken pains to secure that the mathematical statements in his work are correct, giving them generally in the *ipsissima verba* of Hamilton himself, and, where in doubt, consulting friends of competent authority. This course begets a desirable confidence in the accuracy of the entire work, — which is, however, taken as a whole, almost purely a literary biography. It is not so much to the credit of Mr. Graves as may at first seem probable, that he leaves the letters of Hamilton almost unaided to tell the story of his life. The contributions from the author's pen are very largely of the nature of disconnected comment, usually upon a subjoined letter: in fact, there is nothing approaching a continuous analysis of the life or work or character of Hamilton, such as we may hope to see in a subsequent volume, and which Mr. Graves, from his evidently keen insight, and thorough acquaintance with the subject of his biography, is of all persons most fully qualified to write. Nor could the book have been otherwise than improved, had he drawn very largely from his own association and personal recollection of Hamilton in the interest of those who never knew him.

The name of William Hamilton has conferred a threefold distinction upon the kingdoms of Great Britain. An early article on the subject of this biography reminds its readers that each isle has its Sir William Hamilton. The Englishman was noted for his patronage of art, the Scotchman was among the first in philosophy, and the Irishman was among the first in mathematics. And the promise of greatness the young Irishman gave at that early day failed in no sense of entire fulfilment in the development of mature years. Of the three Hamiltons, William Rowan was easily the chief. We recall in this connection what some of his most distinguished contemporaries have said of him. The celebrated Dr. Brinkley, astronomer royal of Ireland (later Bishop of Cloyne, and whose successor in the former office the youthful Hamilton was so soon to be), said of him at the age of eighteen, "This young man, I do not say *will be*, but *is*, the first mathematician of his age." The brilliant and learned Professor Sedgwick, referring publicly to Hamilton in 1833, spoke of him as "a man who possessed within himself powers and talents perhaps never before combined within one philosophical character." Hamilton was born in Dublin, Aug. 4, 1805, and died in the same place, from an attack of gout, Sept. 2, 1865, being then royal astronomer of Ireland. His early life is the story of alarming precocity, not of invention, but of acquisition. Nothing could have seemed more certain to those who knew the boy of half a score than that middle life would easily insure him rank as the chief of linguists. At five he was able to read and translate Latin, Greek, and Hebrew; at eight, he knew Italian and French; and before the age of ten his father wrote of him, "His thirst for the oriental languages is unabated. He is now master of most, indeed of all except the minor and comparatively provincial ones. The Hebrew, Persian, and Arabic are about to be confirmed by the superior and intimate acquaintance with the Sanskrit, in which he is already a proficient. The Chaldee and Syriac he is grounded in, and the Hindoostanee, Malay, Mahratta, Bengali, and others. He is about to commence the Chinese." One of Hamilton's earliest productive efforts was the preparation of a little manuscript book of thirty pages, formally entitled 'A Syriac grammar, in Syriac letters and characters,' etc. (p. 51). He was not as yet twelve years of age; and before another year had passed, his works included (these are the titles given by the boy himself) 'A grammar of the Sanskrit language,' 'An Arabic praxis,' 'An analysis of a passage in Syriac,' and 'A compendious treatise of algebra,' which latter proceeds as far as quadratic equations. Up to this point, Hamilton seems to have had no marked disposition toward scien-

tific studies. He had been fascinated by telescopic views of the planets, and had visited the Royal observatory at Dunsink. Unquestionably one of the most important events in his early career was the meeting of Zerah Colburn. The two had engaged in trials of arithmetical skill when the former was only twelve; but two years later they re-met, Hamilton being "not so much the antagonist as the critic and the investigator of the methods of the gifted computist." That it would be difficult to over-estimate the significance of this occurrence is evident from a letter by Hamilton to his cousin Arthur, in 1822, wherein he says (p. 111), —

"I was amused this morning, looking back on the eagerness with which I began different branches of the mathematics, and how I always thought my present pursuit the *most* interesting. I believe it was seeing Zerah Colburn that first gave me an interest in those things. For a long time afterwards I liked to perform long operations in arithmetic in my mind; extracting the square and cube root, and everything that related to the properties of numbers. It is now a good while since I began Euclid. Do you remember when I used to go to breakfast with you, and we read two or three propositions together every morning? I was then so fond of it, that, when my uncle wished me to learn algebra, he said he was afraid I would not like its uphill work, after the smooth and easy path of geometry. However, I became equally fond of algebra, though I never mastered some parts of the science. Indeed, the resources of algebra have probably not been yet exhausted."

The practical bent of his young mind in scientific matters is interestingly shown by his invention of a telegraphic signal-code, which, for a youth of fifteen, is not a little remarkable. The letters of the alphabet were first arranged in the following scheme (p. 88): —

	1	2	3	4	5
1	A	B	C	D	F
2	G	E	H	J	K
3	L	M	I	N	P
4	Q	R	S	O	T
5	V	X	Y	Z	U

Twice U = W

Then five readily distinguishable positions of the arms were chosen. Each letter, thus, would be indicated, after the manner of a double-entry table, by its position at the intersection of a horizontal and a vertical column; and the numbers of these intersecting columns, transmitted from one station to the other by the pre-arranged signals, would thus spell out any desired message. It will be observed that the duplication of any given position of the arms always indicates a vowel. This device for communicating at a distance was for a time practically employed by Hamilton and a playmate of his, each being provided with a telescope, so that he could readily discern the successive positions of the arms of the other. His devotion to astronomy had by this time taken firm hold; and Hamilton realized this so fully himself, that he forcibly made in his studies a 'sudden transition to natural philosophy,' excusing himself therefor to his friends by explaining that the "intention was to prevent my giving up too much time to astronomy by diverting my thoughts to another channel: '*atqui emovit veterem mire morbus novus*,' for I am now as deeply engaged in the study of pendulums." In a short paper, at the age of sixteen, he brings science to the assistance of the classics, finding astronomical calculation to help in the decision of a moot-point in the chronology of the Aeneid.

It is most interesting to follow the growth of Hamilton's young mind as his fondness for the mathematics increased, and his devotion to the classics waned. His pre-collegiate letters abound in passages evincing the radical change which was going on, and the solid permanency with which his new favorites had taken possession. A passage from a letter to his sister Eliza, shortly after his entering Trinity college, is cited here as a vigorous illustration of this: —

"One thing only have I to regret in the direction of my studies, that they should be diverted — or rather, rudely forced — by the college course from their natural bent and favorite channel. That bent, you know, is science — science in its most exalted heights, in its most secret recesses. It has so captivated me — so seized on, I may say, my affections — that my attention to classical studies is an effort, and an irksome one."

Immediately on abandoning his absorbing interest in the classics, his work of original research in mathematical optics began. Mr. Graves quotes the title of an "Essay on equations representing systems of right lines in a given plane," etc., — a paper of twenty-one folio pages, to which Hamilton himself had appended the following note: "(This curious old paper, found by me to-day in settling my study, must have been written at least as early as 1822. It contains the germ of my investigations respecting Systems of rays, begun in 1823. W. R. H., February 27, 1834.)"

Hamilton's college career was a most brilliant one. During no small portion of his leisure, he was at work developing the germs of the above-named investigation, which, in the spring of 1827, was presented to the Royal Irish academy, having been expanded into 'A theory of systems of rays.' The first part was published the following year in the fifteenth volume of the academy's transactions. His collegiate course had not been completed, when, less than twenty-two years of age, he was unanimously elected Andrews professor of astronomy in the University of Dublin, and royal astronomer of Ireland, — an extraordinary preference for an undergraduate, who had for competitors men of high standing and eminence in two universities. His appointment under these circumstances involved another exceptional event: by the donor's direction, the professor of astronomy is one of the examiners for Bishop Law's prize, which is yearly bestowed upon the best answerer in the higher mathematics among candidates of junior bachelor standing. The new occupant of the chair of astronomy was, within a few days of his appointment, called upon to take his part in the examination; an undergraduate thus officially examining graduates in the highest branches of mathematics.

In the following autumn, Hamilton met the poet Wordsworth. Their correspondence of years, in terms of close intimacy, is very fully given by Mr. Graves, and forms the richest extra-scientific contribution to this biography. We may appropriately allude, in this connection, to Hamilton's poems, with which a very considerable fraction of this large volume is filled. Wordsworth criticised these effusions very freely, and not a few of them are certainly unworthy of Hamilton's better moments. The subjects chosen for versification, however, show an instinctive correctness in the choice of objects and impressions, which, treated by a poet, would be poetry, but, as dealt with by Hamilton, are in general merely healthy ideas plainly and unpoetically expressed in rhyme or verse. Another friendship of Hamilton's we should not omit to mention, — that of the philosopher Coleridge, whom he met in London shortly before the former's death. Their spirited metaphysical correspondence is a very agreeable feature of the present work.

To the wisdom of the same board of electors which, without doubt, saved Hamilton to science from the church (for he had at one time serious intention of entering that body, and was more than once offered ordination), are due the thanks of mathematicians perpetually for their prompt recognition of the true sphere of his intellectual activity. The duties of his university chair, as director of the observatory, were in large part uncongenial to him, and his brief career as a practical astronomer was not a successful one. His tastes being almost entirely in the direction of mathematical research, it was ultimately fortunate, that, from the commencement of his practice as an observer, his vigor of constitution was seriously impaired. Near the close of 1830 he writes to Sir John Herschel, "I cannot say much for my diligence in observing, but perhaps may have a better account to give of this department after some time; though among other temptations to indolence, I have that of always suffering in health when I attempt night work in the transit-room." He had constant cold in the head and chest, and was much of his time confined to the house. The proposal was soon made that he should change the professorship of astronomy for that of mathematics; and consulting with his friend, the late Dr. Robinson of Armagh, the latter replied. —

"Your course appears to me so clear that there can be no hesitation. As a mathematician you will probably have no equal in Britain, as an astronomer some superiors; for you certainly have not the *practical* enthusiasm which is essential to make one sustain the uniform progress of observing. I was well aware that you are not very fond of observing; but you know you have that in common with Encke (who *hates* it), Airy, and Pond (now never observing)."

In November, 1831, the university board passed a resolution which more than doubled Hamilton's salary, and completely defined his future relations to the university; giving him entire liberty to pursue, as a first object, his mathematical researches, and thus assuming the responsibility of his continuing as a mathematician rather than an astronomer.

Hamilton's friends were not slow to do themselves the honor of proposing his membership of scientific bodies. Through Sir John Herschel he became a member of the Royal astronomical society at the age of twenty-two; three years later he was introduced to the British association for the advancement of science; Lubbock was ready to insure his election to the Royal society (of which, however, he never became a fellow); and in a letter, in 1832, to his intimate companion, Aubrey de Vere, he says, (p. 610), "A hand has lately been stretched forth to me across the Atlantic; a diploma having been sent, with great pomp of broad-seal, and so forth, to tell me that I have been

elected fellow of the American academy of arts and sciences —

"Ueber länder und meer reichen sich beide die hand."

A picture of curious interest may be drawn from Mr. Graves's occasional touches, portraying Hamilton as a speaker and lecturer. He "had two voices — one deep, rich, sonorous, rhythmical, and solemn, which flowed forth when he delivered a prelection or a speech, or recited poetry; the other soaring acutely into high regions, when he burst into an explanation, or gave vent to some ebullition of good spirits or cheerful comment." At the meeting of the British association in 1832, at Oxford, his speech returning thanks on behalf of the Royal Irish academy contained "a graceful expression of the feelings stirred in him by his peculiar position as the solitary and youthful representative of Ireland on the occasion." Babbage told him, in congratulation, that "an astronomer had no business to be able to speak so well." We have space for only a word from Mr. Graves's charming sketch of Hamilton as a lecturer (pp. 497–498): —

"When he spoke . . . it was plain to see that he was absorbed by a reverential consideration of the grandeur of astronomy. . . . As he poured out in his sonorous tones his thoughts thus blending poetry and science, he appeared . . . absorbed in awed and delighted contemplation of the truths he had the solemn privilege of enouncing; there was no apparent consciousness of his own personality, he was a worshipper revealing the perfections of the object of his worship; and towards the youthful audience who surrounded him he took the attitude not so much of a superior authority and a teacher as of a worshipper desirous that other intelligent spirits should take fire from the flame of his devotion. . . . In these introductory lectures he was wont to indulge himself in refined and eloquent disquisition, in poetic language, quotation and allusion, in tracing the history of the development of the science, and in marking out the achievements of its great promoters. . . . The subsequent lectures of the course were altogether different in style, being rigorously mathematical and demonstrative. . . . They were delivered with an eager simplicity, in a voice often breaking into a high key, strangely contrasting with the deep roll of his oratorical effusions."

One of Hamilton's grandest achievements was the theoretical discovery of conical refraction; and in the popular history of physics he is chiefly known by this. Its prompt confirmation by Dr. Lloyd, in the laboratory of the Dublin university, tended strongly to heighten the dignity of the discovery. It was characterized in terms of most extravagant applause by the greatest physicists of that day. But Hamilton himself, with the unaffected simplicity of true genius, describes it to Coleridge as a 'subordinate and secondary result.' The discovery had no parallel in the history of exact science; and, as Mr. Graves appropriately remarks, it is only "to be classed with that prediction of the existence of the planet Neptune which has immortalized the names of Adams and Le Verrier."

Nothing, perhaps, will better exemplify Hamilton's rare elevation of character than the following brief words of his biographer: —

"It is to Hamilton's honour that the impression he made upon young men, his coevals and his juniors, was such as to create in them the warmest affection, admiration, and respect. This arose from his unaffected humility and his cheerful communicativeness, combined with his power to solve most difficulties admitting of solution, his frankness in confessing ignorance, his reverential and profound treatment of all great questions."

In so far as it is possible to know the distinguished Irishman from his letters, — and they are presented in the fullest profusion, — the most commanding feature of his character is the absolute absence of every thing akin to meagreness of build: in other words, a thorough and genuine nobility. Repeated illustrations of this might be cited from his correspondence; and it is the most conspicuous element of the admirable frontispiece which has been autotyped from a photograph by Chancellor, Dublin, of a miniature bust executed by Terence Farrell in 1833. We should like to express the hope, that, before the conclusion of his task, Mr. Graves will present a print from the other bust of Hamilton, executed, at the request of Lord Dunraven, by the Dublin sculptor, Kirk; in preparation for which a cast was taken from the head, and which thus, as faithfully representing his cranial development, can hardly fail to possess a permanent value.

It is most irksome to be forced from the contemplation of this great genius; for, with this initial volume of his biography, we have to leave him at the age of twenty-seven, and almost in entire anticipation of his characteristic scientific life. His unique researches in the highest fields of mathematical investigation, his great contributions to the science of dynamics, were yet unmade; and the calculus of quaternions, if at all thought of, had no more taken shape than the vague indefiniteness of a dream. If Mr. Graves has disappointed any of his readers in the execution of his task, they must be few, and among those who were so favored as to have enjoyed the intimate acquaintance of the great mathematician. The successive instalments of this exceedingly valuable biography cannot fail to be watched for with eagerness, and welcomed with enthusiasm, by all whose interests embrace the history and development of the exact sciences.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

San Diego natural history society.

Nov. 2. — The following officers were elected: president, Dr. G. W. Barnes; vice-president, Joseph Winchester; recording secretary, E. W. Hendrick; corresponding secretary, Rosa Smith; treasurer, C. J. Fox; librarian, Mrs. Z. R. Cronyn; curator, Dr. D. Cave; directors, D. Cleveland, G. W. Barnes, C. J. Fox, E. W. Morse, J. G. Capron.

The following papers were read. Historical notice of Pinus Torreyana; by C. C. Parry. — In the spring of 1850, when connected with the Mexican boundary survey, my attention was first called to a peculiar species of pine growing on the Pacific coast, at the mouth of the Soledad valley, San Diego county, by a casual inquiry from Dr. J. L. LeConte, then staying in San Diego, asking what pine it was, growing near the ocean beach at that locality. Not having any specimens to show, he simply mentioned at the time its dense cones, and its long, stout leaves (five in a sheath). Not long after, an opportunity offered to the writer for a personal investigation, having been ordered by Major W. H. Emory to make a geological examination of the reported coal-deposits on the ocean bluff above Soledad. From the notes and collections there made, a description was drawn up, dedicating this well-marked new species to an honored friend and instructor both of Dr. LeConte and the writer; viz., Pinus Torreyana, Parry. Of the few specimens then collected, a single cone and bunch was sent to Dr. Torrey to be figured for the Mexican boundary report. While there, it fell under the notice of some inquisitive botanist, who extracted some of the loose seeds, which were planted, but by some inadvertence were mixed with another three-leaved species. When growing, the two different kinds became confounded, and it was inferred that the present discoverer was mistaken in regarding this species as five-leaved. Prof. Parlatore, the elaborator of Coniferae in de Candolle's 'Prodromus,' added to this confusion by ignoring the name first proposed, and substituting that of Pinus lophosperma. Subsequently, frequent collectors have visited this locality, bearing away to the remotest portions of the world seed of this pine, which, as far as is known, is exclusively confined to a coast-line of not more than four miles, lying between San Dieguito and about a mile below Soledad, and extending scarcely a mile inland. The bulk of the tree-growth is here mainly confined to a series of high broken cliffs and deeply indented ravines on the bold headlands overlooking the sea south of Soledad valley, and within the corporate limits of the town of San Diego. Here, within a radius of not more than half a mile, this singular species may be seen to the best advantage, clinging to the face of crumbling yellowish sandstone, or shooting up in more graceful forms its scant foliage in the shelter of the deep ravines, bathed with frequent sea-fog. One of the finest specimens seen reaches a height of nearly fifty feet, and shows a trunk eighteen inches in diameter at base.

The chair was instructed to appoint a committee of three (to be named hereafter), to report and act upon such measures as may be deemed best for the preservation of the remnant of the Pinus Torreyana at Soledad, treated of in the communication of Dr. Parry.

Additions to our flora and fauna; by C. R. Orcutt. — The writer stated, that, since the last annual meeting, over a dozen discoveries have been made in species of plants indigenous to this section, while many more have been discovered unknown hitherto in California.

Notes upon spiders; by Rosa Smith. — Zilla rosa, which I discovered at San Diego less than a year ago, is the commonest orb-weaver in San Francisco and vicinity, spinning its delicate snare on trees, bushes, and fences about the city, at Golden Gate Park, and at the Cliff House. Even inside the walls of the California academy of sciences, I have seen its lovely web, accompanied by silken cocoons of its eggs. This spider is easily known by the free radius in the snare, — 'a good wedge cut out of the pie,' Dr. McCook expresses it, — which is peculiar to the genus Zilla. At Aptos, near Santa Cruz, I secured an Epeira, and cocoon of eggs and young spiders, which have revealed some curious facts in regard to insect parasites. Of these Dr. McCook writes, "One interesting thing about the Epeira atrata cocoon is, that it is strangely infested by parasitic and other enemies, no less than four. There were first a number of small reddish ants alive, probably a species of Solenopsis, who no doubt were feeding upon the eggs and *débris*; second, several larvae of Dermestidae, probably Attagenus pellio. These were creeping into the silky interior at will, though some of them were ensconced within the empty cells of some ichneumon. Next I found alive a very small ichneumon fly. I have never yet seen quite such a 'happy family' within the bounds of a spider's egg-nest. The spiderlings seemed to be contented, and indifferent to the presence of these intruders." A few days later, Dr. McCook sent more information, as follows: "Since writing you, I find from Mr. Cresson that the larger ichneumon is a Pezomachus; and the small one, as I conjectured, a chalcid of some sort, which is parasitic upon Pezomachus. As Pezomachus is parasitic upon spiders' eggs, their presence within the cocoon is thus accounted for. By the way, there is a yet minuter chalcid that is parasitic upon the chalcid, that is parasitic upon the Pezomachus, that is parasitic upon the eggs of Epeira atrata and other spiders."

Natural science association of Staten Island.

Dec. 8. — Mr. Hollick gave an account of the recent discoveries of fossil leaves at Tottenville. There are three distinct kinds of rock containing these fossils, — a hard red or gray ferruginous sandstone, a soft gray sandstone, and a peculiar conglomerate composed almost wholly of vegetable remains cemented together with what is apparently limonite or sesquioxide of iron. In the soft gray

sandstone the remains are not yet destroyed, but are in the form of carbon or lignite. In the other rocks the vegetable tissue has almost entirely disappeared, and only the impressions remain. The rocks are found in blocks or fragments, none of them greater than a foot square, scattered along the beach, mostly at the base of the bluff, which is composed of drift. From our present knowledge, it is not possible to decide whether they were torn up from an outcrop below high-water mark and cast upon the beach, or washed out from the base of the bluff: they no doubt belong to the cretaceous, although our present proofs are not yet sufficient to state this to a certainty.

A note was read from Dr. Britton of Columbia college, in which he stated that the occurrence of similar fossiliferous sandstones on the beach near Glen Cove, Long Island, and vicinity, had been known for some time. There they are found in precisely the same position as at Tottenville, and are associated with extensive beds of fire-clay, kaoline, etc. The Tottenville station is not immediately on these clays, but they are found near by in several directions, notably at Kreischerville. That the two localities mark outcrops of the same geological formation, and probably approximately of the same strata, is almost certain. The physical structure of the Glen Cove series is exactly parallel to that of certain of the clay beds of Middlesex county, N.J., which are well known to belong to the cretaceous epoch. In the absence of sufficient fossil evidence, we cannot state with absolute certainty that the two deposits are equivalent; but there is little doubt that this will ultimately be proven, and that the New Jersey and Staten Island clays, kaolines, lignites, etc., find another and their most northern outcrop on the north shore of Long Island, at or near Glen Cove.

The exact parallelism between our Staten Island specimens and those from Glen Cove, continued Mr. Hollick, can be seen at a glance: in fact, they would be indistinguishable but for the labels, with the exception of the leafy conglomerate before described, which does not seem to be represented elsewhere; it is possibly peculiar to Staten Island.

In determining the genera and species of fossil plants, we have to depend mostly upon the veining of the leaves, which is not by any means so satisfactory as we could wish. Genera can be determined with comparative accuracy. Thus we have no doubt that one of our Tottenville fossils is a willow, though what particular species, it is impossible to say; another is undoubtedly an evergreen, allied to our juniper or arborvitae. The larger specimens are probably willows, viburnums, and sour gums. There are also a few fragments with parallel veins, — no doubt, belonging to the grasses, — a small fruit or nut, and a piece of what appears to be an equisetum or horse-tail rush. These, with other indistinguishable fragments, complete our list.

Cambridge entomological club.

Dec. 14. — Mrs. A. K. Dimmock showed a collection representing stages of thirty-eight species of insects which are found upon Betula alba, the white birch, which will be given later in *Psyche.*

Mr. G. Dimmock showed the two halves of a split wing of Attacus cecropia, in which the two layers of the wing had been separated by the following mode. The wing from a specimen that had never been dried is put first into seventy per cent alcohol, then into absolute alcohol, and from the latter, after a few days' immersion, into turpentine. After remaining a day or two in turpentine, the specimen is plunged suddenly into hot water, when the conversion of the turpentine into vapor between the two layers of the wings so far separates these layers that they can be easily parted and mounted in the usual way as miscroscopical preparations on a slide. This is an easy way of demonstrating the sac-like nature of the wings of insects.

Dr. H. A. Hagen showed preparations to illustrate organs of undetermined function, found on the larvae of Gomphidae, Libellulidae, and Aeschnidae, but not as yet found on Agrionidae, which he believes to be traces of segmental organs. The organs in question are little cavities or invaginations of the epidermis between the segments, one on each side of the median ventral line, on one, two, or three abdominal segments, according to the family to which the larva belongs.

Ottawa microscopical society.

Dec. 18. — Mr. Henry M. Ami read a paper on the use of the microscope in determining fossils, with especial reference to the Monticuliporidae. Late microscopic investigations proved that the more minute organisms found in our rocks were both deserving and requiring such careful investigations; for geologists had been led into erroneous ideas regarding the particular horizon, and range in geological time, of certain species of these fossils from the mere cursory examination given them. Later paleontologists, pursuing their researches in a more scientific manner, had recourse to thin sections of these Monticuliporidae, or fossil Polyzoa, by means of which the true external and internal structures of the zoarium or skeleton of the genera and species belonging to this family were satisfactorily ascertained.

The work of foundation and means devised by Dr. Nicholson (at one time a professor in one of our Canadian universities) inaugurated a new era in the study of these interesting forms. The mode of procedure in preparing thin sections of these fossils was then considered and explained. The different kinds — tangential, longitudinal, transverse, and axial sections — were described, and illustrations of them exhibited in charcoal drawings of some of the common species found about Ottawa city, — Prasopora Selwyni Nicholson, Batostoma ottawaense Foord, and Monotrypella trentonensis Nicholson; the various points exhibited in these sections — such as the large and smaller tubes; cystoid, curved, and straight diaphragm or floors; the spiniform tubuli, etc. — were then described, showing how minutely and accurately their structures and affinities can by this means be detected.

There was still a rich and wide field open for investigation in the study of the Monticuliporidae; and care should be taken first to ascertain with the new and more scientific means the true relations and affinities of the species described previous to 1881.

Mr. Whiteaves exhibited a choice series of recent Polyzoa for comparison with the fossils described in the paper.

Ottawa field-naturalists' club.

Dec. 20. — Mr. James Fletcher read a paper entitled 'Notes on the Flora ottawaensis, with special reference to the introduced plants,' which was explanatory of the lists of plants hitherto published by the club, and in which the non-indigenous species are not indicated. Mr. Fletcher first defined the district from which the plants had been collected, and which lies within a circle of twelve miles radius. He then noted certain of the more interesting of rare or introduced species, and presented lists tabulating the latter plants under the headings of 'Aggressive species,' 'Species able to perpetuate themselves indefinitely,' 'Species dying out after short periods,' etc. An animated discussion ensued, confined principally to the conditions affecting introduced plants, and the spreading of certain species.

Philosophical society of Washington; Mathematical section.

Dec. 19. — Mr. M. H. Doolittle gave a paper on the rejection of doubtful observations, in which observing-errors were sharply divided into two classes, — those resulting from blunders in recording, pointing on wrong objects, neglect of essential precautions in instrumental adjustment, etc.; and those resulting from an unusual accumulation of similar elements of error. The latter class, because by their magnitude in one direction they indicate that the remaining observations are in error in the opposite direction, he proposed to call *instructive* errors, and claimed that the larger they were the more instructive, and the greater the necessity of retaining them. In practice, however, the best rule with suspected observations is to reject them when they exceed the limit of error possible to the 'instructive' class, and when they fall within it to assign a weight proportional to the chance that the error belongs to the latter class, and not the former. As the law of distribution of the former class of errors (if any such law exist) is very different from the recognized law of the latter class, these questions cannot be decided by computation with a 'criterion,' but must be left to the judgment.

Prof. A. Hall gave as a general result of the debate of this vexed question by Peirce, Airy, De Morgan, Stone, Glaisher, Chauvenet, Gould, Winlock, and others, that *every one can devise a criterion that suits himself, but it will not please other people.* He strongly opposed using such machinery in the discussion of observations as eliminated the knowledge and judgment of the investigator, and giving to results a fictitious accuracy by any sweeping rejection of discordant data.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Topographical field-work. — Mr. H. M. Wilson, in charge of one of the topographical parties in Prof. A. H. Thompson's Wingate division, surveyed, during the season of 1883, about ten thousand square miles in north-western New Mexico and north-eastern Arizona. The area covered by his work lies between parallels of latitude 36° and 37°, and extends from meridian 109° to 111°. He also worked some smaller detached areas outside of the limits thus indicated. This region has hitherto remained a *terra incognita*, partly on account of its aridity and barren condition, and partly on account of the difficulty of traversing it. So little has been known of it, that within the area surveyed by Mr. Wilson a small mountain range has been indicated as occupying two places on the same map. On the engineer's map of 1879 it is called Calabesa Mountains in the northern place, and Squash Mountains in the southern; and, on the land-office map for 1882, both are indicated without names. Mr. Wilson's work proves that they are one and the same, occupying a position very close to that assigned to the Squash Mountains.

On the 11th of September Mr. Wilson and one of his men made the ascent of Navajo Mountain (called by the Indians Nat-sîs-aú), and they are probably the first white men who have ever stood upon its summit. Navajo Mountain lies on or near the line between Utah and Arizona, and is a dome-shaped mass rising about four thousand feet above the general level of the surrounding country, and sixty-five hundred feet above the beds of the San Juan and Colorado rivers, which are close to its base, the former on the north, and the latter on the west. Its elevation above sea-level is ten thousand four hundred feet. It slopes abruptly, especially on the east, to a plateau of six to seven thousand feet, which extends south-eastward for fifteen or twenty miles to the cañon where Mr. Wilson left his pack-train in camp. This was on a trail that leads to Fort Defiance, *viâ* the north side of the Mesa de la Vaca and the valley of the Rio de Chelly. Another trail leads southward to Mo-eu-kap-i (a Mormon settlement) and to Oraybe and the other Moqui villages. From a point a few miles south of the Navajo Mountain, a third trail leads westward to Lee's Ferry, on the Colorado River. Mr. Wilson thinks there is also a trail leading to the mountain from the north-west. He says all the trails in this section are exceedingly rough and difficult to travel, on account of the numerous cañons, of five hundred to a thousand feet in depth, which are cut into the red sandstones (triassic?) that form the

surface-rock of the country. On the summit of the mountain, which is about a mile in length, a brownish sandstone occurs, which may possibly be Jurassic or even cretaceous; but all the rocks are probably referable to the Jura-trias, with the exception of some dark igneous rocks which occur as dikes on the slopes of the mountain. Within about a thousand feet of the summit is a spring of good water, where there is a good camping-place. The slopes are timbered; scrubby firs and balsams occurring on the top, with scrub-oaks below, and tall pines still lower down. Among the latter are many beautiful parks. The plateau-level surrounding the mountain is well covered with fine tall grass, over which are scattered patches of piñon pines and small areas of bare red sandstone.

In the walls of a short cañon on the east side of the mountain, passed through by Mr. Wilson in his ascent, ruins of cliff or cave dwellings were seen in a cave or hollow in the rocks about five hundred feet above the bottom, and a hundred feet below the top.

Ascent of Mount Shasta.— Mr. Clarence King, in his 'Mountaineering in the Sierra Nevada,' says, "There is no reason why any one of sound wind and limbs should not, after a little mountaineering practice, be able to make the Shasta climb. There is nowhere the shadow of danger, and never a real piece of mountain climbing, — climbing, I mean, with hands and feet, — no scaling of walls, or labor involving other qualities than simple muscular endurance."

Mr. Gilbert Thompson, who, during the past summer and fall, spent about two months in topographic work on the slopes and summit of Mount Shasta, indorses this statement of Mr. King, and would add that there is no reason why a train of pack-mules may not be taken to the top of the peak. Mr. Thompson and one of his packers (Thomas Watson), on Sept. 10, 1883, tied their riding-mules to the iron signal-post which marks the extreme summit of the cone, and are the first who have ever taken riding-animals to the top of Mount Shasta. On Oct. 12, 1883, the pack-train was taken to an altitude of 13,000 feet, and would have been taken to the top had not the early snows prevented. Another season, however, Mr. Thompson expects to camp with his entire train upon the summit of Mount Shasta. From one of his camps, at an elevation of 7,400 feet, it required seven hours to go to the top with the riding-animals, while one member of the party, starting from the same camp on foot (taking, of course, a more direct route), reached the summit after a climb of six hours. It took two hours to get back to this camp, and three-quarters of an hour sufficed for the return to the camp which was located at the elevation of 13,000 feet. Mr. King and his party in September, 1870, made the ascent from the north-west. The first day they left their riding-animals at an elevation of about 10,000 feet, and climbed as far as the crater on the north-western spur, which point they reached about half-past one o'clock in the afternoon. They spent the night here, and on the following day, after a climb of four hours and a half, reached the summit. Mr. Thompson's ascent, mentioned above, was along a spur that extends toward the south-east. Up this spur he says there is a natural trail, only 500 or 600 feet of which will require any work to make it perfectly safe for mules or horses with packs. The route described by Mr. King, and the one *viâ* a south-western spur, are the routes usually followed by those who make the ascent from Strawberry valley, on the west side of the mountain. One member of Mr. Thompson's party climbed the mountain also from the east, which makes, altogether, four different routes by which it has been ascended. Mr. Thompson says there are two other possible ways by which the mountain can be climbed. These are on the north-east side. He reports, also, that there are seven glaciers located on the north and east slopes of Mount Shasta. Those on the north and north-east are connected at their heads. A north-west and south-east line would divide the glacier-bearing side of the mountain from the non-glacier-bearing half. However, some of the fields of snow and ice on the west side have considerable resemblance to glaciers, and may eventually be so determined.

Mr. Thompson suggests that Mount Shasta would be the best point in this part of the west for a permanent high meteorological station like those located on the summits of Mount Washington and Pike's Peak. Among the several reasons for this opinion, he mentions its accessibility, and the presence of hot-springs, which might be utilized in heating such a station, but more especially the fact that it is an isolated peak, rising high above the surrounding low country, and free, therefore, from the disturbing meteorological conditions induced by the presence of contiguous mountain ranges. Mount Shasta, Mr. Thompson says, does not belong to the Sierra Nevada nor to the Cascade Range, but stands alone.

During the season a line of levels was begun at Berryville, where connection was made with the railroad level, and carried some distance up the mountain. Next year this line will probably be carried to the summit of the peak.

NOTES AND NEWS.

THE Society of naturalists of the eastern United States, whose organization and aims were described in *Science* last spring, held a very successful and interesting meeting at Columbia college, New York, on Thursday and Friday of last week. The attendance was very large, and included many distinguished men. The membership has grown very rapidly, and now includes a large majority of the leading professional naturalists of the eastern states. The papers presented were of a high character, and many of them provoked a discussion such as is rarely heard in any scientific body; for seldom are so many men, devoted to one branch of pure science, gathered together. The communications, almost without exception, referred to problems of practical interest, and dealt especially with methods and the organization of scientific work, and also with methods of teaching.

Upon methods were read several papers, — Pro-

fessor James Hall, On a method of preparing rock-sections; Prof. B. G. Wilder, On the preservation of hollow organs, particularly the heart and brain; Prof. S. H. Gage, On the uses of peroxide of hydrogen in preparing skeletons; Dr. George Dimmock, On the uses of carminic acid in microscopical work; Mr. J. H. Emerton, On models of gigantic cephalopods; Dr. E. B. Wilson, On methods of section-cutting. Upon organization we may note Professor Wilder's paper, On the arrangement of a museum of vertebrates, and Professor Cope's, On academies of science in America, etc. Among the educational communications were those of Dr. Wadsworth, Upon methods of teaching in petrography and mineralogy, and Professor Bickmore's, Upon methods of teaching employed at the American museum, etc. The meeting surpassed in interest all expectations, and assures the future standing and prominence of the society, which, although so young, is yet through its membership so strong. The following officers were elected for the ensuing year: president, Professor Alpheus Hyatt; vice-presidents, Profs. H. N. Martin and A. S. Packard, jun.; secretary, Dr. Charles S. Minot; treasurer, Professor William B. Scott; members at large of the executive committee, Profs. H. C. Lewis and Lester F. Ward.

— The Swiss earthquake of 1881 had its centre of intensity in Berne and nearest vicinity, and is one of the best observed as to its extent and details. The geologic formation of the Swiss plateau, where the motions were most intensely felt, consists of a tertiary sandstone of unknown depth, called molasse, while the limestone rocks of the northern Alpine belt and of the Jura ridge were scarcely touched by it. Prof. Dr. A. Forster, the director of the telluric observatory at Berne, has collected a large amount of well-ascertained details on this earthquake, and published it in an interesting quarto memoir of twenty-nine pages, — 'Das erdbeben der schweizerischen hochebene vom 27 Januar 1881 (Berner beben),' Berne, *B. F. Haller*. The scientific results obtained by him may be summed up as follows: the principal shock occurred on Jan. 27, in the afternoon, at 2h. 19 m. 53 sec., and was preceded and followed by light oscillations of the soil. It took place at a coincidence of the perihelion with the perigee, the new moon being two days and a half later. There were no disturbances of terrestrial magnetism noticed for several days before and after; but a long period of frost had just given way to a sudden thaw, and the upper culmination of the moon had occurred five hours before. The whole area of seismic motion, with its longitudinal axis of two hundred and sixty kilometres, experienced the shock at one and the same astronomic time. There was no central shock, for the dislocation following the shock took place simultaneously upon the whole line. In the majority of places, villages, etc., it consisted of a brief, succussory shaking, followed immediately by a few lateral and less energetic oscillations, all of them possessing a direction running approximately from east to west. The mean duration was but three to four seconds, the intensity varying from three to eight degrees of the Swiss-Italian seismic scale. Noises usually connected with the heavier earthquakes were heard by most observers who happened to be outdoors: they preceded the shock or were synchronous with it, and none were heard after the shock. South of Martigny (Valais) and north of Mulhouse (Alsace) no disturbance was noticed; though numerous oscillations had occurred one and two weeks before, in southern Germany, Piedmont, and Lombardy. Compare A. Heim, on 'Swiss earthquakes in 1881,' published in the Annual of the telluric observatory of Berne (1881).

— Messrs. Cassino & Co. and Estes & Lauriat, of Boston, have issued a prospectus of the 'Standard natural history,' — a work in six volumes, imperial octavo, fully illustrated, and under the editorship of Dr. Elliott Coues and Mr. J. S. Kingsley. The staff of writers announced consists of forty-two names, including the larger part of our best-known authors, and all are men of repute. The first volume, on the lower vertebrates, will be by W. K. Brooks, S. F. Clarke, J. W. Fewkes, A. Hyatt, C. S. Minot, A. S. Packard, and others; the second, on the arthropods, by E. A. Birge, J. H. Comstock, A. J. Cook, J. H. Emerton, G. H. Horn, J. S. Kingsley, A. S. Packard, C. V. Riley, P. R. Uhler, etc.; the third, on the lower vertebrates, by E. D. Cope, T. Gill, S. Garman, D. S. Jordan, etc.; the fourth, on birds, by Dr. Elliott Coues alone; the fifth, on mammals, by E. D. Cope, E. Coues, T. Gill, S. Lockwood, G. Macloskie, R. R. Wright, and others; and the sixth, on the races of man, by C. C. Abbott, L. Carr, W. H. Dall, F. W. Putnam, and S. Salisbury. The work will be published in about sixty serial parts, of forty-eight pages each. The numbers already issued leave nothing to be desired in typography, good taste, and excellence in illustration; and we heartily wish so serious a venture every success.

— A new work on the "Theory of deflections and of latitudes and departures, with special applications to curvilinear surveys for alignments of railway-tracks" is in press by Van Nostrand. The author, Isaac W. Smith, is an engineer for some time connected with the construction bureau of the Northern Pacific railroad.

— 'The legends of the Panjab,' in monthly numbers from August, 1883, by Capt. R. C. Temple, Bengal staff corps, records, in a form useful to investigators, the stories and legends preserved in the memories of the wandering bards of the Panjab. The legends are given in original in the Roman character, exactly as they were taken down from the lips of the narrators, with translations. The work is being published at the Education society's press, Bombay, and by Trübner & Co., Ludgate Hill, London.

— 'The Nautical almanac and astronomical ephemeris for the meridian of the Royal observatory at Greenwich' for the year 1887, commonly known as the British nautical almanac, was published in London late in November. According to *Nature*, the sales of this publication for the last five years have exceeded 15,500 annually.

SCIENCE.

FRIDAY, JANUARY 11, 1884.

COMMENT AND CRITICISM.

THE authorities at Washington show hopeful signs of an interest in the administration of the Naval observatory by proposing the appointment of three eminent astronomers as a board of visitors, who shall annually inspect the establishment, advise with the superintendent respecting the scientific portion of his duties, and report to the secretary of the navy. This measure was recommended by the secretary in his annual report, with the hope that many of the objections now urged against the administration might thus be removed. That he should have expected such a result from this simple measure, leads us to doubt whether the grounds of the objections referred to are fully appreciated, and to suspect that the subject is viewed too much from the stand-point of the politician. The astronomers of the country stand in readiness to give any department of the government any advice which they are assured will be followed, at least in spirit; but they have no taste for the cheap compliment of being consulted for the pleasure of the thing. That fondness of being 'consulted,' that appreciation of the privilege of giving advice, and that love of carrying 'weight' in public affairs, which are so strong in the breast of the politician, are nearly unknown among eminent astronomers. The latter have too many more important affairs on hand to permit of their enjoying the pleasures and duties which fall annually to the boards of visitors of the naval and military academies. They are quite ready to give the government the benefit of their advice, provided they have some assurance that the advice will be acted upon, but not otherwise. Their complaint against the observatory is not that they are not sufficiently consulted, but that the organization of the establishment does not fulfil the condition which common sense shows to be necessary to the efficient administration of a scientific institution.

We have already pointed out what we believe to be the chief administrative wants of the observatory. Briefly summarized, they are, a well-considered plan of operations, to be devised by the highest expert talent of the country, within or without the establishment, and to be obligatory upon the superintendent, and such an organization as shall give reasonable assurance that the plan agreed upon shall be carried out in all the details necessary to its success. For a mere board of advice, it is difficult to see the slightest necessity. The observatory has never been without one or more able astronomers, whose advice the superintendent can command whenever he desires, and who have the great advantage of an intimate acquaintance with the instruments and other means at the disposal of the superintendent. If there is any difficulty in getting and using advice from this source, it is because the situation is such that something else is needed.

JAPAN may well be proud of the honors that have just been won by two of her sons in two of the best universities in Germany. A gold medal was offered about a year ago, by the University of Leipzig, for the best original work that should be produced within a year, on the embryology of the fresh-water planarians. The subject is a very difficult one, and on this account has hitherto received very little attention. Mr. Isao Iijima, formerly a student in the University of Tokio, under Professor Morse, and subsequently under Mr. Whitman, was one of the few students selected by the Japanese government in 1882 to be sent to German universities. Mr. Iijima began work at Leipzig, in the laboratory of Professor Leuckart, early in the spring of 1882. At the

suggestion of Professor Leuckart, he turned his attention to the subject announced for the prize. From the report of the rector, Professor His, which was read at the last *Rectorwahl*, it appears that the prize has been awarded to Mr. Iijima. The following remarks, taken from the printed report, will certainly be of interest to all who are watching the course of events in Japan: —

"The work receives the highest commendation of the faculty. With regard to its actual contents, it must be pronounced a highly successful work. It is rich in fine observation and thoughtful discussion, and furnishes the best evidence of the ability, knowledge, and insight of the author. It is a permanent gain for zoölogy, inasmuch as it places in clear light the organization and development of a group of animals, which, notwithstanding the importance of its systematic relations, was hitherto very imperfectly understood. *Aperta scidula repertum est nomen auctoris, Isao Iijima.*"

In Berlin another Japanese student, whose name we have not obtained, has recently been appointed, over the heads of able competitors, to the post of assistant in anatomy.

The report of the secretary of the navy for 1883 contains a repetition of his recommendations of last year, that all national work connected with the ocean, carried on by other departments, should be transferred to the navy department, to be supervised and performed by naval officers. Most important among the transfers suggested is that of the coast-survey, which is now under the treasury. This he would have placed under the naval hydrographic office, because there are now sixty-seven naval officers and two hundred and eighty seamen employed in the coast-survey; and he adds, that in view of the facts that no part of the hydrographic work of the coast-survey has the faintest traceable connection with the general purposes of the treasury, that its effectual performance is of vital importance to the navy, and that an office exists to-day in the navy department where similar work is necessarily carried on, it is inconceivable why so inconvenient, artificial, and indefensible an arrangement should be perpetuated.

The secretary ignores the fact that the work which these officers perform is routine, the plans and methods for which have been devised and developed by civilian experts; and he fails to compare the character and quality of the work which the hydrographic office and the coast-survey have performed, and to show that an improvement in the quantity or quality of work would be consequent on the transfer.

Since, then, the present method of employing our superfluous navy, under the intelligent supervision of civilian experts, works no injustice to the navy, and since it is and has been found essential to employ civilian experts to carry on the work of the hydrographic office, we see no benefit which can result from the transfer, except the aggrandizement of the navy; and we doubt if this be a sufficient reason. Should the efforts of Mr. Chandler to absorb all the national work on the ocean prove successful, the fish-commission, like the coast-survey, must be transferred to the navy department.

The red glow in the skies long after sunset and before sunrise has attracted the attention of every one in all parts of the world during the last few months. As showing the hesitation of physicists to attack the matter, it is singular that nothing on the subject had been sent to us until within three weeks, since which time a number of letters, describing the appearance as seen by single observers, have been received. In this number an article is printed in which the facts at the disposal of the signal-service are made use of, and the often-broached Java earthquake theory, which has so many adherents among the best scientific men, is again put forward. The not inconsiderable upheaval in Alaska may also have played its part. It would be interesting to know if the records of earlier times contain any mention of similar red skies following large volcanic eruptions.

LETTERS TO THE EDITOR.

**** Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Sense of direction.

I HAVE been much interested in the different methods of preserving the relative situation of places, as given in late numbers of *Science*, and will venture to add my own experience.

I refer all objects to two rectangular co-ordinate axes which agree with the cardinal points. In all places where I feel at home, these lines are consciously present, and all roads running north and south, or east and west, coincide with, or seem to be parallel to, these axes. All places which I have visited, from Massachusetts to Nebraska, are, with few exceptions, connected together in one system.

The principal origin of this system is in the northwest corner of a schoolhouse in Hamilton county, O. There, when a boy, I sat under the direction of a teacher to study geography. With face toward the north, I looked through a window along the meridian. I could at pleasure see east or west, or, if need be, south, through opposite windows. A thorough course in geography fixed in my mind the axes of my system, which have been present with me ever since, a secondary origin going with me everywhere. All places with which I am familiar form parts of this system, and any new place visited is immediately referred to its proper location.

Now for the exceptions. There was another schoolhouse, where I attended sometimes, at which I was turned a quarter round. East was north, south was east, etc. I account for the anomaly in this way: in going to the schoolhouse where my system was fixed, I went east, along a road from which I turned to the left into the south or front door of the schoolhouse; but, in going to the second school mentioned, I went through fields into a road along which I passed toward the south some distance, and then turned toward the left into the west or front door of the schoolhouse. I lost the direction of my axes of reference in crossing the fields; so that the west side of the new schoolhouse seemed to coincide with the south of the old, and thus unconsciously my axes were turned a quarter round. No plan I could adopt had the least effect in changing the apparent position of the cardinal points. Many a laugh was raised at my expense because of my promptness in pointing in wrong directions; and to this day, after nearly half a century, if I wish to think of directions from that schoolhouse, I am obliged to change my first decisions through an angle of ninety degrees.

Washington City is another place which is entirely out of my system. I entered the city after nightfall. Somewhere between Baltimore and Washington, I lost my co-ordinate axes, so that, when I came to consider directions, Pennsylvania Avenue was turned half round, east was west, west, east; and I had not and have not the least sense of north or south. No study of maps, and no thinking over the subject, has the least effect in arranging things properly.

Boston is another place which is not in my regular system. In that city and vicinity, Washington Street takes the place of my usual east and west axis, and the street that leads to Mount Auburn is the other axis; but these are not in my mind coincident with my principal axes.

Mistakes made at different times have been quite a study to me. Once, in a city which is regularly laid out, going along the west side of a street toward the south, I crossed the street, and turned toward the north upon the opposite side, and went into an office at my right hand. Coming out, and wishing to continue my course toward the south, I really went north, and spent several minutes before I could convince myself of my error. Possibly the mistake arose in the following manner. I lost my axes in passing from the street-crossing to the sidewalk, and turned north when I supposed I turned south; going into the office toward the right, I seemed to go west; coming from the office, I seemed to be going east; and turning to the right, I was to my mind going south.

It is my custom to travel with a map before me; and, on visiting a city for the first time, I secure a plan and study the direction of the principal streets, obtaining correct knowledge of the points of compass. I then carefully classify my acquisitions, and commonly have no difficulty in finding my way without a guide.

Barn-owls in southern Ohio.

Until recently barn-owls have been of rare or accidental occurrence in this part of the Ohio valley. In the records of the birds in the vicinity of Cincinnati, there were only three specimens noted; and in the record of the birds of Franklin county (Indiana), there has been a vacancy under the head of this species. On Oct. 25, 1883, I was pleased to have a friend bring me a fine male of this species, killed within a half-mile of this town. Soon after this a number of specimens were taken near Cincinnati, at Glendale, where they had taken up their quarters in the town-hall; and others were killed near Jones Station, O. In all, this makes fourteen specimens that I know to have been taken within fifty miles of Cincinnati.

Phosphates in North Carolina.

The successful exploration last spring, under the direction of our board of agriculture, of the large beds of phosphatic nodules embedded in marl in New Hanover and Pender counties, started the search for phosphates in North Carolina again. Stray coprolites had frequently been found; but these nodules, forming beds four to five feet thick, and extending through the country for twenty miles or more, suggested an origin different from that of the true coprolite.

Phosphatic rock has recently been discovered in the up-country, which corresponds exactly to the water-worn nodules entering into the calcareous conglomerate of the lower Cape Fear.

In the latter region, about Wilmington, and twenty miles above, we find the nodules embedded in, and forming the lowest layer of, a ground and hardened eocene marl. The nodules show the same fossils, but differ from the marl in the large amount of sand they contain. They vary in composition from fifteen to fifty-two per cent of phosphate of lime, neighboring fragments having often very varied composition, of all shapes, but mostly kidney and egg shaped; perforated; color, gray to greenish black; specific gravity, 2.6 to 2.7. Freshly broken or rubbed, they give the odor of burnt powder characteristic of such phosphates.

Higher up the country, in Sampson, Duplin, and Jones counties, we find the eocene marl above, and the phosphatic rock below, in distinctly separate layers. Here the formation is such as to leave little doubt that the rock is phosphatized marl (according to Holmes's theory), and not true coprolites. It is found in large indented slabs, six to eighteen inches thick, and weighing sometimes several tons, or in

smaller pieces, evidently broken from this, and somewhat worn. This rock presents all of the characteristics and all of the grades of the nodules found in the marl conglomerate, — the same shells, same large amount of sand, and the same appearance. The character of the rock changes gradually here. Between Warsaw and Kenansville it is richest, yielding forty to fifty per cent phosphate, while both east and west it grows more sandy. Between Sampson on the west and Jones on the east we find all the grades of rock which were found in a single place in the conglomerate beds of the lower country. We conclude, therefore, that this conglomerate was formed from extensive breaking up and mingling of beds similar to those seen at the present time in Sampson, Duplin, and Jones counties, and not from stray coprolites, as has been supposed.

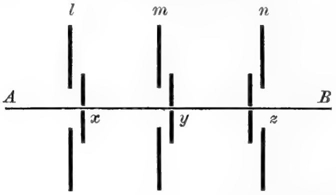
Whether this field will yield any phosphate of more than local value depends upon conditions yet to be determined. CHAS. W. DABNEY, Jun.

N. C. experiment-station, Jan. 2.

Radiant heat.

While it appears that Mr. Fitzgerald's criticism upon Dr. Eddy's hypothesis is conclusive, yet the latter makes a statement in your issue of Dec. 21 which is misleading, since it implies that the device will produce the desired result. Dr. Eddy says, —

"Thus the fact remains, that, although a definite amount of heat from *B* remains entangled in the region *m n*, which is not increased with the lapse of time, there is a continued passage of heat through this region into *B*, that being the very object sought to be accomplished by my process."



Now, the fact is, there cannot be 'a continued passage of heat through this region into *B*,' without permitting the passage of heat from *B* to *A*, by any of the processes described. Granting that heat is entrapped in the space *m n*, it will escape into the space *l m* whenever the door *y* is opened for the passage of heat from *A* into the space *m n;* and the heat so entrapped in the space *l m* will pass on to *A* whenever *x* is opened to admit heat from *A*. This is so plain, that it is only necessary to call attention to the fact, to have it admitted. If the only object sought, as stated in the above extract, was to permit the passage of heat from *A* to *B*, it could be secured at once without any device between *A* and *B*. As originally stated, the object was to transfer more heat from *A*, the colder body, to *B*, the hotter one, than was passed in the opposite direction. The writer has shown in another place[1] that Dr. Eddy's system of moving screens fails to accomplish this result. DE VOLSON WOOD.

Limits of tertiary in Alabama.

The announcement in *Science* (ii. 777) of Professor Johnson's extension of the border-line of the tertiary in Alabama to a position ten miles north of Allenton, and six north of Camden, recalls similar observations made by Alexander Winchell in 1853, and published in *Proc. Amer. assoc. adv. sc.* for 1856, pp. 88, 89. These sub-Claiborne beds he designated 'buff sand;' and the overlying ledge of calcareous grit was traced by him "eight and a half miles north of Allenton, which" was "twenty-five miles farther north than the tertiary beds had been hitherto recognized in this part of the state." The undescribed fossils collected were left with Professor Tuomey, who pronounced them eocene, and held them for description till his death in 1857. A few years later the vicissitudes of war involved the destruction of the Tuscaloosa cabinet by fire. Mr. Winchell's observations were communicated orally in December, 1853, to Professor Tuomey, who noted them down on a manuscript map, from which was compiled the map published in 1858 in Tuomey's (posthumous) second report, edited by Mallet. This places the boundary of the eocene a mile north of Allenton, which, as shown above, is not so far north as Winchell traced the formation. There is, however, nothing in the text of the report on which any change in the older map of this region could be based. Professor Tuomey's observations had been directed to other parts of the state; and Mr. Thornton, his assistant, reports tracing this line through Monroe county, while the map shows it located nine or ten miles north of that county, and, if fully conformed to information in Professor Tuomey's possession, would have shown it seventeen and a half miles north. These statements are only important on the principle of *suum cuique.*

A. W.

Italics for scientific names.

The scientific name of every described plant and animal consists of two or more words: namely, that of the genus, used as a substantive; and the specific name, which follows, and is an adjective adjunct. A species may have a dozen or a hundred common or vulgar names, in half as many languages; but there is only one name in the dead, unchanging, scientific nomenclature. It seems to me that the importance of scientific names, over all others, makes them deserving of a more emphatic type than that of the general text. In the ordinary print — as that of this page of *Science* — any scientific name should be given in italics. Take, for example, the American larch, tamarack, or hackmatack. This tree of our swamps may have many local names, but it has only one in science the whole world over. The emphasis of this fact is largely lost if it is written without an underscore, or printed thus, Larix Americana. It would be only a short step farther to have it larix americana.

It does not follow that names of groups need to be italicized. Thus we can have the order Liliaceae, which contains the genus *Lilium* with its Canada lily (*Lilium Canadense*), the golden-banded lily of Japan (*L. auratum*), and *L. candidum*, or the common white lily. *Quercus, Pinus, Prunus, Ranunculus,* and the thousands of other genera of plants and animals, when used alone, may be set in the common type of the page, and stand thus, — quercus, pinus, prunus, and ranunculus; but I do not like it. Many of the generic names are derived from proper names, as Linnaea, Magnolia, Tournefortia, Begonia, etc.; and these certainly should begin with capitals. When, however, the name of any genus is the common name of all the plants in that genus, it is reasonable to use it without a capital, when employed in a general way. We may say of a plant, it is a fine begonia, or a stately magnolia, or a delicate linnaea, and the absence of

[1] *American engineer*, Chicago, 1883, Jan. 12, Feb. 9, 23, and April 6; also *Journ. Frankl. inst.*, May, 1883, 347.

capital letters is well enough, even though the names have been derived from proper names; but, if we say it is a choice specimen of *Begonia Rex*, the case is different. The word 'begonia' now becomes a part of the scientific name of a species of plant. In the same manner the stately magnolia may be *Magnolia glauca* or *M. grandiflora*.

Science does not use emphatic type for the scientific names of genera or species, and doubtless for good reasons. I should like to learn what views the editor and other authorities in scientific nomenclature hold on the above subject. BYRON D. HALSTED.

New York, Dec. 31, 1883.

[We do not agree with our correspondent in his estimate of the value of the scientific names of plants and animals. They are a simple convenience, and have no higher value; and the use of italics for their proper mission — that of emphasis, or as catch-words — is lost if the page bristles with italics having other meaning.]

The skidor in the United States.

In *Science*, No. 44, mention is made, in Nordenskiöld's account of the Greenland inland ice, of the 'skidor,' or Norwegian snow-shoe. It may be interesting to your readers to know that it is the snow-shoe most commonly used in Colorado. It is much preferred to the Canadian or web snow-shoe, and in the mountains in winter is often the only means of getting about from place to place — as from the mines on the mountains to the towns, and from one small mining town to another — when there is not enough travel to keep a road open through the deep snow. I know of one case in which a daily mail is carried twenty-five miles on snow-shoes; two men having the route, each making a single trip in a day, but going in opposite directions. The motion can hardly be called 'running,' as it is in the footnote on p. 737, as the shoes are not lifted from the surface of the snow at all, but slid forward at each step, the foot being raised slightly at the heel as in commencing a step in ordinary walking. The shoes that I have seen are from six to eight feet long, and about four inches wide. A pole about seven feet long is used as a guide and support, especially in sliding down hill, when a tremendous pace is often attained on a long slope. E. R. WARREN.

Colorado Springs, Jan. 1.

Standard thermometers.

In your editorial in this week's *Science* you quote the report of the chief signal-officer of the army, implying that a sensible difference exists between the theoretical standard thermometer adopted by this observatory and that of the International committee of weights and measures, and that the signal-service of the army has adopted a new standard thermometer more nearly agreeing with the latter.

I should be very greatly obliged to the chief signal-officer if he will anticipate the regular course of publication of the scientific work of his office, and give to the scientific public the results, at least, of the work from which it is concluded that the signal-service of the army has reached a nearer approximation to the standard thermometer of the International committee.

I have no doubt that there is a small difference between the standard air thermometer and the particular mercurial standard adopted by this observatory as its practical representative, at points distant from the freezing and boiling points; but, as our own standard has never been compared with any air standard in the possession of the signal-service of the army, I shall be quite interested to see the work by which it is concluded that there exists a sensible difference between the two. LEONARD WALDO.

Dec. 31, 1883.

Romalea microptera.

In 1879, in Alabama, I had many opportunities for observing the habits of the 'lubber grasshopper;' and, if my memory serves me, my observation showed that the hissing referred to by Capt. Shufeldt (*Science*, ii., 813) is due in large part to the forcible expulsion of air from the thoracic spiracles. It was always noticed on the occasions referred to by him, but at no other time. W. T.

Synchronism of geological formations.

I cannot agree with Professor Heilprin in the line of argument adopted in his letter to *Science* of Dec. 21, based, as it mainly is, on the assumed non-occurrence of 'evidence of inversion.' Professor Heilprin asks, "Why has it just so happened that a fauna characteristic of a given period has *invariably* succeeded one which, when the two are in superposition all over the world (so far as we are aware), indicates precedence in creation or origination, and *never* one that can be shown to be of a later birth?"

In reply I would say, that some years previous to Professor Huxley's address on this subject, Barrande, in his 'Système Silurien de la Bohême,' had shown such evidences of inversion to exist in the Silurian formation of Bohemia; and though many geologists and paleontologists disagreed with Barrande at that time, as to his theory of 'colonies' by which to account for the facts, yet none could dispute the facts cited by him. If we now turn to the old red sandstone of Scotland, we find still further evidences of inversion of like kind; for, while the crustacean genus Pterygotus, common to both the upper Silurian and lower old red sandstone, has been recently found also high up in the middle series of this formation, the carboniferous limestone shells, Productus giganteus, P. punctatus, Spirifer lineatus, and others, have been found in the old red sandstone far below the fish genera Pterichthys and Holoptychius, so characteristic of the upper old red division. Though there appears to be no reason why such instances of inversion should not have occurred over and over again, one can readily understand why, through the imperfection of the geological record, and the comparatively small fraction of the earth's surface which has been systematically examined, their occurrence is almost unknown.

With reference to the doctrine of migration, I judge, that, from Professor Heilprin's argument, we look at the matter from two different stand-points. He apparently takes no account of the generally accepted view of biologists, that, while organic development has been closely similar in all parts of the world, the rate at which it proceeded has varied within the widest limits, even in adjacent regions. I cannot help looking on the various formations as the records of that development; and, judging of the past distribution of life on the earth from what we at present see before us, I am forced to believe that identity of organic contents in widely separated strata, instead of being evidence of chronological contemporaneity, is exactly the reverse.

Instead of encroaching further on your valuable space, I would refer to Prof. A. Geikie, who, in the current issue of the Encyclopaedia Britannica (9th

edition, subject geology, part 5), gives exactly that view of the matter which I consider the logical basis on which Professor Huxley rested his argument, and which recent researches have in no way tended to upset. E. NUGENT.

Pottstown, Dec. 27, 1883.

SIR CHARLES WILLIAM SIEMENS.

CARL WILHELM SIEMENS died in London on the 20th of November last, at the age of sixty. This distinguished man, better known to the people of Great Britain and the United States as Charles William Siemens, one of eight sons of Ferdinand Siemens, was born at Lenthe, near Hannover, April 4, 1823. He was one of a family of men of science several of whom have become well known by their success in the invention and introduction of improvements and modification of standard methods of engineering and metallurgical work. Among these, his brother, Ernst Werner Siemens, is the most famous. The two brothers have worked together, with frequent assistance from a younger brother, Friedrich, in nearly every field of applied science. They have been most successful in the departments of metallurgy and electricity.

The elder brother, Ernst, entered the army of Prussia, joining the artillery; and Carl was sent to the University of Göttingen. Carl received his preparatory education at the Gymnasium of Lübeck and in the Art school of Magdeburg, near what was formerly the home of Otto von Guericke. After graduation from the university, he entered the Stolberg engineering-works, in 1842, as an apprentice, but remained only a year, leaving for the purpose of going to London to patent and introduce his first invention, the 'differential governor' for steam-engines, and a method of silvering devised by his brother Ernst. He settled in London, opening an office as civil engineer, and making that city his home, becoming 'naturalized' in 1849, but frequently visiting Germany to meet his brothers, who finally joined him in business.

In 1846 the brothers began the study of methods of economizing in the use of fuel in metallurgical operations demanding high temperatures; and the result of their labors, in course of time, was seen in the invention of the Siemens regenerative furnace, — an invention which has since revolutionized the methods of production of steel and of heating iron, and which is still modifying all the industrial operations dependent upon the attainment of maximum heat in furnaces; such as the manufacture of glass, and the reduction of ores of zinc and other 'useful' metals. In 1849 the brothers William and Werner, as they came to be called, attracted the attention of all who were interested in the applications of science by the announcement of their invention of a method of 'anastatic printing,' modifications of which have now become generally introduced for the production of the simpler kinds of line-engravings. This invention greatly interested Professor Faraday, and he was very soon sufficiently well convinced of its value to volunteer to describe it in a lecture before the Royal institution. His helpful aid was one of the most effective means of making the talented young inventors known and of giving them a start in a career bringing them continually increasing fame.

Siemens next turned his attention to the newly announced dynamical theory of heat, and in 1847 adapted a 'regenerator' to a superheated steam-engine. Modifications of the governor for controlling the motion of clock-work were proposed by him at nearly the same time, and his 'chronometric governor' has been long in use on the instruments of the Greenwich observatory. In 1851 he brought out his water-meter, — an instrument in which was a screw with its recording or indicating mechanism sealed in a chamber having a glass window, through which the readings could be made, and so free from friction that it gave most accurate measures of the flow. The regenerative furnace now began to take such shape that the brothers found it to their interest to devote their attention to that; and in 1856 they worked the invention into such form that they could see in it the promise of complete success. By the year 1861 they had patented some of its most essential features. The inventors succeeded in raising the necessary capital, and erected their furnace in works at Birmingham in 1866, and made steel by their process, which was exhibited at Paris at the international exhibition of the following year. The primary object held in view by the inventors was the manufacture of steel directly from the ore. In this they were less successful than in the making of the steel by mixture of wrought-iron scrap with cast iron on the hearth of their reverberatory furnace. This last-named process has become a well-known method of producing the soft ingot-irons misnamed steels, 'mild' or 'low' steels, which materials are now so exclusively adopted by many makers of steam-boilers and of rails. Such steel is steadily driving puddled iron from the market: it is called, sometimes 'Siemens,' and often 'Siemens-Martin' steel; the first attempts to manufacture steel by this method having been

successful in Great Britain through the efforts of Siemens, and in France by application of the Siemens furnace to this use by Martin. The Landore steel-works, started at Landore, Wales, in 1868, were the first to make steel by the Siemens methods on a considerable scale; and it was there that the great engineer conducted the more successful experiments of later years.

The tastes and the studies of the brothers led them, at an early date, to the examination of the lines of development of applied electricity. In 1848, or earlier, they became interested in telegraph-work, and both Charles and Werner began to apply their inventive talents to the production of telegraph instruments and apparatus of various kinds used in electrical measurements. Ten years later the firm of Siemens & Halske, of Berlin and of London, was formed; and they soon became the most extensive manufacturers of electrical apparatus in Europe. They began the construction of submarine telegraph-cables at an early date, and established, later, factories at Woolwich, England, and in Berlin and St. Petersburg. They finally built up their business to such an extent that it became necessary to have a large steamer constantly and exclusively employed in laying down their cables. The Faraday, named for their early friend, was constructed under the direction of Dr. Siemens, and has been since employed in the laying of the principal long cables under the Atlantic, in the Pacific, and under parts of the Indian Ocean. From this branch of electrical work to that of electric lighting was but a short step for these great men; and they have, during the past half-dozen years, been as well known for their success in the introduction of the Siemens system of lighting, and for inventions of apparatus and machinery in connection with it, as for their earlier inventions in other fields. All successful dynamo-electric machines have the Siemens armature; that method of winding, and its peculiar form, being especially fitted for introduction into the modern forms of dynamo. Their lamp has proved to be one of the best in use; and a multitude of details, worked out with characteristic ingenuity and care, has given their system, as a whole, a completeness, and a degree of perfection in operation, which have contributed in no small degree to the fame of Dr. Siemens. The wonderful combination of scientific knowledge with practical experience and information possessed by Siemens made him eminent in every department of application to which he chose to turn his attention. His success in raising capital for large operations was due to

his personal character, however, quite as much as to his reputation as a scientific man and a talented engineer. The firm of Siemens & Halske was thus able to secure concessions from the Austrian government for probably the most extensive system of elevated electric railways yet projected, and has begun its construction in the city and suburbs of Vienna. The success of such railways at the electrical exhibition was such as to give great confidence that such railway systems will supersede those now in operation by steam.

Physicists will honor Sir William Siemens as the inventor of the 'electric resistance pyrometer,' to which is so closely related Professor Langley's 'bolometer.' They will remember him as the discoverer of the influence of the electric light on vegetation, and as the inventor, also, of the 'bathometer' and the 'attraction meter.'

His papers are numerous, and many of them important: they usually relate to subjects closely connected with his work and his inventions and discoveries.

The greatest commercial and financial successes of Siemens and his partners have been in their telegraph-cable work, and, above all, in the introduction of the Siemens system of generating heat for metallurgical operations. This system is estimated to save, in the steel-works of the country, thirty to fifty per cent of the fuel used by earlier methods, to permit an increase of work done per furnace used in nearly equal proportion, to give a finer product in consequence of the purity of the flame, and many incidental advantages. It has saved to the people of the United States alone between twenty-five and thirty millions of dollars during the comparatively few years that these furnaces have been in general use.

The name of Charles William Siemens is honored in every civilized country; and every nation capable of appreciating the good work done by him has given expression to this appreciation. The British institution of engineers admitted him to membership many years ago, and made him a member of its council. He was awarded the Telford medal for his inventions, a distinction only accorded to the greatest of engineers for the greatest of inventions or constructions, and was given the Royal Albert and the Bessemer medals later. He was made a fellow of the Royal society of Great Britain, a member and a president of the British association for the advancement of science, and a member of the councils of both those societies. He was elected president of the British institution of mechanical engineers and of the Society of telegraph engineers, and was made a member of many foreign societies, both scientific and engineering. He was an honorary member of the American philosophical society and of the American society of mechanical engineers. He was given the degree of D.C.L. by Oxford, and of LL.D. by the universities of Dublin and Glasgow. He received many decorations, one of the latest of which was that just offered him by Austria at the Vienna electrical exhibition. He was knighted, a few months before his death, by Queen Victoria; and his sudden and premature death — for he was a man physically strong and sturdy, and evidently constructed for an octogenarian — did not occur so early as to deprive him of more numerous and greater honors of this formal sort than usually fall to the lot of even the greatest of men.

Sir William Siemens was a man of large, well-shaped frame, muscular rather than fat in his early years, but inclining to stoutness as he grew old. He had a noble, well-shaped head; large, strong, and characteristic features, which were mobile, kindly, and unusually expressive. His manners were those of a man who had grown to know his place in the world and to feel sure of a high place among men, quiet, composed, confident, without being in the slightest degree self-asserting, or at any time disagreeable to his associates, to friends, or to competitors in business. Equally at home in the courts of royalty, in the halls of science, and in the offices of business-men, he impressed every one whom he met with his strength, talents, knowledge, and *savoir faire*. He numbered among his friends the great in every department, — statesmen, men of science, engineers, inventors, and capitalists. He was equally honored and beloved by all, and loved equally well to entertain them all in his fine London mansion and in his beautiful country place, in both of which hospitable homes he met his guests with a plain, simple, and kindly greeting and conversation, which made them at once at home, and at ease with their entertainer. One of his most pleasing powers was that of adapting himself to the temperament and the methods of conversation of those whom he met, whatever their rank in life or their personal interests and lines of thought.

In his death is lost, to his intimates, one of the truest and best of friends; to his employees, a kind benefactor; to science, one of her most splendid workers; to the arts, one of the greatest among their promoters; to the world, one of the noblest among its few great benefactors.

ROBERT H. THURSTON.

THE RED SKIES.

THE remarkable atmospheric phenomenon which has recently attended sunrise and sunset, has attracted great attention not only from the general public, but from scientific men, who have endeavored to give a satisfactory explanation of it. Similar appearances have been noted in former years; but they have been of limited extent, and attributable to local causes. The distinguishing characteristics of the present manifestation are its enormous extent, since it has been observed over nearly the whole earth, its persistence, and the fact that the times of its first appearance have varied in different countries, thus suggesting a progressive motion.

In the United States the reports of observers of the signal-service show that its earliest appearance was in October. At Pensacola, Fla., on the 8th, the phenomenon was observed at both sunrise and sunset. Near the middle of the month it was noted along the southern border from southern California to the Gulf of Mexico. At the close of the month it was observed in great brilliancy in the southern and south-western states. In the more northern portions of the country, during October, the sunsets were characterized by unusual brilliancy; but the peculiar 'afterglow' which marked the later appearances was not noted. In the early part of November the phenomenon was still observed on a few days in the south and west; but after the 20th it appeared in its full beauty over nearly the whole country. In New England, the Atlantic, Gulf, and central states, the lake region, the north-west, and along the Pacific coast, the phenomenon was observed, beginning at various dates after the 21st, according to the weather conditions of the different localities. The 27th was the date in which the appearance was first especially marked in the eastern states. Since that date, to the end of the year 1883, the skies have been characterized by the same brilliancy, whenever the weather conditions have been favorable to its observation; the 27th and 28th of December revealing the appearance in the eastern section of the country to a marked degree.

The sky seems to have had essentially the same characteristics wherever the phenomenon has been observed. In Europe and America, however, if we may judge from the published descriptions, the green or blue appearance of the sky has been less noticeable than in India, where the earliest observations were made. In this country the 'afterglow' has been ruddy, with at times an orange or greenish tint. The observer at Memphis, Tenn., under date of Oct. 30, writes, "For more than one hour after sunset there was in the west a segment of red light, whose intensity and brilliancy appeared equal at all points in the segment. The position (altitude?) of the segment was about 30°, azimuth 45° to 120°." On Oct. 31 the appearance was similar, "except that in the north-east quarter of the segment a few converging bands, apparently dark, entered the segment from a clear sky. While no stars were visible in the illumined part of the segment, they were visible in all other parts of the sky, and also in the bands, which, it appears, were dark in contrast." At Washington, on Dec. 29, a ruddy arch arose in the early morning, and was about 25° high an hour and ten minutes before sunrise. Soon after, the usual twilight arch appeared, also of a ruddy tint; and the two were seen simultaneously, the former losing its outline, and growing paler as it became tranfused over the sky. During the day, the material causing the appearance was plainly visible as a white haze surrounding the sun to a distance of about 30°. At sunset on the 27th and 28th the phenomena were as at sunrise, but in reverse order, the secondary glow lasting an hour and three-quarters after sunset. While the glow at the end of December is perhaps not as intense in color as when first seen a month earlier, it is the same in other respects. It has been described in profuse detail in the daily press; and several English magazines, notably *Nature*, have devoted much space to it.

Three different hypotheses have been advocated to explain the phenomenon, assigning its cause to aqueous vapor, meteoric and volcanic matter respectively. It is undoubtedly atmospheric, and due to the presence of some matter in unusual quantities. The persistence of the phenomenon, and its great extent, are objections to the view that it is due to aqueous vapor. There would certainly have been, ere this, extensive precipitation, were aqueous vapor the cause; but reports indicate nothing abnormal in the rainfall. Moreover, the glow has been most noticeable when the air has been driest: it has been a characteristic of the cold, dry weather, which attends areas of high barometric pressure. In addition, the spectroscope has confirmed the indications of the psychrometer. The pocket-spectroscope shows a very weak rain-band, and a strong development of the bands designated by Piazzi Smyth as a and δ, and ascribed by him to 'dry air,' the

latter known especially as the 'low sun-band.' The same result has been obtained in England and in America. A careful examination of the spectrum with a powerful grating spectroscope, made at sunset on Dec. 28, showed that the aqueous lines were feeble; and the spectrum, at its disappearance, was much farther extended towards the green than is usual in a clear sky. From all these considerations, it seems that the hypothesis of an excess of aqueous vapor in the atmosphere is not tenable.

It seems not unreasonable to suppose that the upper regions of the atmosphere have received from some source an accession of light matter which reflects the sunlight. Of the two suggested sources, — meteoric dust encountered by the earth in its progress, and volcanic matter projected to an enormous height, — either would be a satisfactory explanation. The former would seem in itself the more reasonable, were there not in this instance special considerations which give additional weight to the latter. Both of these hypotheses have been independently suggested by various writers. Mr. Ranyard advocates the meteoric view in *Knowledge* for Dec. 7, and Mr. Lockyer the volcanic theory in the London *Mail* of Dec. 10, and current numbers of *Nature*. English scientific men have shown great interest in this investigation; but few references to it have been made, as yet, in the publications of other countries.

It will be of interest to classify the dates at which the atmospheric phenomenon has been earliest observed in different countries. The following table contains a list of the dates and countries, with the approximate distance and direction of each country from the Straits of Sunda, in which occurred the tremendous volcanic outburst of Aug. 26. It should be noted, that, while the dates given have been collated from the best evidence at hand, there is a possibility that they may be too late in some cases, either from the fact that earlier observations have not been reported, or were not made owing to unfavorable weather: they must therefore be taken as only approximately accurate. A few have been derived from general statements in which the exact dates were not mentioned.

This table has been derived mainly from English periodicals and from the records of the U. S. signal-service. The important references to New Ireland and the Hawaiian Islands were received by letter from Mr. S. E. Bishop of Honolulu, who has also obtained from shipmasters the information that the phenomenon has been extensively seen on the Pacific Ocean since Sept. 1. It is also reported from China, but no date is assigned.

Date.	Country.	Distance and direction from Straits of Sunda.	
1883.		*Miles.*	
Aug. 28	Rodrigues	3,000	S.W.
28	Mauritius	3,500	S.W.
28	Seychelles	3,500	W.
30	Brazil	10,500	W.
Sept. 1	Gold Coast	7,500	W.
1	New Ireland	3,000	E.
2	Venezuela	12,000	W.
2	West Indies	12,000	W.
2	Peru	13,000	W.
5	Hawaiian Islands	7,000	N.E.
8	Southern India	2,000	N.W.
8	Ceylon	2,000	N.W.
15	Southern Australia	3,000	S.E.
15	Tasmania	4,000	S.E.
20	Cape of Good Hope	6,000	S.W.
Oct. 8	Florida	13,000	N.W.
19	California	9,500	N.E.
20	Southern United States	11,000	N.E.
Nov. 9	England	7,500	N.W.
20	Turkey	7,000	N.W.
21	United States	11,000	N.E.
25	Italy	7,000	N.W.
26	France	7,500	N.W.
28	Germany	7,000	N.W.
30	Spain	8,000	N.W.
30	Sweden	7,500	N.W.

An examination of this table shows at once the wide-spread character of the phenomenon, and its progressive motion. It is impossible not to conjecture a connection with the volcanic eruption in the Sunda Straits, by which, on Aug. 26, the island of Krakatoa disappeared wholly from the face of the earth. The terrible nature of this outburst can hardly be realized: the sky was darkened for several days, the noise was heard two thousand miles, magnetic disturbances were noted, the tidal wave was distinctly felt at San Francisco, and the atmospheric disturbance was sufficient to cause marked barometric fluctuations, which were noted by the barographs on the continent, in England and America, for several succeeding days. Coincidence in dates is not a proof of a connection between the atmospheric and the volcanic phenomena; but it is certain that the former were first observed near the scene of the latter, and that similar atmospheric effects have been heretofore recorded over limited areas in connection with volcanic outbursts. Assuming the origin of the atmospheric effects to be the volcanic eruption, the table shows an extremely rapid progression in both an easterly and a westerly direction, — the former over the Pacific Ocean, the latter over the Indian and Atlantic oceans, to South America and the West Indies. Mr. Lockyer considers that the latter continued westward to the Hawaiian Islands, and does not regard an eastward pro-

gression at all; but the later evidence from the Pacific shows that the phenomenon was seen several thousand miles east of Java on Sept. 1. This extremely rapid progression has been mentioned as an objection to the volcanic theory, but it is not impossible to believe in its truth; and we know little or nothing of the motions of the higher strata of the atmosphere. Besides, it is not necessary to reckon from Aug. 26, the date of the volcanic catastrophe; for the volcano had been in eruption since May 20, and the steamship Siam, on Aug. 1, in latitude 6° south, longitude 89° east, sailed for more than forty miles over floating pumice. There seems also to be a well-marked southern progression, though the dates for Australia and Tasmania are probably too late.

It is difficult, however, to trace with certainty a progression northward. The October appearances in the United States, and the November appearances in the United States and Europe, if the result of the August eruption, show a rate of progress very much slower than that in an easterly or westerly direction. There seems also to be a gap in the dates; for, with the exception of the three dates in October, there is a September group covering a large territory, and a similar group in November over a different territory. The October records, which are all in the United States, are definite, but few in number. During this month, and up to the 20th of November, there was a well-marked brilliancy in the sunrise and sunset colors over a large portion of the United States, but it did not possess the marked intensity which seemed to suddenly begin after the 20th. It is possible that the sudden increase in the latter part of November, which was noted both in America and in Europe, was due to the arrival over these countries of the volcanic matter which had been moving slowly northwards for ten weeks; and the October appearances may have been either the sequel of the progression towards the West Indies in September, or the forerunner of the later, more marked appearances.

Another explanation, in consonance with the volcanic hypothesis, may be given. The eruption in the Sunda Straits is not the only volcanic outburst of great intensity which has recently occurred, though it has been better known because occurring in an inhabited region. Meagre accounts have been received of a great outburst in Bering Sea, to which brief allusion was made in *Science*, No. 46. The October weather review of the signal-service contains a letter from Sergeant Applegate, the observer at Unalashka, Alaska, in which he says, referring to some sand which fell in a rain-storm of Oct. 20, —

"This sand is supposed to have come either from the Mukushin, or the new volcano adjacent to Bogoslov. The former is at a distance of about nineteen miles south-west, but for years has only issued forth smoke or steam. The latter is a new one, which made its appearance this summer, and burst out from the bottom of Behring Sea. It has been exceedingly active, as it has already formed an island from eight hundred to twelve hundred feet high. According to the report of Capt. Anderson, the discoverer, who sails one of the company's vessels, and who went within two thousand yards of it, it presents a most magnificent sight. The fire, smoke, and lava are coming out of many crevices, even under the water-line. Large bowlders are shot high in air, which, striking the water, send forth steam and a hissing sound. Bogoslov is about sixty miles from here, in a west direction. The new volcano is about one-eighth of a mile north-west of it."

This makes the position of the volcano, latitude, 54° north; longitude, 168° west. The San Francisco *Chronicle* of Nov. 23 contains a more detailed report, but adds nothing essential to the above description. As this extensive eruption has been taking place for some months, it is not improbable that the atmosphere has received a large accession of volcanic material from this source also; and possibly to this cause may be due, at least in part, the appearance of the sky in November.

It would seem as if an examination of the dust particles brought to the earth by rain or snow would furnish final proof as to the source of the matter causing the phenomenon, provided that it is not wholly above the influence of the descending precipitation. The force of gravity would certainly eventually bring to the earth portions of the material. It is not uncommon for meteoric matter to be found in the analysis of freshly-fallen snow; and an anonymous writer in the *New-York herald* of Dec. 29 implies that the late snows have given indications of meteoric matter. This, if verified, would tend to confirm the truth of the meteoric theory; but results of quite a different character are announced in *Nature* for Dec. 20, which has been received since this article was begun. An analysis of fresh snow, made by Mr. McPherson in Madrid, Spain, revealed the presence of "crystals of hypersthene, pyroxine, magnetic iron, and volcanic glass, all of which have been found in the analysis lately made at Paris of the volcanic ashes from the eruption of Java." Similarly a microscopic examination of the sediment from a violent rain-storm on Dec. 13 was made at Wageningen, Holland, by Messrs. Beyerinck and Dam, and compared with a sample of ash from Krakatoa.

It was found that "both the sediment and the volcanic ash contained, (1) small, transparent, glassy particles; (2) brownish, half-transparent, somewhat filamentous little staves; and (3) jet black, sharp-edged, small grains resembling augite. The average size of the particles observed in the sediment was of course much smaller than that of the constituents of the ash. These observations fortify us in our supposition, expressed above, that the ashes of Krakatoa have come down in Holland."

These analyses certainly tend to confirm the volcanic hypothesis, though it is interesting to note that some of the substances found by Mr. McPherson are also characteristic of meteoric matter. The evidence thus far accumulated seems to point positively to the truth of the volcanic hypothesis. The opponents of this view dwell upon the improbability of so much matter being thrown up to such a great height, and of its remaining so long a time in the atmosphere. But the magnitude of the Java eruption has certainly not been overrated; and the amount of material thrown into the atmosphere from this source alone is probably sufficient to account for the observed effects. If we add the amount from the Alaskan volcano, there is less reason to doubt the ability of the hypothesis to account for the quantity of material required. The objection on the ground of the persistence of the phenomenon has been met by Messrs. Preece and Crookes on electrical grounds. If the matter thrown up is charged with negative electricity, it would be repelled from the earth, and its particles would repel each other, thus causing the rapid dissemination of the material in the atmosphere, and its retention for an indefinite period. The decline of brilliancy has been slow during the time it has been observed in this country. In the Hawaiian Islands it is still a marked phenomenon, after a lapse of several months. We may therefore expect that for some time to come we shall observe it under favorable weather conditions, but that it will gradually become less prominent until it is known only as a fact of past history.

W. UPTON.

Washington, D.C., Jan. 1, 1884.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1]—VII.

WE are now prepared to consider and explain the actual distribution and motion of cyclones.

The limitation of violent cyclones to the ocean is natural enough: the level surface of the sea allows a great accumulation of warm, moist air before the upsetting begins, and permits the full strength of the winds to reach a very low altitude. On land the air never waits so long as it may at sea, before upsetting; it never becomes so moist; and, when in motion, the inequalities of hill and valley hold back the lower winds by friction. On land the strong part of the cyclone is relatively higher than at sea, as the records of mountain observatories show; and we know less of it.

No violent cyclones are known to have occurred within four hundred miles of the equator. Here, — where the air is warm, quiet, and heavily charged with moisture; where heavy, quiet rains are frequent; where the conditions which have been mentioned as essential for starting a cyclone are of common occurrence, — cyclones are nevertheless unknown. They occur often enough, however, in the embryonic form of thunder-showers, but they never reach the adult stage; and this must be because at the equator the deflective effect of the earth's rotation is zero, and the inrushing winds are allowed to move directly toward the low-pressure centre and fill up the depression, instead of increasing it by their deflection and their centrifugal force. From this we learn, that, while warmth and moisture may be sufficient to begin a cyclone, they alone cannot maintain it. There would be no violent cyclones if the earth stood still.

It might be inferred from this that cyclones should increase in frequency and intensity as we recede from the equator toward the poles, for in the higher latitudes the earth's deflective force is known to increase. It is true that storms are much more frequent in high latitudes than near the equator; and this is very likely due to the greater ease with which moderate indraughts are here deflected so as to produce a central baric depression. But the more intense storms are all within thirty or thirty-five degrees of the equator, because, in more polar latitudes, the air is not warm or moist enough to co-operate effectively with the deflective forces, and produce violent winds. It has already been explained that a rising column of moist air cools more slowly than one of dry air; and on this there was shown to depend much of the greater energy of oceanic storms over that of desert whirls. It should now be added, that, of two ascending currents of saturated air, the warmer will rise much more vigorously than the cooler: hence the warm, saturated air of the tropical sea breeds hurricanes, cyclones, and typhoons of greater strength than the

[1] Continued from No. 45.

storms that are raised in temperate latitudes, although the latter outnumber the former on account of the more effective aid of the earth's rotative deflection at a distance from the equator.

We must next examine the cause that determines the season of cyclones, throws them near the western shores of their oceans, and requires them to move toward or parallel to the eastern coast of the adjoining continents. This will be found to depend on the general circulation of the winds, as may be seen on examining the air-currents of the North Atlantic at the seasons of the most frequent hurricanes. Poey has compiled a list of hurricanes observed in the West Indies since 1493, amounting to three hundred and sixty-five in all; and of these, two hundred and eighty-seven, or nearly eighty per cent, occurred in July, August, September, and October. Now, these are the very months when the equatorial calms or doldrums are farthest north of the equator, and hence in a position to allow the embryonic storms to develop by the aid of the earth's deflective force. At other seasons the trade-winds extend nearer to the equator; and then, in a latitude where storms might grow if once started, the steady blowing trades prevent even the formation of an embryo. The few storms that occur at these other seasons have less evident causes: they may arise in conflicting winds, and may be fairly thrown among those unexplained effects that we call accidental. Once formed, the storm is carried along, by the general circulation and by the strong winds, toward the West Indies. On nearing them, it moves to the north-west and north, mostly because branches of the trade-winds here turn to that direction in the cyclone season, so as to avoid the mountains farther west, and to run up over the warm land of our country; partly because of the continual polar tendency, or excess of deflection on the northern side of the storm. Even if the general surface-winds do not blow along the storm-tracks, it is very probable that the upper current, returning from the equatorial calms toward the prevailing westerly winds of the temperate latitudes, follows a course closely parallel to the average of the cyclone paths; and there is good reason to believe that the upper winds have a great control over the storm's progression. If the storm should begin on the eastern side of the Atlantic, it would probably be held so near the equator by the indraught of the trade-winds that it could not reach a destructive size. The greater Atlantic hurricanes are therefore those that begin in the western part of the calms or doldrums when they are farthest from the equator, and then, passing along their curved paths, take the West Indies and our south-eastern coast on their way up into the North Atlantic. As they go, their diameter greatly increases; because they draw their wind-supply from longer distances, and because in the temperate latitudes the earth's deflective force is greater than it was in the tropics. But with this increase in diameter there comes a diminution of intensity, because the winds are cooler and contain less vapor; and finally the storm dies away when the weakened updraught at the centre fails to throw its overflow outside of the limits of the whirl. The storm is then not working its way: friction will soon cause the winds to cease, and the disturbance will come to an end.

As for the South Atlantic, it possesses no cyclone region, because the doldrums never extend south of the equator. In spite of the sun's passing to the south in winter, the heat-equator, which determines the position of the doldrums, hardly passes the geographic equator in the Atlantic; the excess of land in the northern hemisphere, and the strong general winds of the southern hemisphere, keep it back: and so the South Atlantic has no cyclones such as occur in all the other oceans. The cyclones of the Pacific and Indian oceans depend on conditions such as have been described for the North Atlantic. They are commonest in the southern hemisphere in February for the same reason that they are most frequent in the northern in the months about September.

We have now considered the origin and motions of the cyclones and hurricanes, and the regions of their occurrence. This study has its highest aim in giving timely warning of their approach and in devising rules for avoiding them. If their tracks lay over the land, the telegraph could in all cases give sufficient notice of their coming, for their motion is slow; but they are at sea during much of their life, and the questions now arise, How can the captain of a vessel gain the first intimation of their coming? and, What should he best do to avoid their dangerous centre?

The storm's earliest effect on the atmosphere is shown by the barometer. It is ordinarily stated that the first effect is seen in a diminution of pressure; but it is very probable, both from theory and from careful observation, that a slight abnormal increase of pressure precedes this diminution. The tropical seas, where cyclones are most violent, have, as a rule, very small and very rare irregular changes in at-

mospheric pressure; and careful watching will pretty surely show a rising barometer, as the annulus of high pressure that surrounds the storm (see fig. 8) moves over the observer. The weather may still be clear, and the wind moderate and from its normal quarter; but this change in the glass demands renewed watchfulness. Let us suppose that such an observation be made on board a vessel lying east of the Lesser Antilles. The chart shows the captain that he is in the stormy belt. He may be directly in the path of the advancing storm, where he will feel its full violence; and he must make the best of his way out of it. Following the rising pressure, three other signs of increasing danger may be observed, — first, faint streamers of high cirrus-clouds may be seen, slowly advancing from the south-east to the north-west, or from the east to the west, in the high overflow from the storm's centre; this unpropitious change may accompany the rising of the barometer, or may be first seen when the barometer is highest: second, the barometer begins to fall, slowly at first, but more and more quickly when it reaches and passes twenty-nine inches; the vessel is then within the limits of the storm: third, the wind has shifted so as to blow from a distinctly northern quarter, and its strength goes on increasing; this is the indraught, blowing spirally toward the centre. There is then no longer any question that a storm is approaching; and as soon as a heavy bank of clouds makes itself seen, moving southward across the eastern horizon, then the central part of the storm is in sight. These clouds are the condensed vapor in the rising central spirals, and rain is falling from them. In deciding on a course to be pursued, the first point to be determined is, where is the storm's centre? That being known, its probable path can be laid down with considerable certainty in this part of the ocean; and then, perhaps, the greatest danger may be avoided. But here a very practical difficulty arises. To find the direction of the storm-centre, we must know the incurving angle of the wind's spiral, — the angle of inward inclination that it makes with a circle whose centre is at the storm's centre. The earlier students of the question — Dove, Redfield, Reid, and Piddington — considered the course of wind to be concentric circles, or inward spirals of very gradual pitch; so that they said the inclination of the wind is practically zero, and a line at right angles to its course must be a radius leading to the centre. Later studies showed this to be incorrect. The inclination of the wind inward from the circle's tangent was found to vary from 20° to 40° or 50°: but it was thought that this inclination was symmetrical on all sides; so that, with an average inclination of 30°, the storm's centre must always bear 60° to the left of the wind's course. Finally, the most recent results seem to show that the wind's course is neither circular nor symmetrically spiral; that the wind's inclination is very distinctly different in different latitudes, on different sides of the storm, in the different conditions found on sea and land, at different distances from the centre and at different altitudes. In so complicated a case, much judgment will be required to find where the storm-centre lies.

First, in regard to the latitude of a storm. Without considering its progression, the nearer it is to the equator, the less its indraught winds will be deflected to the right by the earth's rotation, — the more nearly radial they will be. But, as they move with much energy, they will gain in rotary motion rapidly as they approach the centre, and there will whirl around in almost perfect circles. Storms in low latitudes will therefore tend to have a comparatively small but violent central whirl, only one or two hundred miles in diameter, within which the winds may be almost circular; and the centre will there be nearly at right angles to the wind's course. Farther from the centre, the winds would be nearly radial; and, if storms could arise on the equator, they would have simply radial indraughts with a very small central whirl. On the other hand, in the temperate zone the inflowing winds will be strongly deflected to the right of their intended path; and they must depart widely from a direct line to the centre of low pressure, forming a whirl often one thousand miles in diameter: but, unless they inclined inward at a distinct angle, it would take them too long to reach the centre, and their strength would be lost in overcoming friction on the way. Their average inclination is therefore well marked. The steeper inclination of the winds close to the centre, observed in some northern storms (Toynbee), may be an effect of the tornado action in the cyclone, yet to be described.

Second, in regard to the sides of the storm, as affected by its progression. The inclination will generally be less than the average in front and on the right, and greater in the rear and on the left of the centre; for in whatever manner the storm advances, either by bodily transference or by successive transplanting, the motion of the wind must partake both of the direction of whirling and direction of progress, when seen by an observer not moving in either of these directions. In the case of bodily trans-

ferrence, the direction of the wind as shown by a vane will be the simple resultant of its whirling and progressive motions: in the case of successive transplanting, it will be the resultant of the earth's deflecting force and a curve of pursuit; a curve of pursuit being the path followed by a body moving towards a point that is continually changing its position. In either

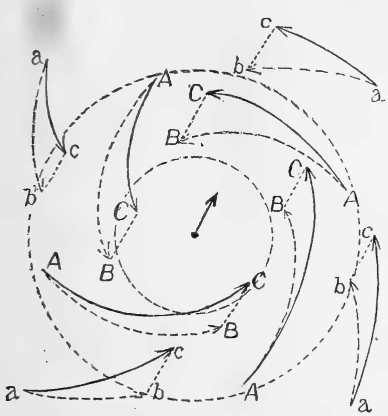


FIG. 18.

case, the effect may be sufficiently represented by fig. 18, in which the broken arrows show the motion of the wind with respect to the storm-centre, and the straight dotted lines measure the velocity of the storm's advance. The wind will seem to blow along the resultant of these two directions, as shown by the full arrows; and the resulting inclinations are

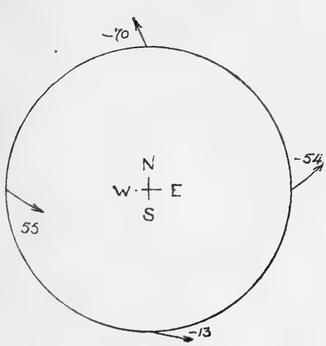

FIG. 19.

manifestly less in front than in the rear, and less on the right than on the left. With the variation of inclination, there will be an inverse change in the wind's velocity. It will blow faster on the right and rear or dangerous side of the storm, and slower on the left and front or manageable side. In the North Atlantic, where the storms often move rapidly, while a hurricane prevails south of the centre, very moderate winds may blow on the north; the difference between the two being about twice the storm's progressive motion. The change in inclination has been shown to occur in some of the West-Indian hurricanes, but it is not very pronounced in the land-storms of the temperate zone. Its best application is in storms on mountain summits; as on Mount Washington (fig. 19), and again in the case of the outflowing winds in the upper half of the storm, as shown by the motion of cirrus-clouds, and illustrated in fig. 20. Of course, in this case of outward motion, the less inclination is in the rear, and the greater in the front.

Third, in regard to land and sea storms. The inclination will be greater in the former than in the latter. On the sea, the centrifugal force of the earth's deflection will be most pronounced, and the winds will be more nearly circular than on land, where friction will tend

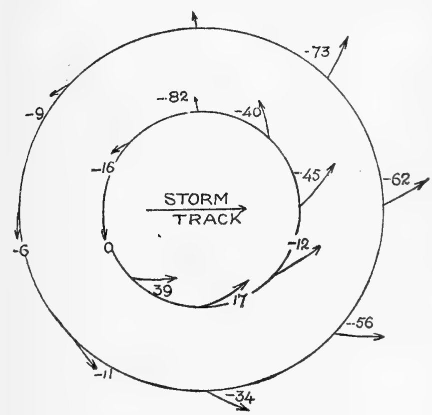

FIG. 20.

to destroy their original motion, and so allow them to run more directly into the storm-centre. This is fully borne out by observation, and is especially well shown in the contrasted cases of storms on the opposite sides of the northern Atlantic. Fig. 21 shows an average storm in the eastern United States, about ready to embark on the ocean; and in this the inclination of the winds is less on the sea than on the land side. This effect is doubtless produced in part by the preceding condition concerning the front and rear sides of the storm. But in examining a storm just about landing on the western shores of Europe, as shown in fig. 22, it is seen that here the front winds have the greater, not the lesser, inclination: hence position in regard to the centre cannot be the cause of the differing inclinations here. A better explanation is found in the fact that the eastern

side of the storm receives its winds from the land, and the western side from the sea; and, in accordance with this, the eastern side should have the greater, and the western side the lesser inclination, as is the case. The fact that European storms have a less velocity of progression than those in this country would still further allow the land and sea conditions to control the inclination in the former region.

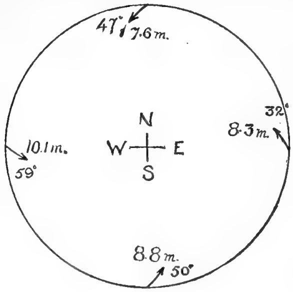

FIG. 21.

Fourth, it is manifest from all the preceding cases that the outermost winds of a storm are nearly radial, and that their direction becomes more circular as they advance. This results directly from the faster motion and less radius, consequently the greater centrifugal force near the centre, and requires no special illustration. It need only be noted, in recalling the first or latitude condition, that, at large distances from the centre, equatorial storms are generally more radial than those of the temperate zones; but, at small distances from the centre, this rule may have to be reversed. This is quite in accordance with the greater size but less intensity of the storms in the temperate zone.

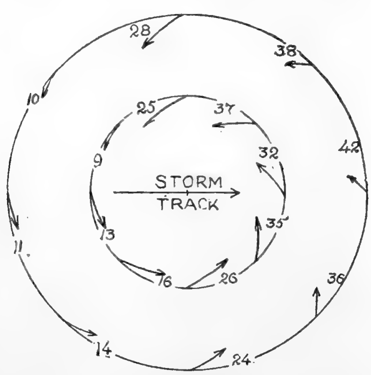

FIG. 22.

Fifth, in regard to altitude. The absence of strong friction will allow the upper winds to whirl in even more circular paths than they do at sea. Indeed, at a moderate altitude, say 7,000 feet, the winds are probably perfectly circular in the core of the storm; and at a little greater height they assume an outward inclination as they change to the outward spiral of the upper overflow. It is common, therefore, to note that the surface-winds of a storm are not parallel to the motion of the clouds. As the latter are more fully in control of the earth's deflecting force, they will always tend to the right of the former; and, in the extreme contrast of surface-indraught and uppermost outflow, the cirrus-clouds may drift slowly (in appearance) 90° or 120° to the right of the surface-winds. It is therefore usually to storm-disturbances of the general atmospheric circulation that the irregular drifting of different cloud-layers is to be ascribed. And now, after this long digression, we may return to the rescue of the vessel in the West-Indian hurricane.

(To be continued.)

THE BUSINESS OF THE NATURALIST.[1]

THE Society of naturalists of the eastern United States is an association in which all preliminaries should be brief, and ceremonious speeches out of place. Our first official meeting at Springfield was, however, almost wholly occupied with the technicalities of organization, and we necessarily gave but little time to other matters. The attendance at that meeting, on account of the natural aversion of scientific men to details of such an uninteresting nature, was small, compared with the numbers now present; and our list of members is also more than double what it was then. Under these circumstances a few preliminary words of explanation will not be wholly without usefulness. Our correspondence with scientific men also shows that the novelty of the organization and objects of this society requires some explanation in a comprehensive and condensed form from some one person.

So far as I am aware, this is the first attempt to form an association for the transaction of what may be called, without derogation to the dignity of our future labors, the business of naturalists.

Heretofore scientific associations have been founded and conducted upon the idea that the technical interests of science were necessarily inseparable from the results of scientific work, and should be considered by the same body which also attends to the presentation, discussion, and publication of the records of discovery and research. It has seemed to me for at least seven years past, that, on the contrary, a division of labor was necessary, and ought to be brought about. The technicalities of science have increased to an enormous extent within the last decade; and some effectual means of mutual culture and

[1] Address delivered in New York before the Society of naturalists of the eastern United States, Dec. 28, by the president, Professor Alpheus Hyatt of Cambridge.

co-operation should be found which can be of great benefit, not only to those whose opportunities have been small, but also not less to those who are capable of contributing most in such a scheme for the general good of science-workers. The contact of fellow-workers not only stimulates the intellect to its best efforts in the presence of appreciative hearers, but enables the mind to broaden its outlook, and avoid the effects of the cloister-like seclusion in abstraction, which has had such fascination for the students of all ages, and which has also had such serious effects upon the usefulness of individual life. The misconceptions and difficulties which science has to contend with have also become of greater importance; and one has only to mention the word 'vivisection' to justify this remark, and at the same time indicate a field for practical effort on the part of this society, which should bear good fruit in the immediate future. In fact, whichever way we turn, whether to the purely practical details of making sections, or other preparations in any branch of natural science, or to the broader questions of a technical nature which interest the public at large, we find in every direction paths of usefulness opening, which must lead to beneficial results for the future of science and science-workers, if properly and judiciously handled.

They seem to us to embody questions which are vital to the unimpeded progress of science. We can, it is true, get along without any efforts to ameliorate the present condition of affairs; but will this be the most desirable course for the interests of science and for our own future satisfaction? Will the amount of time we may gain for investigation by remaining at home, and standing aloof from disturbing causes, repay us for the inevitable loss of influence, and the possible loss of future facilities for the prosecution of work? In some classes of work such losses are sure to be visited upon us, or our immediate successors, through the growth of ignorant prejudices we have taken no trouble to correct or prevent.

An able writer in *Science* of Oct. 26, on the subject of vivisection, points out the necessity of taking some immediate steps for the information of the public upon this question, and, it seems to us, uses very able arguments to support the conclusion, which is, that "the only danger lies in the ignorance of the great majority of ordinarily well-informed people regarding such subjects." This writer, in conclusion, remarks with great force, "*Secrecy*, not publicity, is what American physiology has to fear."

The society may disagree with me, and perhaps consider it unnecessary to take any active steps in this direction; but the unavoidable effects of the general discussion of such a question will be very reassuring to the men who will have to bear the brunt of the coming struggle; and every one who takes part in it will find that his opinions and future course may be more or less influenced, and perhaps even determined, by what he may hear.

Those most deeply interested in the American association will surely be willing to grant that such questions can be more effectively handled in a society composed of purely professional men, whose undivided attention can be given to them, whose interest is of the deepest nature, and who can be depended upon to give sufficient time and work when appointed on committees.

Another question which seems to me of absorbing general interest relates to a matter about which great differences of opinion may exist, even among scientific men themselves; and in this I speak purely as an advocate of one side. What can we do to call the attention of the institutions of learning to the fact that their duties to science and the future of investigation demand a change of policy? Throughout the country, and even in the higher institutions, false views are prevalent with regard to the qualifications necessary for teaching science. We find science-teaching placed on the same basis as mathematics and the languages, in which books are the necessary media for the communication of ideas. It is commonly supposed that a man can learn his lesson, and repeat it to scholars, and that one may be a good teacher of a science of observation without being himself an observer. In some places even, a tendency towards investigation is considered a disqualification, since it withdraws the mind from giving full attention to the practical duties of the classroom. In such places education is measured by the quantity, and rule of thumb, by the amount of supposed knowledge gained, without relation to how it is gained, or what habits of mind are cultivated in the operation. Undoubtedly, the teacher in such places may need and acquire a certain amount of dexterity and success as a mental taxidermist; but that he will ever intentionally train a single student to do original work is beyond belief.

The slight amount of respect and consideration shown to the claims of the investigator are in part due to this evil, and in part to a custom which is excessively hard to deal with. We refer to the habit, very prevalent in this country, of sending children to the same colleges at which the parents themselves have been graduated. This habit shows some signs of breaking up, and the technical schools are doing fine work in this direction; still, the American mind is conservative in respect to education, and tends to keep the hereditary colleges full, irrespective of their intrinsic worth. If these institutions should have to rely solely upon their educational attractions, we should find that the individuality of instructors, their reputation for sound learning and original thought, and their capacity to do the highest kind of teaching, would eventually command the same respect, and perhaps the same emoluments, as in Germany.

Can we, as a body, arrive at any general agreement of what should be done with regard to such vital questions? or can we even do any thing towards the formation of an opinion of what it would be desirable to do? This last result will seem tame to many energetic minds; but the speaker is old enough to have seen the mighty effects of active and determined agitation upon what is familiarly known as public sentiment. Sooner or later — and generally much sooner than any but the most sanguine agitator can anticipate — the times become ripened, and the last

steps of the process of change to the new order of things follow in rapid succession. An event may be long in preparation, but its consummation takes place with a rapidity which must be experienced to be fully appreciated.

Another question of the greatest and at present time-absorbing interest is, what can be done to force the schools to properly prepare students for the colleges and universities? We use the word 'force,' rather than 'induce,' because all arguments except those which can be supported by the pressure of the entrance examinations fail to awaken these schools to the needs of science-teachers in these higher institutions. The following remarks appeared in *Science* of May 18, 1883, and can be used appropriately in this connection: —

"In the brief, informal discussions [which took place at the Springfield meeting], the opinion was very generally expressed, that one of the most important questions with which we have to deal, and one which needs immediate attention, is the preparation necessary for the study of natural science in colleges. The great difficulty in making a success of college instruction in the sciences lies in the fact that not one young man in twenty knows either how to observe, or how to think about facts of observation. His education in that line is very deficient, or else entirely wanting; he is utterly helpless without his books, and seems quite unable to see or to correlate facts for himself. No other branch of the curriculum is so inefficiently treated by the preparatory schools and academies. It is the reverse of right that the college professor, with a class of from forty to eighty men, should have to make the vain attempt to teach the lowest step in the observational sciences. Methods which can alone guarantee success in imparting to the eye and the mind the rudiments of science cannot be employed under such conditions. Moreover, it is a matter for the deepest regret, that young men who are soon to be in places in the world where they have no books, and where the keenest exercise of the powers of observation, and the judgment of facts, are demanded, should in so many cases have no opportunity, or next to none, either in school or college, for the acquisition of a training upon which the success of their life-work, in the larger number of professions and occupations, is dependent.

"It is to be hoped that one needs only to mention such objects as these, to bespeak for this new association the sympathy and support of all naturalists, and earnest workers in science."

In the above remarks expression is given to opinions some of which, we know, will meet with general approbation, and others will very properly be regarded as merely personal views. We shall, however, have attained the object for which this address was written, if we have made it evident that this society can, if it be so disposed, take up questions of the highest importance to the public service of science, and help towards their solution by its deliberations. We believe it can do this wherever it can unite the majority of scientific men in opinion and in effort. The power which can be wielded by such an organization is in exact proportion, not to its numbers, but to its earnestness, determination, and especially its fearless support of what is just and right.

After referring further to the work of the society, as outlined in the article already referred to, Professor Hyatt proceeded: —

Enough papers to occupy nearly the whole time which can be devoted to them will be announced by the secretary. Though these and kindred subjects will be our most important objects, it was due to the society to show that its scope was not necessarily wholly confined to such details; and this we have endeavored to accomplish in the first part of the preceding remarks.

In conclusion, we beg leave to report that the executive committee has had great responsibilities thrust upon it since the first meeting. These they have endeavored to meet to the best of their ability; and we believe that the present attendance, and the many honorable names on our list, will help to extenuate the errors inseparable from haste and overwork.

In place of Professor Clarke, whose absence in Europe we regret, the executive committee appointed Dr. C. S. Minot, and he has faithfully and acceptably performed the duty of secretary *pro tem.*

THE NEW MORPHOLOGICAL ELEMENT OF THE BLOOD.

WITHIN recent years it has been established beyond doubt by the labors of Hayem, Bizzozero, and others, that there exists in the blood of mammals, and apparently of other vertebrates, a third type of corpuscle, differing morphologically from both the red and the white corpuscle, and possessing certain distinctive properties of the greatest importance in coagulation. These elements were called hematoblasts by Hayem upon the supposition that they are eventually transformed into red corpuscles. As this view is by no means established, it will be better to speak of them as blood-plates, the name given to them by Bizzozero. These blood-plates must not be confounded with the 'invisible corpuscles' of Norris. The latter, according to the testimony of most observers, are simply ordinary red corpuscles, from which the haemoglobin has been removed by the method of preparation. As might be supposed, the presence of these bodies was more or less clearly noticed by some of the many observers who for years past have made the blood a subject of investigation. That they escaped detection in the great majority of cases, is owing, doubtless, to the very rapid alterations which they undergo after the blood is shed, unless especial measures are taken to preserve them.

To Hayem belongs the credit of their real discovery. His investigation of their form, and, to a certain extent, of their properties, was so thorough, and his method of demonstrating their presence so simple, that the attention of other observers was forced to the subject; and his results were soon confirmed, with the exception of certain details of structure which are still open to investigation. On account of the quickness with which they are destroyed after the blood has escaped from the vessels, it is necessary to make use of certain preservative liquids which have the power of fixing these corpuscles in their normal shape. The solution recommended by Hayem is composed, of water 200 parts, sodium chloride 1 part, sodium sulphate 5 parts, and mercuric chloride .50 parts. Bizzozero recommends a .75% solution of sodium chloride, to which some methyl aniline violet has been added. Osmic-acid solution, 1%, may also be used. To obtain good specimens of the blood-

plates, the following method is suggested by Laker. A drop of preservative liquid is placed on the slide, and a drop of blood on the cover-slip, and the slip laid quickly on the slide, so that the two drops come in contact. As many as possible of the red corpuscles are then drained off by means of a piece of filter-paper applied to the slip on the side opposite to the drop of preservative liquid; or the two drops may be placed on the slide, and the cover-slip laid on from the side of the preservative liquid. The one precaution which it is necessary to observe is to lose as little time as possible in transferring the blood to the preservative liquid.

Obtained in this way, the blood-plates of the mammal are small, non-nucleated, discoid bodies from one-fourth to one-half the size of the red corpuscles. Hayem states that they are bi-concave, like the red corpuscles, and that many of them have a slight greenish or yellowish color due to the presence of haemoglobin. Bizzozero, on the other hand, maintains that they are perfectly colorless and not bi-concave. Mayet supports Hayem's statement with regard to the presence of haemoglobin in some, at least, of the blood-plates; while Laker thinks that the pale greenish hue possessed by them is owing to a reflection of light from the upper surface. The same tint may be observed in white corpuscles; and, furthermore, when the blood-plates are collected in masses, this color does not become more distinct. Laker confirms Hayem's statement that the plates are bi-concave, and says that he has often obtained from them the well-known optical phenomenon shown by the red corpuscles. The blood-plates occur in considerable numbers. According to Hayem, they are forty times more numerous than the white corpuscles, and twenty times less numerous than the red corpuscles. Staining-reagents have but little action upon them. Water causes most of them to disappear, though some individual plates may resist its action for a long time. Dilute solutions of acetic acid or caustic alkali quickly destroy them, while a 35 % solution of caustic potash is without any marked action. Laker states, that, in their general behavior towards reagents, they resemble most the nucleus of the white corpuscle. With regard to their origin, nothing is known. That they are not simply remnants of broken down white corpuscles is evident, in the first place, from the typical form they possess, and, in the second place, from the difference in chemical composition between the two, as shown by reagents. Bizzozero has proved conclusively that they are not pathological formations arising after the blood has been shed, since he has seen and studied them in the mesenteric blood-vessels of living animals.

Hayem believes that the blood-plates are finally transformed into red corpuscles. His reasons for this belief are as follows: 1. They possess a similar form; 2. They have a similar chemical composition, both containing haemoglobin; 3. The appearance of many intermediate forms between the typical blood-plate and the ordinary red corpuscle, especially in certain pathological conditions — after a severe hemorrhage, for instance. Under these conditions, Hayem states that the plates become more abundant, and gradually return to their normal proportion as the number of red corpuscles increases. In the main, these statements are confirmed by Mayet; but, as we have said, the similarity in form, and the presence of haemoglobin, are denied by others, especially Bizzozero; and neither Bizzozero nor Laker was able to detect any intermediate forms between the blood-plates and the red corpuscles. Perhaps the most interesting result that has come out of the study of these elements is the knowledge of the important part they take in the coagulation of blood. This property has been thoroughly investigated by Bizzozero. His conclusions may be briefly stated as follows. Liquids which have a tendency to prevent coagulation also preserve the blood-plates more or less completely from destruction. Experiments made upon blood kept within the living blood-vessel show that as long as the blood remains uncoagulated the blood-plates are unchanged, while the rapid coagulation of portions of the blood removed from the vessel is always preceded by a destruction of the plates and the formation from them of granular masses. When a drop of blood is whipped with small threads for about fifty seconds, the threads withdrawn, washed gently in .75 % sodium-chloride solution, and then examined under a microscope in the methylated soda solution, they are seen to be covered with a layer of plates, together with some white corpuscles. If the whipping is continued longer, the plates are converted into a granular mass, and covered with a layer of fibrine. If this process is reversed, and a slow stream of blood is allowed to pass over a thread watched under the microscope, the different stages of the process can be observed, — the deposition of the plates, their fusion into a granular mass, and the subsequent formation of fibrine. When one of these threads, to which the blood-plates and a few red and white corpuscles are adhering, is added to a liquid containing the two fibrine factors, but not fibrine ferment, coagulation takes place. That this coagulation is not owing to the thread or to the red corpuscles is easily demonstrated: it must result from the addition of either the white corpuscles or the blood-plates. When, however, bits of tissues rich in leucocytes — such as the spleen, lymph-glands, medulla of bone — are added to the above liquid, no coagulation at all, or else a very imperfect coagulation, follows. The inference, then, is, that the coagulation in the first case results from the addition of the blood-plates. In his latest communication, Bizzozero states, that if to a few drops of peptonized plasma, which coagulates very slowly, some water or carbon dioxide is added, and the preparation is examined under the microscope, the blood-plates will be seen collected into large heaps in which the individual blood-plates may still be recognized. In a few minutes the plates fuse together into a granular mass which becomes vacuolated, and at this moment coagulation begins. From the periphery of the granular heaps hundreds and thousands of fine processes radiate, and form a network which slowly spreads into the surrounding plasma.

Bizzozero attributes the origin of thrombi in blood-vessels to the destruction of these corpuscles. He has been able to watch the process of formation in the mesenteric vessels of living animals when a lesion of the walls of the vessels was produced in any way.

In the blood of animals with nucleated red corpuscles, Hayem has described a form of corpuscle which has properties analogous to those possessed by the blood-plates of mammals. These corpuscles may be preserved for study by the use of the liquids mentioned above. They are colorless, nucleated, slightly flattened bodies, bearing a general resemblance in shape to the red corpuscles, though usually more elongated at one or both of the poles. They vary greatly in size, but as a rule are somewhat larger than the white corpuscles. They are distinguished from the white corpuscles mainly by a difference in form and by the changes which they undergo after the blood has been shed. The white corpuscles are always more or less spherical, while the plates are flattened disks. After the blood has been shed, they become exceedingly viscous, and form granular masses from which fibrous processes radiate. Their functional value in coagulation appears to be the same as that of the blood-plates in mammals with non-nucleated red corpuscles.

William H. Howell.

THE COMSTOCK LODE.

Geology of the Comstock lode and the Washoe district. By George F. Becker. (Monographs U.S. geol. surv., iii., with an atlas.) Washington, 1882. 422 p. 4°.

The appearance of the second of the new series of monographs published by the U. S. geological survey will be greeted with pleasure by the scientific world, not only on account of the amount of new information it contains regarding the geological and physical character of one of the most important ore-deposits on the globe, but also as an index of the increasing interest which is being taken in this country in a very important but comparatively new branch of geological research. Becker's report contains, with perhaps one exception, the most considerable contribution yet made by an American to microscopical petrography, and deserves for this reason, aside from its other merits, high commendation.

Referring, for a historical, economic, and technical treatment of the Comstock lode, to the works now in preparation by Messrs. Lord and Eckart, the author devotes himself to a purely scientific investigation of this interesting region. A *résumé* of the results reached by von Richthofen, Zirkel, King, and Church, is given, which is followed by a detailed description of the rocks in connection with which the ore-deposits occur. This work is carefully done, and, notwithstanding a very apparent lack of acquaintance with the literature and many important methods of modern petrography, is a valuable contribution to the subject. For instance: the actual presence of the suspected sodalite in the granite might easily have been placed beyond a doubt by a simple microchemical test. Again: the measurement of extinction-angles would have been much more satisfactory had they been made on cleavage pieces from their isolated powder instead of in the sections; while Boricky's test would certainly have yielded as good results as Szabo's.

The variety of rocks in the area studied is very great, comprising, in order of their ages, granite, metamorphics, granular diorite, porphyritic diorite, metamorphic diorite, quartz-porphyry, earlier diabase, later diabase, earlier hornblende andesite, augite andesite, later hornblende andesite, and basalt. None of these exhibit in their occurrence or structure any thing very striking or abnormal, if we except the sodalite in the granite, whose presence is, however, left very doubtful. Of especial interest are the decomposition processes, which have altered the rocks in the area between the Comstock and Occidental lodes almost past recognition. These are thought to be due to solfataric action, which was not earlier than the eruption of the later hornblende andesite; and they have received a good share of the author's attention. All the rocks of this area are equally decomposed; and, in the case of all, the same minerals have undergone the same alteration. Hornblende, augite, and mica change into chlorite, and this in turn generally to epidote, though sometimes to a mixture of quartz, calcite, and limonite. The felspar becomes filled with secondary fluid inclusions, and finally forms a mass of calcite, quartz, and a substance of unknown character, which, according to the author, is certainly not kaoline.

By far the most interesting results of the author's studies, from a petrographical standpoint, are those arrived at in reference to the origin and nature of that much-discussed rock-type, propylite. As is well known, this name was given by von Richthofen to certain early tertiary, andesitic rocks of Hungary, possessing a fibrous green hornblendic constituent and a granitic habit. Both von Richthofen and Zirkel regarded the Washoe district as a locality where this type was especially well developed; and the present author entered upon his work fully convinced of the correctness of their views. All the more interesting, then, is the fact that a careful and elaborate study of these

very rocks forced him to the opinion that propylite has no right whatever to be regarded as an independent rock-type, but is always an alteration product of diabase, diorite, or andesite, by the change of the bisilicates to uralite or chlorite.

In chapter iv. the author discusses theoretically the structural results of faulting. He regards the schistose structure, so often observed in the andesite, as the result of faulting under intense lateral pressure, and shows that such sheets would naturally tend to arrange themselves in a logarithmic curve, as seems to be the case at the Comstock.

The chapter on chemistry is not very satisfactory. But few new rock analyses are offered, and none are ably discussed in connection with the microscopic diagnosis. The finding of very small quantities of ore in the accompanying rocks, especially the diabase, would seem to suggest just the reverse course of reasoning from that adopted; and certainly none of the facts presented appear to warrant the supplanting of von Richthofen's theory, that the ores came from great depths, by one ascribing their deposit to segregation produced by ordinary solvents (hydrogen sulphide and carbon dioxide) from the rocks at the side of the lode.

The discussion of the heat-phenomena of the lode receives especial attention in chapter vii. The rapid increase of temperature is well known to be one of the great hinderances in working the mines, being nearly double the average observed elsewhere. This has been accounted for by some by chemical action: as, for instance, the oxidation of pyrite, or the kaolinization of felspar. The author concludes, however, in light of the careful experiments conducted by Dr. Barus in reference to the latter theory, that such an explanation is untenable; and that the source of the heat must be sought in former, and not entirely extinct, volcanic activity.

The observations of Dr. Barus, bearing on the electrical activity of ore-bodies, are recorded in chapter x. They relate as well to the deposits at Eureka as to those in the Comstock, and, while not directly productive of results of practical importance to the prospector or miner, possess a very considerable scientific interest.

The execution of the plates and maps is up to the usual high standard of the survey publications. The chromolithographic representations of rock-sections in polarized light are particularly successful, and, as far as my experience reaches, are the best of the kind yet produced anywhere.

MARTIN'S ELEMENTARY PHYSIOLOGY.

The human body: an elementary text-book of anatomy, physiology, and hygiene. By H. NEWELL MARTIN. New York, *Holt*, 1883. 11+355 p., 4 pl., illustr. 16°.

THIS volume forms the second volume in the 'American scientific series, Briefer course,' published by the Messrs. Holt. It is an abridgment of a larger work by the same author, and is intended for use in schools and academies. The demand for such a book, and the difficulty of preparing one, are well known to any one who has sought in vain, among the numerous text-books now in the market, for one really scientific, and suited to the age and needs of his pupils. It is a book of about three hundred and fifty pages, but how it could well have been made smaller we do not see. The language is simple, the style clear, and the book, at the same time, easily comprehensible and thoroughly scientific. It is elementary without being superficial. The essential facts are pointed out to the pupil without taxing his memory with a mass of unimportant details, or vexing him with conflicting theories on unsettled questions. At the end of each chapter these are condensed, and their connection shown in a brief summary, which aids the memory, and excites the interest of the pupil. From the physiological facts are deduced the most important laws of hygiene, while the student gains glimpses of wider fields of anatomy and zoölogy in the footnotes.

A new and most important characteristic of the work is the series of directions to teachers for demonstrating on frogs and rats the main outlines of anatomy, and for physiological experiments accompanying each chapter. These are all clearly explained, and easy, yet it is to be feared that they will be neglected by three-fourths of the teachers using the book. Their importance might well and justly have been far more strongly urged in the preface. We hear every year less of the objections to such dissections. The great difficulty is, that most of the teachers in our schools and academies have been taught physiology in the old way; and many of them have never even seen the inside of a frog. They greatly over-estimate the difficulties of such dissections and experiments, and do not appreciate that the sight of the real organ or process is worth more to the pupil than an hour's study of text-books or charts. If the teacher will once try fairly the experiment of following these directions, he will be surprised at the small amount of extra work caused, and at the enthusiasm

which they call forth in his class. The figures of the book are large and clear: in one or two of the plates so much has been attempted that they appear, at first sight, confused; but this is a slight blemish in a book worthy, in other respects, of all commendation. The book is well fitted, in the language of the author in his preface, to "prepare the student for the work of subsequent daily life by training the observing and reasoning faculties."

PACKARD'S BRIEFER ZOÖLOGY.

Zoölogy. By A. S. PACKARD, jun. New York, *Holt*, 1883. 5+334 p., illustr. 16°.

THE Zoölogy of the same series as the preceding is also an abridgment of and introductory to the larger text-book by the same author. Of the 315 pages of the text, only 130 are devoted to invertebrates: of the 180 pages devoted to vertebrates, many are occupied by large and very ornamental but hardly useful pictures. Of about 300 cuts, 90 are devoted to birds and mammals, and 40 to fish: of these a few are anatomical, the rest illustrations. The removal of many of these cuts would leave room for more print, without affecting the attractiveness of the book. The book is intended for young pupils, and yields to the common prejudice that birds and mammals are most interesting to this class. Yet precisely these animals come least within their reach, and their study of birds especially involves far more memorizing than observation on the part of most young pupils. These same pupils, in one afternoon excursion, could collect scores of insects, in which Professor Packard, as his other books show, could easily interest them. But to insects proper only 16 pages are devoted. Here a few pages of tables for determining the families, at least with one or two of the most common and familiar species as examples under each, would encourage the young student to new search and observation.

Of most of the lower types and classes the young student sees generally only one or two specimens, if any. Here clear, sharp, and exact definitions are needed to enable him to distinguish between essential and non-essential characters. These we miss; and here, as under certain types in the larger text-book, the student becomes bewildered in the attempt to burden his memory with a mass of, to him, equally important data. This is especially noticeable in the treatment of the difficult type of the Coelenterata, but more or less marked elsewhere. The points of affinity and difference between the succeeding types and the structural characteristics which form the basis of classification in the subdivision of those types are not clearly or sharply stated. There are no grand outlines to direct the student's attention. In a text-book intended exclusively for use in the laboratory, it is perhaps admissible that typical and specific characteristics should appear side by side, and with equal emphasis; in a text-book designed largely for use in the classroom as well, it is a great defect. These outlines are little, if any, clearer in the abridgment than in the larger book. The anatomical cuts are generally good, but they are most of them small, much smaller than those of the elk or moose; and in some of them so much has been attempted that the organs are sometimes difficult to trace. Larger and more schematic drawings would have been more useful. Barring certain of these defects, Professor Packard's larger work is the best text-book which we have for use in our higher schools and colleges, but it certainly has not been improved by abridgment.

MARIE'S HISTORY OF THE SCIENCES.

Histoire des sciences mathématiques et physiques. Par M. MAXIMILIEN MARIE. Tome I. De Thalès à Diophante. Paris, *Gauthier-Villars*, 1883. 286 p. 8°.

THIS volume is devoted to the mathematics of the Greeks, and covers nearly a thousand years (640 B.C. to 325 A.D.).

The author divides this time into three periods, roughly distinguished by the nature of the work done in geometry; the first period (640 B.C. to 310 B.C.) being that in which no attempt was made to apply arithmetic to geometry, but exclusive attention was given to dealing with and comparing concrete magnitudes without reference to their numerical measures. During the second period (310 B.C. to 150 B.C.), numerical measures of complex magnitudes began to be investigated, — for example, Archimedes obtained a first approximation for the ratio of the circumference of the circle to its diameter; but the numerical work was merely incidental, and was usually suggested by some problem connected with astronomy: while, in the third period (150 B.C. to 325 A.D.), reasoning on concrete magnitudes began to be largely replaced by reasoning on their measures, and geometry developed mainly in the direction of trigonometry.

At the beginning of the history of each of these periods is an introductory chapter con-

taining a brief *résumé* of the principal characteristics of the period, together with a short account of the progress made during the period in each of the branches of the mathematical science of the time, — geometry, arithmetic, physics, and astronomy. This is followed by the biographies of the mathematicians and physicists of the period and an analysis of their work.

The three introductory chapters, taken together, form a short and interesting history of Greek mathematics; while the biographies are sufficiently full, and the analyses are remarkably clear and concise.

SECONDARY BATTERIES.

The chemistry of the secondary batteries of Planté and Faure. By J. H. GLADSTONE and ALFRED TRIBE. London, *Macmillan & Co.*, 1883. (Nature series.) 11+59 p. 16°.

THE valuable papers of Gladstone and Tribe, originally printed in *Nature*, have been published in a collected form in the present volume, which contains much information as to the chemical actions going on in the Planté and Faure batteries. In successive chapters the authors consider the subjects of local action, the chemical changes occurring in the charge and discharge of the cell, the function of the sulphate of lead formed, and some minor topics. The chapter devoted to the function of the sulphate of lead, which the authors have shown to be formed in the normal action of the battery, is especially interesting. In the formation of a Faure cell, sulphate of lead, originally produced by local action, is oxidated to a peroxide on one plate, and reduced to spongy metallic lead on the other; and, when the cell is discharged, lead sulphate is finally produced on both plates. On recharging the battery, the authors consider that the lead sulphate is again oxidated on one plate, and reduced on the other, as when the cell was originally formed, — a point which is a very practical one, as the lead sulphate, if not oxidated, will soon prove fatal to the usefulness of the cell. This view, announced in the original papers, is substantiated by a number of recent experiments, notwithstanding the doubts that have been thrown upon it; so that, in charging and recharging, the plate of the cell is not corroded. It is also shown that the fact noticed by Planté, that elevation of temperature facilitates the formation of the cell, is explained by the more rapid formation of lead sulphate under these conditions.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Vassar brothers' institute, Poughkeepsie.

Dec. 5. — Professor W. B. Dwight gave the results of a recent re-examination by himself of Van Duzer's iron-mine, Cornwall station, Orange county, N.Y. Here a low ridge presents a red rock of sandstone and conglomerate, running into red shales to the south, in contact conformably with a highly fossiliferous limestone in nearly vertical layers. No other combination of the kind is apparent in this region, and there was much speculation among early geologists as to the horizon. W. B. Rogers called the red rock the triassico-jurassic sandstone; Dr. W. Horton considered it the Medina group, and assigned the limestone some place lower; Prof. Mather, with some doubt, concurred with Horton, and further assigned the limestone to the Catskill shaly limestone. Prof. Dwight, after a careful study of the locality, is satisfied that the red rocks are of the Medina epoch, and the limestones lower Helderberg; but by the fossils he identifies, in addition to the Catskill shaly limestone, the tentaculite limestone and the lower pentamerous groups. He finds no foundation for the statements of Horton, indorsed by Mather, that the iron ore occurs in layers between the layers of limestone. On the other hand, it is a bed of limonite formed at the base of the ridge superficially, as in other iron-mines of the region, by the decomposition of the red ferruginous shales at the junction with the limestone.

Five hundred and sixty-two specimens, representing various departments of natural history and archeology, were reported to the museum by the secretary.

Franklin institute, Philadelphia.

December 19. — A special committee, appointed to consider the propriety of recommending the councils of the city of Philadelphia to pass an ordinance requiring steam-engineers to pass an examination and to be provided with a license, as evidence of their competency, made majority and minority reports; the first taking the view that such action on the part of the society would be inexpedient, and the latter recommending such action. The reports were freely discussed, *pro* and *con;* and the subject was postponed for final action until the stated meeting in January.

Mr. G. Morgan Eldridge then read a paper on 'The British patent designs and trade-marks act of 1883 as affecting American inventors,' explaining the provisions of the new law to go into operation on the 1st

of January, 1884, and especially clearing up many points wherein the technical journals, which had favorably reviewed its provisions, had erred.

Prof. E. J. Houston introduced Mr. Patrick B. Delaney of New York, who thereupon described in detail his lately invented system of synchronous-multiplex telegraphy, illustrating the same with the aid of detail-drawings and lantern-slides of essential portions of his apparatus. Mr. Delaney's system, as thus far perfected, permits of the sending of seventy-two separate and distinct messages over a single wire simultaneously.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Geological field-work. — Mr. J. S. Diller, in his reconnaissance of the Cascade Range, passed through the Dalles, at the north end of the range, and followed it southward into California. The following is an abstract of the preliminary report made by him to Capt. C. E. Dutton, who has charge of the investigation of the volcanic rocks of that region. Andesites and basalts are found on the west side; and at Oregon City the lavas have a thickness of three hundred feet. The massive rocks stretch far southward towards Salem; and on them rest extensive alluvial deposits which form fertile plains in the valley of the Willamette, French's Prairie being one of them. Between Salem and Albany the eruptive rocks also occur; but at Jefferson, a short distance north of Albany, the miocene sandstone occurs, and is extensively used in the neighborhood for building-purposes. From Albany to Eugene City, both eruptive rocks and the miocene sandstones occur, the latter being well exposed at Springfield and before reaching the Calapooia Mountains. Thirty-five miles south of Eugene City the miocene sandstone is frequently penetrated by basaltic and other eruptive rocks. Near Cottage Grove the sandstone resembles somewhat a tufa, but contains coal, like the miocene north-east of Lebanon. Coal with a thickness of five feet is said to occur at the great bend of Pit River, but was not seen by Mr. Diller, as he did not visit the locality. The Calapooia Mountains are made up mainly of recent volcanic rocks, especially on the north side. Fragmental rocks are found on the south; but whether they are paleozoic, or not, remains in doubt. These beds extend to near Oakland, where well-marked tertiary appears. South of Rosebury is a belt two miles in width, of olivine enstatite rocks, altered, for the most part, into serpentine. It is bounded on the south by a highly tilted conglomerate, which resembles the millstone grit of the Alleghanies. No fossils were found in it, but on petrographical grounds it was referred to the cretaceous, which Mr. Diller says has not been recognized north of Rogue River valley, from which it is separated by a belt of crystalline stratified rocks, — the eastward continuation of the Rogue River Mountains. South of Myrtle Creek, schistose rocks occupy a belt along the southern branch of Umqua River to Cañonville, where crystalline schistose rocks form the prominent mountain ridge through which the gorge of Cañon Creek is cut. These rocks are penetrated by a granite which has probably been land-surface for a long time. This granite outcrops frequently in southern Oregon and northern California, especially in the Siskiyou Mountains, which are principally made up of it: it also forms Trinity Mountain and Castle Rock.

The crystalline rocks representing the eastern prolongation of the Rogue River Mountains are limited on the south by the supposed cretaceous rocks of Rogue River valley. Mr. Diller thinks that both cretaceous and tertiary rocks are embraced in the section seen on the north-east side of Stewart's Creek (a tributary of Rogue River extending eastward from Jacksonville). These rocks extend into California, where they are covered by the great flow of recent eruptive rocks in the plain north of Mount Shasta.

Little Shasta valley, especially between Shasta post-office and Mount Shasta, is an extensive plain covered by a flow of basic lava like that on the great plain east of the Cascade Range in central Oregon. Mount Shasta rises above a similar plain.

At the Haystacks, a short distance north of the base of Shasta, granite occurs. Between Mount Shasta and Lassens Peak, Cambrian, mesozoic, and tertiary occur. Around the eastern base of Shasta to Burney valley, and westward over the mountain crest to Buzzard Roost, little else is seen than basic volcanic rocks. Four miles west of Furnaceville the road leaves Cow Creek, and ascends to the 'plain,' which is covered with angular bowlders and thin soil underlaid by coarse conglomerate. From Buzzard's Roost a cañon along Cow Creek is cut in carboniferous limestone and other altered sedimentary rocks.

At Furnaceville, in the metamorphic rocks found west of the limestone, mining operations have been carried on; but at present the openings are deserted. Farther west, cretaceous (?) strata come in, dipping towards the Sacramento; and above them, tertiary rocks full of fossils. The latter extend to the alluvial plain of the Sacramento.

The Cascade Range, constituted almost wholly of basic lavas, is a low, broad arch, not less than seventy-five miles in diameter, rising from 3,300 feet at Summit Prairie, near Mount Hood, to 5,600 feet at Crater Lake. About the head of Deschutes River the general plain, which more or less gradually merges into the slope of the mountains, has a height of 4,700 feet. Throughout Oregon this plain lies about a thousand feet below the general crest of the range; and both are formed of lava sheets arising from fissure eruptions. There are numerous topographi-

cal elements on the broad arch produced by local extrusions, or subsequent erosion; lava having been poured from many craters that rise from eight hundred to eight thousand feet above the arch, forming an irregular series of ridges having here and there a radial arrangement. Some are on a line, as if from a common fissure; but, for the most part, they are irregular in distribution. The great peaks of the range are all remnants of old craters. The larger ones form the most prominent peaks of the system, and, although post-miocene in age, are older than many of the smaller ones, which are mainly cinder-cones, which retain their crater-form more or less perfectly. As a rule, also, the latter are basaltic, while the chief mass of the larger ones is andesitic.

While Pit River, and perhaps some of its prominent tributaries, as well as the Umqua and Rogue rivers, are examples of antecedent drainage, it is probable that the Klamath and Columbia rivers, with their tributaries, are, in part at least, consequent. However, the trip was too hasty to make completely trustworthy observations on this point.

—During July, August, and September, Dr. F. V. Hayden, with Dr. A. C. Peale as an assistant, made a geological reconnaissance along the line of the Northern Pacific railroad from Bismarck, Dakota, to Helena, Montana. Geological sections were made at various points, especially with reference to the line between the Fox Hills cretaceous and the Laramie group. Collections of fossil plants and shells were made at Sims, Gladstone, and Little Missouri, in Dakota, and at Glendive, Miles City, Billings, the Bull Mountains, Stillwater, Livingston, Bozeman, and other places, in Montana. The various coal-mines along the line of the road were visited and examined, as were also the borings for artesian wells at Bismarck, Dakota, and at Billings, Montana.

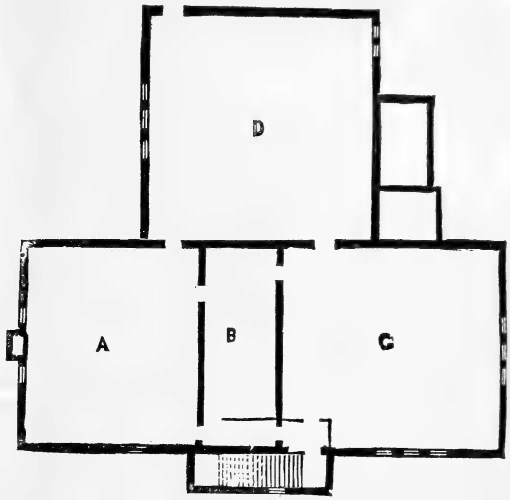
STATE INSTITUTIONS.

University of Kansas, Lawrence.

The new chemical laboratory.—The regents of the university have wisely provided for the increased growth and importance of the chemical department by the construction of a building for laboratory purposes. It is built of native limestone, with dressed stone and brick trimmings, and, as may be seen from the engraving, is in the form of a T.

The part extending east and west is 80 by 35 feet, and the L north of this is 40 feet square. The main laboratory and lecture-room are finished to the rafters, and all the rooms on the main floor are provided with additional light and abundant ventilation by skylights. The ground-floor rooms are 12 feet in the clear, and well lighted. These are occupied by an assay-room with crucible and muffle furnaces and complete apparatus for the fire assay of ores, and also by laboratories for blow-pipe work.

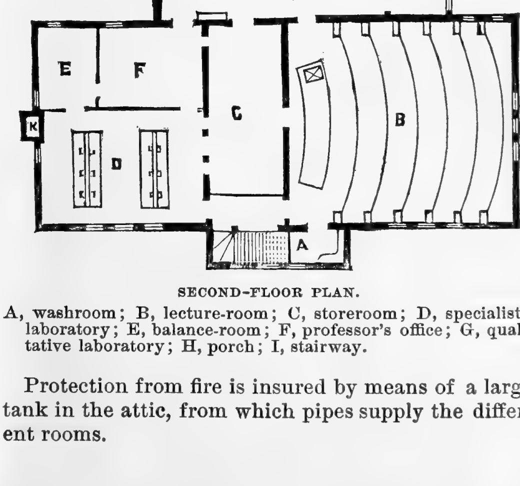
The east wing of the main floor, which is 14 feet to the eaves, is occupied by a lecture-room, seated in amphitheatre style, and capable of accommodating from 80 to 100 students. In addition to the ventilating apparatus above mentioned, the plan includes flues in the wall, connected with hoods, and hoods in the centre of the main laboratory, which are ventilated by glazed pipes terminating above the roof.



GROUND-FLOOR PLAN.

A, fire assay room; B, storeroom; C, metallurgical and blow-pipe laboratory; D, wet assay room.

All the rooms are supplied with running water, and gas, and heated by steam. The laboratory intended for qualitative students has over 25,000 cubic feet of air-space, and is intended for 54 students, each to be supplied with cupboards, sets of reagent bottles, etc. The tables are to be furnished with slate tops, and, in the quantitative room, with filter-pumps.



SECOND-FLOOR PLAN.

A, washroom; B, lecture-room; C, storeroom; D, specialists' laboratory; E, balance-room; F, professor's office; G, qualitative laboratory; H, porch; I, stairway.

Protection from fire is insured by means of a large tank in the attic, from which pipes supply the different rooms.

The building was erected at a cost of $12,000; and this sum, wisely and economically expended, leaves the chemical department as amply provided with facilities for instruction as any institution west of the Mississippi. E. H. S. Bailey.

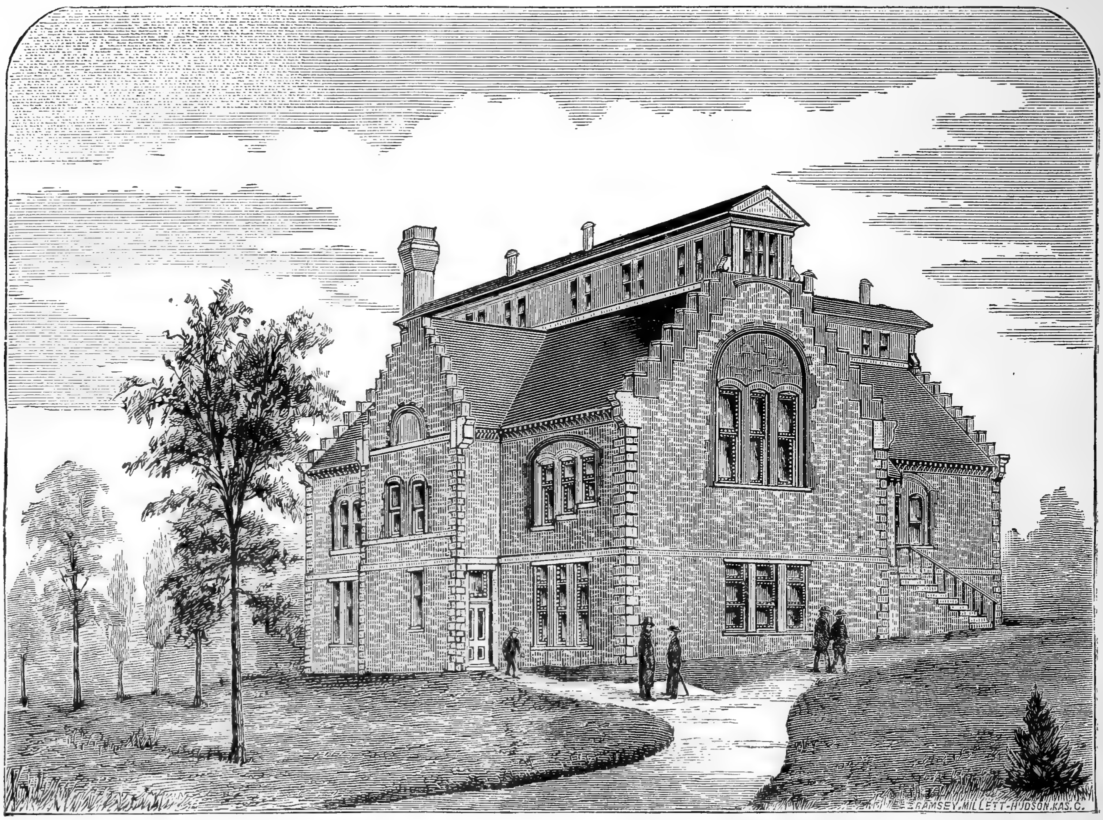
Lawrence, Kan.

NOTES AND NEWS.

Nature states that the Swedish frigate Vanadis has just started on a cruise round the world. King Oscar's second son participates in the cruise, as well as Dr. Hjalman Stolpe, who has been commissioned by the government to collect materials for the nucleus of a national ethnographical museum in Stockholm. The frigate, whose mission is chiefly scientific, will call at many places of interest, as, for instance, the Straits of Magellan, the Marquesas and Hawaiian Islands, the remarkable Malden Island, etc. A Swedish merchant, M. Fürstenberg of Gothenburg, has contributed six hundred pounds for the purchase of objects of scientific value.

— The Conseil municipal of Paris has granted a subsidy of 38,000 francs for the construction of a building in the Parc de Montsouris for the use and annual exhibitions of the Central society of apiculture and insectology. It is hoped to hold there the exhibition of 1885.

— M. Bourdalou having published in 1864, in his work 'Nivellement général de la France,' that the average level of the Mediterranean is by 0.72 metre lower than that of the Atlantic, this result was received with some distrust by geodesists. Gen. Tillo points out now, says *Nature*, that this conclusion is fully supported by the results of the most accurate levellings made in Germany, Austria, Switzerland, and Spain, which have been published this year. It appears from a careful comparison of the mareographs at Santander and Alicante by Gen. Ibanez, that the difference of levels at these two places reaches 0.66 metre, and the differences of level at Marseilles and Amsterdam appear to be 0.80 metre when compared through Alsace and Switzerland. The 'Comptes rendus de la commission permanente de l'association géodésique internationale' arrive at 0.757 metre from the comparison with the Prussian levellings; whilst the fifth volume of the 'Nivellements der trigonometrischen abtheilung der landesaufnahme' gives 0.809 *viâ* Alsace, and 0.832 *viâ*



NEW CHEMICAL LABORATORY OF THE UNIVERSITY OF KANSAS.

Switzerland. The difference of levels at Trieste and Amsterdam, measured *viâ* Silesia and Bavaria, appears to be 0.59 metre. Each of these four results (0.72, 0.66, 0.80, and 0.59) having a probable error of 0.1 metre, their accordance is quite satisfactory; and we may admit thus that the average level of the Mediterranean is in fact lower by 0.7 metre than that of the Atlantic.

—Many years ago the late Mr. Leonard Horner communicated to the Royal society the results of a series of borings which he had caused to be made in the upper part of the delta of the Nile, with a view of ascertaining the antiquity of the civilization of Egypt. Since that time, Figari Bey, an Italian geologist in the service of the Egyptian government, has made and published the results of a large series of borings effected in different parts of the delta; but his work is hardly on a level with the requirements of modern science. It has been thought advisable, therefore, by the British government, to take advantage of the presence of its troops in Egypt in order to carry out a series of borings across the middle of the delta, in the full expectation that such borings, if made with proper care, and carried down to the solid rock, will afford information of the most important character, and will throw a new light upon the natural and civil history of this unique country. Instructions have been sent to the officer commanding the engineers to undertake the operations; and it is hoped, that, before long, information will reach us which will be of no less interest to the archeologist than to the geologist.

— The committee of the British association for the advancement of science, consisting of Profs. G. H. Darwin and J. C. Adams, for the harmonic analysis of tidal observations, made its report at the Southport meeting of the association last year (1883). Professor Darwin, who is the author of the report, states, that, although it is drawn up in a form probably differing widely from that which it would have had if Professor Adams had been the author, the latter agrees with the correctness of the methods pursued. The general scope of the paper is to form a manual for the reduction of tidal observations by the harmonic analysis inaugurated by Sir William Thomson, and carried out by the previous committee of the association; and it is intended to systematize the exposition of the theory of the harmonic analysis, to complete the methods of reduction, and to explain the whole process. The method of mathematical treatment differs considerably from that of Professor Thomson; he having followed in particular, and extended to the diurnal tides, Laplace's method of referring each tide to the motion of an *astre fictif* in the heavens, considering that these fictitious satellites are helpful in forming a clear conception of the equilibrium theory of tides. Professor Darwin, however, having found the fiction rather a hinderance than otherwise, has departed from this method, and connected each tide with an 'argument,' or an angle increasing uniformly with the time, and giving by its hourly increase the 'speed' of the tide. In the method of the *astres fictifs*, the 'speed' is the difference between the earth's angular velocity of rotation and the motion of the fictitious satellite amongst the stars. The committee practically found itself engaged in the question of the reduction of Indian tidal observations; since it is only in that country that any extensive system of observation, with systematic publication of results, exists. Professor Darwin has discussed the entire subject with Major A. W. Baird, R.E., the officer in charge, at Poona, of the tidal department of the survey of India; and their general agreement as to the modifications to be made in the notation of the old reports appears to insure a harmonious course of future procedure. Major Baird returned to India in the spring of 1883, and lately began revising all the published results, so as to bring them into the uniform system here recommended.

— The southern part of the peninsula of California has recently been explored by Dr. H. Ten Kate, who reports (*Rev. d'ethnogr.*, ii. 321–326) that there are no longer Indians of pure race dwelling in that region. The blood of the ancient Pericuis and Coras flows, it is true, in a great number of métis; but they resemble the Spaniard far more than they do the Indian. In the graves of the dead few relics are found. Here and there on the cliffs are rock-paintings, a few of which Dr. Ten Kate reproduces. The paper closes with the account of a discovery in Sonora. M. Emeric has found upon the shore of the sea, about ten metres above the water-mark, under innumerable blocks of lava, objects resembling fishes and turtles cut out of marble and a hard green rock. He also found several stone knives smoothly polished.

— The Society of naturalists of Moscow has sent Kudriaotzeff to examine in detail the geology of the region drained by the upper waters of the Oka. Dokuchaeff undertakes similar studies for the region traversed by the Volga. Both these investigations are made at the special request of the authorities of the provinces named; and their results, combined with those already derived from the studies of Russian geologists for other districts, will go far toward a basis for a satisfactory geological map of this part of Europe.

— The calculation by Gladisheff, of Stebnitzki's astronomical data for the position of Ka-uchit Kala, the capital of the Merv oasis, has been concluded, and places it in 37° 35′ 19″ north latitude, and 59° 27′ 20′- east longitude, from Paris, — a position tolerably near that derived from older and less perfect observations.

— Some interesting facts regarding the public collections of American archeology in the United States are given by Henry Phillips, jun., in a paper to the American philosophical society. Judging by this report, there are six museums of the first class in this country, containing upwards of five thousand specimens, — the Academy of natural sciences in Philadelphia, the Davenport academy of natural sciences, the National museum at Washington, the Peabody museum of American archeology and ethnology at Cambridge, the Peabody academy of science at Salem,

and the Wisconsin historical society at Madison. To these must doubtless be added the American museum of natural history at New York, and the Peabody museum at New Haven, from which he received no reports.

Four museums should apparently be grouped in a second class as important ones, but not so extensive as those of the first class; namely, Amherst college, the New London county historical society, the Wisconsin natural history society of Milwaukee, and the Wyoming historical and geological society at Wilkesbarre, Penn. Eleven other museums are reported to have collections of considerable interest. To judge from the statements given in this paper, the Peabody museum at Cambridge is the largest in the country.

A list of twenty-five other institutions believed to have collections, and from which no information was received, is appended. We have already referred to two. It may be remarked concerning these, that the Boston society of natural history has no such collections, and that there is no institution bearing the title 'Academy of natural sciences, Baltimore, Md.'

— Dr. George M. Beard and Mr. Herbert Spencer almost simultaneously sound the alarm against our modern worry in the words, 'The gospel of work must make way for the gospel of rest.' An English writer, signing himself E. S., protests, in the *Journal of science*, against a theory of civilization which makes the acquisition of material wealth almost its sole object, and which brands all men not engaged in such pursuit as idlers. "We have under its inspiration stripped our own country, over a great and increasing part of its surface, of every beautiful feature. We have blackened its skies with smoke-clouds, polluted its air with sulphurous acid, filled its streams with liquid filth, covered its hills with 'spoil-banks,' blighted its green fields, cut down its woods, and extirpated many of its most lovely animal and vegetable species. Our cities, from London downwards, present, as their main feature, meanness, monotony, and ugliness by the square mile; rarely, indeed, relieved by a street or a single building upon which the eye may rest without pain." The diseases caused by over-work, public morals, and the effect of our system on true intellectual progress, receive vigorous treatment. The author concludes that our industrial civilization is found wanting in every particular. "It has broken down more rapidly and more disastrously, even, than the military *régime* which preceded it, and will be found to have left upon the human race even deeper marks of its failure."

— About half way between the mouth of the Santa Cruz River and the base of the Andes, and situated along the left bank, Signor Moreno has discovered an eocene deposit rich in mammalian remains. It lies at the base of an elevated terrace some eight hundred and twenty-five feet in height, and is made up of alternate lacustrine and marine strata (eocene, miocene, and pliocene), whose summit is mantled by an extensive accumulation of glacial detritus. The most important find here was the skull of a huge mammalian named by Burmeister 'Astrapotherium patagonicum,' and by him supposed to be closely related to Brontotherium, but which Moreno (under the new name of Mesembriotherium Brocae) considers to be a generalized type of marsupial, probably aquatic in its habits, and having certain characters in the skull to ally it with the Carnivora. In the same deposit were found the remains of a true marsupial. At a somewhat newer horizon, Moreno found the skulls of two genera of small-sized mammalians, which form a direct transition between the rodents and toxodonts. No traces of either miocene or eocene edendates were detected. In a deposit apparently transitional between the cretaceous and eocene were found two molars, with part of the cranium, of an animal (Mesotherium Marshii) whose true position has not as yet been absolutely ascertained, but which appears to represent the most ancient South American mammalian thus far discovered. Contrary to the opinion of geologists before him, Moreno considers Patagonia as the region whence the mammalia (late tertiary and quaternary) of the more northern regions have been derived. Instead of there having been a late southward migration into Patagonia, it is contended that a northerly migration set in with the advent of the glacial period; of which last, it is further claimed, there is convincing evidence. Patagonia is believed to have been united with the Antarctic continent on the one hand, and with Australia on the other.

— One of the reasons which led to the construction of inductive coils of the large diameter, employed by Professor Rowland in his present work on the ohm, is the hope of using them in a determination of the ohm according to the method of Lorentz. Their large size will admit of the use of a revolving-disk of more than half a metre in diameter.

— *The auk*, a quarterly journal of ornithology, the continuation of the *Nuttall bulletin*, as the organ of the American ornithologists' union, begins with January, 1884, under the editorial supervision of Mr. Allen, with Dr. Elliott Coues, Mr. Robert Ridgway, Mr. William Brewster, and Mr. Montague Chamberlain as associate editors, and with Messrs. Estes & Lauriat as publishers, necessitating the same general character as heretofore the *Nuttall bulletin* has borne, but with increased size and enlarged facilities.

— The Saturday lectures under the auspices of the Anthropological society and the Biological society of Washington will be delivered this year, as heretofore, in the lecture-room of the U. S. national museum, Saturday afternoons, at half-past three o'clock, beginning Jan. 5. The series will include twelve or more lectures, and will be divided into courses of four lectures each. The programme for the first course is herewith presented. The lectures are free, and the public are invited to attend. Jan. 5, Mr. Grove K. Gilbert, Cliffs and terraces; Jan. 12, Professor Otis T. Mason, Child-life among savage and uncivilized peoples; Jan. 19, Professor Edward S. Morse, Social life among the Japanese; Jan. 26, Major J. W. Powell, Win-tun mythology.

SCIENCE.

FRIDAY, JANUARY 18, 1884.

COMMENT AND CRITICISM.

The Philadelphia local committee for the reception of the American and British associations for the advancement of science, which will meet in that city on the 3d of next September, is taking active steps to make the meeting a memorable one. The well-known hospitality of Philadelphia, together with the unusual attractions offered by the combined meeting of the two great scientific bodies, will undoubtedly secure a very large attendance. Under the auspices of the Franklin institute, an international electrical exhibition will be opened simultaneously with the meeting of the associations, and a congress of electricians will at the same time be convened. Excursions of unusual interest and extent are being planned. Hon. John Welsh is president, and Prof. H. Carvill Lewis and Dr. E. J. Nolan secretaries, of the local committee, which consists of a hundred and fifty of the most influential citizens, representing all the prominent institutions of the city. Communications for the local committee should be addressed to its headquarters, — the Academy of natural sciences. The meeting will probably be held in the buildings of the University of Pennsylvania, which have been offered for that purpose.

It is sincerely to be hoped that the local committee at Montreal will take no steps which, by excursions or otherwise, may prevent a full attendance at Philadelphia of members of the British association. The committees at Montreal and Philadelphia should work harmoniously, arranging for combined excursions at the close of the Philadelphia meeting. With the aid of the Montreal committee, the Philadelphia meeting can be made the most important scientific gathering that has ever been held in this country.

Mr. Theodore Link, in the *Naturalist* for December, pleads forcibly for the betterment of zoölogical gardens. These ordinarily are, indeed, to speak paradoxically, nothing but stationary travelling-shows, — Barnum's menageries called to a halt. What is required for the animals' happiness and health is obvious enough; but, as questions like the present are generally decided from man's point of view, let us shift to that. The mission of these gardens, as Mr. Link says, is ostensibly "the study and dissemination of a knowledge of the natural habits of the animal kingdom." Therefore an opportunity for such habits among these animals is essential to the student visiting them. Perhaps most visitors, however, go for amusement, or for the pleasure of easy instruction. We go to see something opposite to the restraints of our own civilization, to behold the wonders of untrammelled instincts, to enjoy the beauties of free motion. But as it is, we seek a pleasure-garden, and find it a prison. We find no animated vigor there to cheer and to excite us, but helpless misery too much like the poorer side of human life.

The great difficulty, it seems to us, is in attempting with limited means too big and miscellaneous collections, imperfect, unsatisfactory, and uninstructive, about in proportion to their excess of size. Would it not be better in a given half-acre to have a single pair of lions, or of any other much admired brute, rather than a subdued camel, a cramped tiger, a dilapidated ostrich, and a discouraged crocodile, all obliged to stand as nearly as possible on one leg, for want of any thing better to do? Any chance and inducement given to the animals to breed naturally and freely, certainly might be a direct and valuable economy to any zoölogical society in keeping up its stock.

According to a communication made to the London section of the Society of chemical in-

dustry by Mr. Weldon, it does not seem that we are much nearer to cheap aluminium than we have been for a long time. A short time since, it was announced that a new method of production had been invented and was in use; but Mr. Weldon says this invention only relates to the production of anhydrous alumina from potash alum; and, if the method of obtaining this were fifty per cent cheaper than that of M. Pechiney of Salindres, it would only cheapen aluminium by five per cent.

Apropos of the present discussion of the excessive requirements of Greek and Latin in our colleges, let us not forget the neglect of English. One of the reasons most commonly given for the study of the ancient languages is that they aid the understanding of our own. This is undoubtedly true, but they are not the best aids; and if a good understanding of English be the desired end, as it certainly should be, there can be no question that it will be sooner and better attained by the study of English itself. The derivation of our words can be very satisfactorily taught along with advanced spelling, and the meaning of a large number of roots, prefixes, and suffixes, can then be acquired, so as to give most practical assistance to the comprehension of English; much better, we venture to say, than if etymological study be limited to the languages from which the roots, prefixes, and suffixes come, and direct statement of their use in building up our own language be omitted. It is certainly very common to find students who have 'passed' in Greek and Latin still unable to explain the meaning of not unusual scientific terms. Indeed, so large a share of the time allowed to linguistic study is now given to Greek and Latin considered simply as dead languages, without reference to their living descendants, that no time is left in which the general student can learn what he certainly should know about his mother-tongue.

There is pressing need of collegiate study of English as a language: and few subjects would be more attractive than this might be made by a lecturer who would tell his class where and when the language attained enough of its present characteristics to be entitled to its present name, what were its ancestors, and how they mingled and changed their form in producing their descendant; who would describe how the language itself has varied in recent centuries, and how its unsystematic spelling, so unlike the phonetic simplicity of Italian and Spanish, depends on its complex origin; who would point out the historic reasons for its *dependence* on earlier languages for words expressing abstract ideas, in contrast with the relative *unabhängigkeit* of German. All this would no more require a knowledge of ancient or foreign languages than an appreciation of elementary lectures on chemistry needs an understanding of organic analysis; but it would give a very different knowledge of English from that derived from the study of Latin declensions and Greek accents. We cannot doubt that it would be of great service to all who have to write out what they think, and that it would attract to philological studies many students who are now repelled from them.

We understand that the scientific work of the Army signal-office is likely to form a feature of increasing importance in the future development of that department, and that Gen. Hazen desires to secure the services of the best talent in the country. It would seem that the study of mathematics, mechanics, and physics, as bearing on meteorology, has been sadly neglected in our universities; and it is by no means easy to find any who have been studying the sciences with a view to the pursuit of investigations in meteorology. As a general rule, those who have studied and practised astronomy for a few years are the best prepared to advance meteorology. The fine library of the signal-office, its unequalled mass of observations and maps, its courses of lectures, its annual classes of men under instruction at Fort Myer, its collection of apparatus, all offer to young meteorologists opportunity and stimulus to farther advancement; while the publications of the office offer every facility for making known the results of origi-

nal investigations. Even meteorologists outside the office, or employed by it as consulting specialists, may find it to their advantage to avail themselves of this opportunity for publication. Considering the great future evidently in store for meteorology, it is not surprising that Professor Abbe is, as we understand, diligently inquiring for those who are willing to come to his assistance in the effort to develop a systematic, deductive, and exact science of meteorology. We commend this subject to those whose studies have taken this direction. There are needed the investigator, the teacher, and the expert consulting-meteorologist, precisely as in other branches of science.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Chemical geology.

IT appears to me, that in his interesting communication in the number of *Science* for Dec. 28, Professor Winchell has fallen into an error, which, while diminishing by more than one-eighth his estimate of the secular increase of the earth's mass, is yet more serious from the stand-point of chemical geology. In determining the amount of carbon dioxide abstracted from the atmosphere and fixed in the earth's crust, he estimates, first, that represented by the carbonate rocks (limestone, dolomite, etc.), and, second, that required for the decomposition of an assumed thickness of decomposable silicate rocks; and both these amounts are included in his grand total. But this is certainly bad book-keeping, for a portion of the carbon dioxide is counted twice. The decay of the silicate rocks is a necessary antecedent of the formation of the carbonate rocks; and the carbon dioxide of the latter is precisely the same as that which has previously decomposed the former. In general terms, this grandest of all chemical processes proceeds as follows: the carbon dioxide of the atmosphere decomposes the felspars, hornblende, augite, micas, etc., of the silicate rocks, leaving the alumina and iron with the silica as a more or less ferruginous kaoline, and forming carbonates of the alkalies and alkaline earths, which are carried away in solution, and ultimately reach the sea, where the latter are deposited as limestone and dolomite, and the former react with the calcium and magnesium chlorides of the sea-water, producing alkaline chlorides (chiefly common salt) and more limestone and dolomite. As Dr. Hunt has so clearly shown, the kaoline on the land, and salt in the sea, are merely incidental results of the fixation of the carbon dioxide of the atmosphere in the carbonate rocks.

W. O. CROSBY.

Osteology of the cormorant.

Dr. Shufeldt's letter in *Science* (ii. 822) calls for a few remarks. In relation to his first statement, that 'the occipital style of the cormorant is not an ossification in the tendon of any muscle' of the neck, Selenka wrote as follows: "Eigenthümlich ist dem Carbo cormoranus und C. graculus, aber auch nur diesen beiden, ein an dem *occip. superius* durch bandmasse verbundener, dreieckig pyramidenförmiger, nach hinten gerichteter knochen, welcher die ansatzfläche der den kopf bewegenden muskeln soz. vergrössert; er ist ein sehnenknochen und gehört nicht zum schädel" (Thierreichs, 19). In view of such eminent authority, it would seem that something more than simple denial is required to upset a statement accepted by anatomists for many years. It is worthy of note that Dr. Shufeldt does not mention the nature of the bone in his article, and that, in ignoring the point to which I took exception, he virtually acknowledges his mistake. It is difficult to understand how one who does not know the position of a bone is qualified to expound its nature; and in all cases it is wise, if we would convince, to give reasons for dissent from authorities.

As to his second statement, that my ideas of the morphology of the rotular process are wrong, I would simply remark that the ideas referred to are not mine, but those of Nitzsch, of Meckel, of Tiedemann, of Owen, of Selenka, and of Mivart, and suggest that it would be appropriate to read such eminent authorities before disposing of them with an empirical denial. Dr. Shufeldt's paper clearly intimates that the rotular process of the divers is the homologue of the patella in other birds. The coexistence of the two disproves this by *reductio ad absurdum.* I would invite Dr. Shufeldt to quote the passage to which he refers when citing Owen as considering any process of the tibia as the analogue of the patella.

Lastly, Dr. Shufeldt states "that, furthermore, I find myself misquoted more than once." I would remind Dr. Shufeldt that I quoted him but once; and of the accuracy of this, any one may satisfy himself by referring to *Science*, ii. 642, 2d column, line 19.

J. AMORY JEFFRIES.

Electric time-signals.

Your correspondent who describes his method of making electrical signals in a recent number of *Science* (ii. 823) can greatly simplify and thereby improve his arrangement by inserting within the clock a couple of thin metallic springs with platinum contacts, the circuit being completed by the pressure of the hammer on the 'outward stroke.' The writer has had such an attachment to an ordinary 'programme clock' in constant use for about ten years, as is doubtless the case with many others who have had occasion to distribute time. The signals are transmitted to several buildings, in one of which an electric gong is struck, and in others a number of 'vibrating' bells are rung.

Mercury contacts are generally troublesome. The arrangement described seems unnecessarily complicated: besides, it is difficult to see the necessity for insulating the clock 'on a square of plate glass.'

Capitalization of names of formations.

The use of capitals is a literary rather than a scientific matter; but geologists, nevertheless, suffer as a class from the existing confusion in regard to the names of formations.

Authors who are consistent with themselves in this matter fall into three classes. Those of the first class speak of the *P*otsdam, and of the *C*arboniferous, but of *p*otsdam strata and *c*arboniferous strata. In so doing they class the names of formations as proper nouns, but refuse to recognize proper adjectives. This practice employs a German idiom not otherwise countenanced in our language: we do not say *g*erman

idiom. Another objection is, that the practice introduces a distinction difficult to maintain on account of the graduation of the nominal into the adjective sense. 'The Carboniferous' may or may not imply some such noun as formation, and the degree of such implication is variable.

Authors of the second group speak of the *P*otsdam and *P*otsdam strata, but of the *c*arboniferous and *c*arboniferous strata. The distinction thus made is etymologic, being based on the immediate derivation of the name of the formation. To this there are two objections. First, it is contrary to the analogies of the language, for capitalization is generally controlled by meaning. We speak of 'the *P*acific,' although the designation is etymologically a common noun; and we call the recently popular feminine waist-gear a *j*ersey, although the designation is etymologically a proper noun. Second, it has the effect of recalling attention continually to the derivation of names, and thus retaining their connotative meaning. For mnemonic reasons, and for these only, it is convenient that names of formations should originally be connotative, but it is of prime importance that they should eventually become merely denotative. There was a certain original utility in having 'Potsdam' call to mind a place, and 'carboniferous' a character; but the names having become securely attached to their several formations, it is now imperatively demanded that each shall designate a certain portion of the stratigraphic column and a certain portion of geologic time, without connotating place or composition. Indeed, the reason why modern usage employs geographic terms in the naming of new formations, instead of designating them by their physical characters, is that a minimum of connotation is thus secured from the outset.

Authors of the third class capitalize all names of formations, whether used as nouns or adjectives, and in so doing escape these evils. The only objection I see to their practice is, that it classes with proper nouns a group of names which may fairly be compared with other groups not so classed. The demarcation between common and proper nouns is essentially somewhat obscure; and the drawing of the line is largely a matter of practical convenience. It is noteworthy that no author whatever has so drawn it as to include all names of formations with common nouns.

The capitalization of all formation names has the manifest advantage that it enables one to say that the *C*arboniferous rocks are not the only *c*arboniferous rocks, or, in other words, that it does not deprive the geologist of the independent use of words indicative of rock character which have been appropriated for the names of formations. If the use of capitals were altogether discarded in the designation of formations, this advantage would be lost, but another would be gained; for we should then be able to speak of the rocks of *P*otsdam without implying their *p*otsdam age.

G. K. GILBERT.

Remsen's 'Theoretical chemistry.'

Will you kindly allow me to correct an error into which it seems that I fell, in my notice of Professor Remsen's 'Theoretical chemistry' (*Science*, ii. 826)? It cannot be denied that the statement, "Of the substitution products of benzene which contain three substituting groups, more than three varieties have been observed," is literally true. The context and form of expression were such that I could not but think this assertion was made of those derivatives in which the three substituting groups were alike. Had it occurred to me that the statement was not thus limited, I certainly should not have pronounced it rash, but so cautious and incomplete that it must inevitably mislead even the most careful reader.

THE CRITIC.

Synchronism of geological formations.

I trust that you will permit me a little more space to reply to the further remarks of Mr. Nugent on this subject (*Science*, iii. 33), seeing that your correspondent has failed to grasp the point which I had intended to elucidate in my last communication.

Mr. Nugent is correct when he contends that I rest my case on the non-occurrence of 'evidences of inversions;' and, if my line of argument based on this fact fails to meet with his approval, I sincerely regret it. Paleontology, as far as I am aware, has thus far failed to show a single unequivocal case of faunal inversion such as I have indicated; nor does there appear at the present time very much likelihood of its ever being able to do so. Nor would the discovery of a solitary instance materially affect the question, inasmuch as, upon the theory of very broad contemporaneity suggested by Huxley, instances of inversion ought to be about as numerous as those of non-inversion. My courteous critic admits that "there is no reason why such instances of inversion should not have occurred over and over again," and that at the present time their 'occurrence is almost unknown;' but his appeal to the 'imperfection of the geological record' (both geological and geographical), in explanation of the overwhelming negative testimony, will, I am afraid, scarcely meet the situation.

The special cases referred to — Barrande's colonies, and the intermixture of Silurian and Devonian, and Devonian and carboniferous fossils in the old red sandstone of Scotland — are far from being of the character desired. The former need scarcely to be commented upon, since they have always been involved in a certain amount of obscurity; and their very existence as such has very recently been denied by Marr, who personally examined the region, Lapworth, and a host of other geologists. In the case of the old red sandstone of Arran, where there is an intercalation of a band of marine limestone containing Productus giganteus, P. semireticulatus, P. punctatus, Chonetes hardrensis, Spirifera lineata, and other well-known carboniferous fossils, Professor Geikie (who, we believe, first made the observation) distinctly affirms that these organisms must "have been in existence long before the formation of the thick Arran limestone," and that their habitat during the period of the deposition of the underlying sandstone was immediately outside of the basin or basins that through upheaval were now being gradually isolated from the sea: in other words, we have here merely an instance where the range of a certain number of organic forms has been extended somewhat lower down in the geological scale than it had hitherto been indicated. These same forms re-appear in the superimposed lower carboniferous limestones, and, as Professor Geikie observes, they must have been living during the long interval coincident with the sedimentation of the intervening sandstone 'outside of the upper old red sandstone area.' The same relation holds with the Siluro-Devonian mixture in the basal old red of Lanarkshire. No one can deny the local displacement and interchange of portions of two consecutive faunas, especially at about the beginning or close of their own respective series; but these displacements are not of the nature of the inversions that ought to illustrate the doctrine of broad contemporaneity.

To what extent similar or identical faunas indicate *absolute* chronological relationship can probably never

be determined; but I believe it may be safely assumed that the synchronism is defined within comparatively narrow limits; or, as previously expressed, "formations characterized by the same or very nearly related faunas in widely separated regions belong, in very moderate limits, to approximately the same actual age, and are to all intents and purposes synchronous or contemporaneous" (*Science*, No. 41). Professor Geikie, who is quoted by your correspondent as supporting the orthodox doctrine of homotaxis, or homotaxis in its broadest limits, judiciously refers to chronological divergences of only *thousands* of years, and *not* of *millions* ('Text-book of geology,' pp. 617–619). ANGELO HEILPRIN.

Academy of natural sciences, Philadelphia, Jan. 12, 1884.

Free cervical ribs in the human subject.

I send you a photograph of a notable and very interesting anatomical preparation well worthy of being engraved and published in *Science*. It is the seventh cervical vertebra of the human subject, natural size, viewed from above, showing a pair of free cervical ribs. This demonstrates the fact that the so-called transverse process of a cervical vertebra consists of a diapophysis with a coalesced pleurapophysis, the vertebrarterial foramen so characteristic of cervical vertebrae being an opening between these two apophyses. The photograph shows the preparation so well that little description is required. The whole bone is seen to be a little distorted, and the two ribs are seen to be of different shape and size. The ribs are photographed a little apart from their respective articulations, otherwise *in situ*. Each freely articulates, as usual with ribs, by its head with the body, and by its shoulder with the diapophysis, of the vertebra. The base of each diapophysis presents anteriorly a nick (deeper and more regular on the left than on the right side) which is a part of the vertebrarterial foramen proper, the rest of which is circumscribed by the rib itself; the whole space between the vertebra and the neck of the rib being thus a large continuous opening of irregular contour.

The lower border of the body of this vertebra presents on each side a demifacet (not shown) for half of the head of the next (first dorsal) rib; so that the first dorsal vertebra must also have been anomalous in possessing two demifacets, instead of a full facet above and a demi-one below. The same subject was also badly put together in some other respects; e.g., one of the long thoracic ribs (I think the fifth) bifurcated at the sternal end. The specimens were handed to me by one of my pupils, Mr. Arthur J. Hall. The anomaly here figured, while not new, is so rare that I think I have seen but one illustration of it; namely, that given by Professor Owen in his 'Comparative anatomy and physiology of vertebrates.'

ELLIOTT COUES.

Smithsonian institution, Washington, Jan. 4, 1884.

Seventh cervical vertebra of the human subject, life size, seen from above; showing well-developed and freely articulated pair of cervical ribs.

A possible solution of the standard time question.

Although the adoption of five standards of time for the movement of railroad-trains in the United States has simplified the time question for the travelling public, I believe it is a matter of deep regret, that, since a change has been made, that change could not have been to a single standard instead of five, and that Greenwich time, as Mr. Schott very significantly queries in *Science*, No. 38. This is the more to be regretted, since the railroad companies have found it impracticable to make the changes on the proposed meridians, and since, as Mr. Schott rightly apprehends, all ordinary business must always be conducted on local mean solar time.

It appears to me that this whole question could be very simply and forever settled by the adoption of Greenwich time for the movement of all public conveyances the world over, and the construction of time-pieces which would indicate at once both local mean solar time and Greenwich time. The only modification of the ordinary time-pieces needed, to enable them to indicate both times, is to provide them with two dials, one of which shall be movable about an axis, and capable of being set at any desired point. It is immaterial which dial is stationary: the same set of hands would sweep both dials, and indicate, of course, both times, at once. Thus provided, a person desiring to take the next train would be governed simply by the Greenwich dial. Furthermore, should his time-piece lose or gain, it would only be necessary to set it by either local mean solar time or by that of

any station, to have it right again both at home and with the world.

The adoption of such a standard would not necessitate the substitution of new time-pieces for those now in use, nor expensive alteration of them. A very simple, inexpensive way of adapting existing watches to the suggested change would be to etch the Greenwich dial upon the watch-crystal in a little smaller circle than that of the dial proper. The crystal could then be set to indicate the difference of time between the given place and Greenwich, and secured by a little white wax. Clocks could be similarly changed also.

If the hours are to be read from one to twenty-four, as seems desirable, and as some roads have already agreed to do, this will necessitate not only a change in the rate of motion of the hour-hand of time-pieces, but in the dial also. Now, since a change is to be made anyway, why not avoid twice changing by reconsidering at once the action already taken, and move immediately in the direction Mr. Schott has suggested. This would avoid the necessity of publishing in time-tables local times; while the traveller would have simply to consult his time-table, and refer to his Greenwich dial, to know at what moment to take a public conveyance, not only anywhere in the United States, but anywhere in the civilized world. Train-men and station-hands could experience no inconvenience in being guided by their Greenwich dial, it being necessary simply to make that dial the more conspicuous which is to be consulted oftenest.

River Falls, Wis.

THE DUTY ON IMPORTED SCIENTIFIC TEXT-BOOKS.

AT the last meeting of the American association for the advancement of science, there was some discussion of the effects of the existing tariff on foreign text-books on our school system. This is the first considerable effort to call the public attention to the results of our Chinese commercial policy upon the education of our youth. That system of policy is such a vast elaboration of rules, and the effects of its regulations are so hard to trace in the machinery of our society, that it has derived a strength and a safety from its very magnitude and its obscurity. The ordinary mind shrinks from the effort to trace the complication of its effects on great labor-employing industries like pig-iron manufacture. It requires the courage of a great soldier to give battle to the tariff on such fields; for, however convinced the free-trader may be of the right of his cause, he sees that his victory will mean destruction to many whom he cannot regard as foes. But here and there around the tariff jungle there are places that may be improved without danger of any serious consequences to great interests. Some years ago, in a lapse into discretion, if not into rationality, the tariff men took off the duty on quinine. A few score men had to seek other employment, probably to their serious but not permanent inconvenience, and that greatest of all helpers of the sick was free to go untaxed to its users.

As real though less sympathetic claim may be urged for the removal of the tax on educational materials and methods. Even in our money-earning state of society the amount that can be spared for the education of our children is so small that such money should be the last thing to receive the burden of taxation. What would have been thought, if in the fiercest struggle of the war, when we were taxing the physician's right to minister and the drug's power to heal, if some legislator had proposed to tax each college-student, say, three dollars a year, for the privilege of pursuing his education in the most effective manner? Taxes on this principle may be warranted in a besieged city; but even on our darkest day such a measure would have been laughed out of Congress, would have been denied even the rites of decent burial in a committee. Yet substantially this is what is practically done in this day of unparalleled prosperity, when, for the first time in all history, a government is sore burdened with its revenues. A commission of well-paid experts, charged to contrive some means to clear away this excess of income, retains this amazing tax after a year of pondering on the subject!

The singular character of the tax is evident enough in the most general statement of its nature, but close inquiry shows us that it becomes even less comprehensible the better we understand its details. The books excluded by the tax are not the spellers, readers, arithmetics, etc., that are made by the million. Against these, no foreign books would stand any chance whatever, unless they were introduced to the schools through the existing publication-houses. The books that are affected by the law are those that have at best a narrow sale. They are principally books in French, German, Latin, or Greek, used only in college classes for special purposes, which it would not pay any American publisher to reproduce. But let us suppose that the English, German, or other printers could furnish a set of school-books so decidedly better and cheaper than our own that our thrifty publishers should be driven from the field: will any reasonable man say that we should continue to maintain them by a head-money tax on the pupils of our schools?

There is no good reason to fear that our publishers would lose by a free trade in educational materials. If the change be made in such fashion that they may have as good a chance in foreign markets as foreigners should have in our own, we can trust the business

capacities, and the stimulated energies of our text-book makers, to keep our place in the struggle. But grant the truth of the sad presages of those who see the deluge in free trade, can we afford either the principle or the effects of levying a poll-tax on education?

WHIRLWINDS, CYCLONES, AND TORNADOES.[1]—VIII.

THE barometer was falling more and more rapidly, and the wind blowing with increased violence from the north, in the example that was described. Then, if a transparent storm-card, drawn to proper scale after the pattern of fig. 9, be placed on the chart so that its strong north wind shall pass the position of the vessel, it will give the best indication of the general form of the hurricane; and a course may be laid by which the dangerous centre will be avoided. In this case, the safest course will be to run southward, or a point or two west of south, till the barometer begins to rise; and then, if desired, a more easterly course may be followed. Even if the vessel be on its way to a European port, this will be its safest method of avoiding the storm; for, in attempting to beat against the wind and leave the storm to the south, there is too much risk that its increasing strength will prevent the vessel making sufficient headway to escape being caught in the central whirl: it would be better to sail around the southern side of the storm, and, after the centre had passed on the west, then shape a north-easterly course with the wind on the starboard beam. Sometimes it has happened from ignorance of such sailing-rules as these, or from inability, even with their aid, to escape from the sudden violence of a storm, that a vessel finds itself on the storm-track at the time of the passage of the centre; and there is then observed the peculiar and dreadful calm within the whirl, to which sailors have given the name of 'the eye of the storm.' Let us suppose, in the example given above, that the vessel endeavored to force its way against the increasing north wind, and, failing in this, remained on the path of the storm till the centre advanced on it. During its approach there will be no very marked change in the direction of the wind; but its force increases even beyond what seems its greatest possible strength, and goes on increasing, blowing in tremendous and terrible gusts, till the vessel is stripped of its canvas, and the yards and masts are cracked and broken away, and the hull lies helpless and unmanageable. Rain falls in driving torrents, and the sea rolls in great broken waves. The roaring of the winds rises to a screaming pitch; and when at its most fearful strength, it suddenly dies away. In five minutes, perhaps even less, the air is quiet; and only the heavy sea, and the commotion of the clouds, and a distant fading sound of the retreating wind, tell of the violence that has passed by. The vessel is in a cushion of quiet air left under the core of the storm. There is generally but a short time given to suffer the suspense of this unnatural quiet. In half an hour or an hour, according to the size and rate of motion of the storm, the centre passes away, and the opposite side of the whirl suddenly falls on the unhappy wreck, coming again with all the roar and fury that was felt before, but now blowing in the opposite direction, — a terrific hurricane from the south, chopping the waves into the dreaded cross-sea, where the water rises in pyramids instead of in linear crests, and changes its form so rapidly and with such broken rhythm as to strain great leaks in the worn-out hull, and leave it to founder in clearing weather, while the storm goes on in its destructive path.

There is yet much to be learned concerning the curves followed by the winds in these storms. The diagrams, as described above, are based on observation and theory, but must be regarded only as provisional until proved by the average of many more observations than have yet been made. Rules for various cases may be easily devised on the plan above described, but they are not infallible: there is still much to be done in perfecting them. Only one additional point need be mentioned: care is needed to avoid sailing after and overtaking a slow-moving storm, and so falling into its power. This would seldom happen in our latitude, but might well occur in the Indian Ocean, where some storms have been found to rest almost stationary over one district of the sea for more than a day. A case is reported where a vessel thus fell into the dangerous whirl, and could not escape, but was carried round and round the centre, while scudding under bare poles, till it made five complete revolutions before the storm left it behind.

There remains to be described the storm-flood produced when a storm runs upon a low shore, as often happens at the head of the Bay of Bengal. The cyclone advances with growing strength till it reaches the flat delta of the great Indian rivers. It finds the land here perfectly level, and so little raised above the water that its cultivated surface has to be pro-

[1] Continued from No. 48.

tected from river-overflows by dikes ten or twelve feet high built along the shores. But the inblowing winds brush the water of the bay up against the land; the diminished atmospheric pressure about the storm-centre allows the heavier surrounding air to lift the water here, and for every inch that the mercury falls in the barometer the water will rise a foot; the rain alone may contribute nearly a foot of water in a day; and finally, if a strong tide conspire with these other causes, a great flood is produced, that overwhelms even the dikes, and drowns out all the low country; and the poor people, unprovided with sufficient means of escape from the winds and the waters that come from above and below, are lost by the thousand. Six storms alone, that have devastated this coast since 1700, have, if the records can be trusted, destroyed over half a million lives.

The disappearance of a storm has already been alluded to. The storm will fail, or greatly decrease in strength, when running from the sea on the land; for friction here is greater, and there is less moisture in the air from which heat can be obtained to overcome the increased friction and continue the existence of the disturbance. Again: the storm must decrease in intensity as it recedes far from the equator; for it then enters regions of less warmth, and consequently less moisture. Finally, it must end when the updraught caused by heat derived from the falling rain fails to throw the overflow outside of the storm's limits; for then more air enters the storm than flows out of it, and the pressure at the centre will increase. The reverse of this is worth noting: the storm will increase in size and in total strength, although perhaps not in central intensity, as long as the updraught is active enough to throw some of its volume outside of the area occupied by the surface-indraught; for then the pressure at the centre will decrease, and the development of the embryo will continue.

Before proceeding to the consideration of tornadoes, we may devote a little space to the special features of our own storms east of the Rocky Mountains, as determined chiefly by Professor Loomis in his careful study of the signal-service maps.

The storm-areas, as indicated by the curved lines of equal pressures, are ovals about twice as long as wide, with the longer axis generally north-east and south-west. The average direction of progression of nearly five hundred storms, in 1872–74, was north 81° east, with a mean velocity of twenty-six miles an hour, or six hundred and twenty-four miles a day: the maximum velocity was above eighteen hundred miles a day. Some of these barometric depressions begin on the Pacific Ocean, or in our north-western territories; most of them are first noted within the western mountainous district; and a good share of the remainder arise on the plains. Very few come from the West Indies. After passing us, they sweep out over the ocean, generally turning well to the north-east, and, if continuing long enough, running to Norway or Iceland rather than to Great Britain. The probability that a storm which leaves our coast will arrive in England is only one in nine. The average tracks of a large number of storms from the Rocky Mountains to the Ural are shown on the accompanying map, prepared by Köppen (*Annalen der hydrographie*, 1882).

If storms moved only according to these averages, their prediction would be made easy and accurate; but they naturally fail to do so, and hurry or slacken their pace, or turn to one side or the other of their average course, in what seems to be the most capricious fashion. It is the early discovery of these individual peculiarities that tasks the acuteness of the weather-men.

With regard to velocity, storms advance much faster in February than in August (174 : 100), and in the late afternoon and evening than at other hours (125 : 100). If the telegraphic reports show a rapidly rising barometer, and a weak wind in the rear of the storm, it will probably move rapidly. The rain, also, exercises a marked control on the storm, as is shown by comparing the forward extension of the rain-area with the rate of progress: —

Forward extension of rain.	Progression of storm-centre.
640 miles.	40.1 miles an hour.
568 "	29.2 " " "
539 "	22.3 " " "
422 "	15.3 " " "

further, by comparing the axis of the rain-area with the course of the storm: —

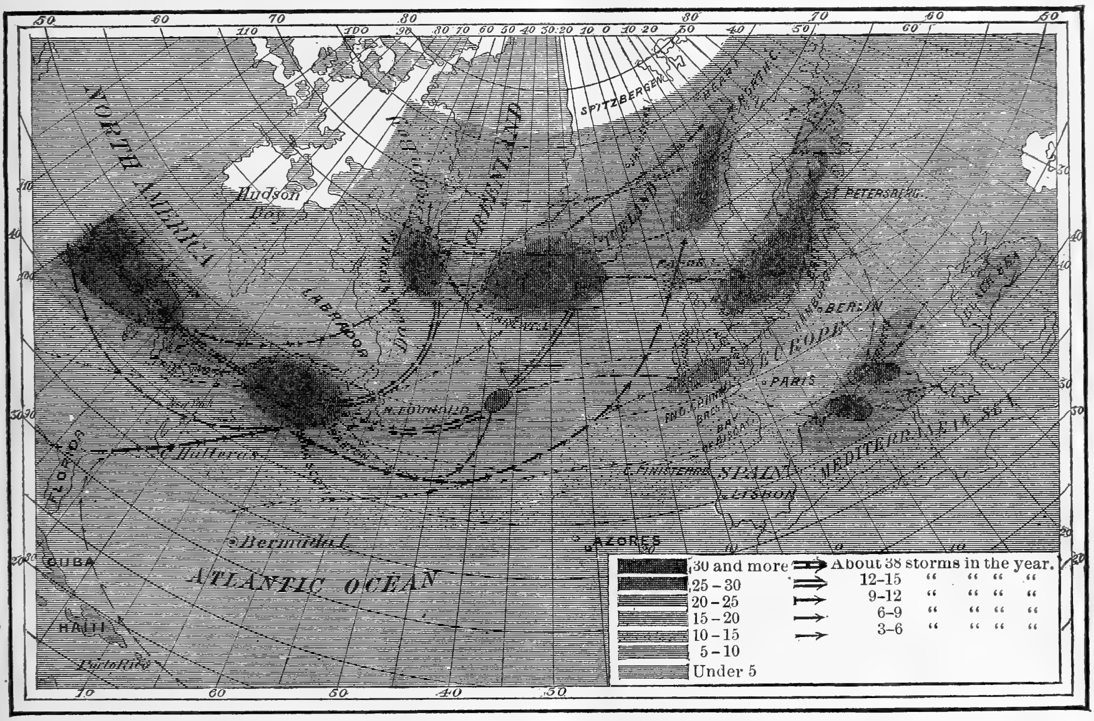
Axis of rain-area.	Course of storm.
N. 53° E.	N. 44° E.
S. 65° E.	S. 69° E.

finally, by comparing the rainfall with the increase or decrease of the central barometric depression: —

Average rainfall within isobar 29.80″.	Change of central depression in twenty-four hours.
0.078″	+ 0.10″ (i.e., storm decreasing).
0.149	− 0.05
0.159	− 0.128 (i.e., storm increasing).

Rain, therefore, is shown to aid in determining the velocity, direction, and development of our storms, as has already been inferred.

Thus far in regard to the motion of the storm as a whole. The winds of the storm blow faster, the more marked the central depression and the closer the isobars. If the space on the signal-service maps between adjoining isobars (the difference of their pressure being one-tenth of an inch) measure one hundred and thirty miles, the wind will probably blow five miles an hour; if eighty miles, thirty miles an hour; if forty-five miles, fifty miles an hour. There is, however, much variation from this rule, depending on the form of the ground and the neighborhood of the lakes or the sea. The average direction, inclination, and velocity of our storm winds in the four quadrants is shown in fig. 21. The relation of the several inclinations here shown has already been discussed. It should be added, that the unexpected approach to equality in the wind's strength on the right and left (south and north) sides of the storm is probably in large part due to the wind on the north coming but little retarded from the sea, while that on the south has lost much of its proper velocity by blowing long over land; so that, while the winds should theoretically show a less velocity on the left than on the right side of the track when the storm moves over a uniform surface, this inequality might be largely counteracted by the relations of sea and land that obtain in the eastern part of our country. This is confirmed by finding the winds on the left side of the storms of northern Europe much weaker than on the right; for here the progression of the storm, and the relation of sea and land, combine to produce this effect. Our space forbids more detailed consideration of the variation of our storms with the seasons; and the reader desirous to pursue the subject farther should provide himself with the government daily weather-maps, which may be had by subscription to the chief signal-officer in Washington, and should consult Professor Loomis's essays in the *American journal of science* for



AVERAGE TRACKS OF STORMS FROM THE ROCKY MOUNTAINS TO THE URAL.

recent years, the circular on the practical use of meteorological reports and weather-maps (issued by the signal-service, 1871), and the appendices on the relation of rain and winds, and on the course of storms in the different months, in the signal-service reports for 1878 and 1874.

(*To be concluded.*)

THE INTELLIGENCE OF BATRACHIANS.

In his recent volume on Animal intelligence,[1] Mr. Romanes devotes less than two pages to the intelligence of batrachians. He remarks, 'On the intelligence of frogs and toads very little has to be said.' That our author should have included toads in the above seems strange; as instances of cunning, and proofs of the general intelligence, of these animals, are numerous. In conversation with practical observers of animal life, I have never yet found one that did not accord a marked degree of intelligence to toads. In short, toads may readily be tamed, will come when called, and have been seen to place matter attractive to flies, their principal food, near their hiding-places, so they could remain at home and at the same time be sure of a sufficiency of food. This evidence of foresight, on the part of toads, is no uncommon occurrence, and quite effectually establishes their claim to a creditable degree of intelligence.

Of the spade-foot or hermit toad (Scaphiopus solitarius) and the tree-toad (Hyla versicolor) I have but little to record. The former is but rarely seen, and I have had no opportunity to experiment with it with a view to testing its mental capabilities. The habits of the animal, as described by Agassiz and Putnam, would lead one to conclude that intellectually they are to be classed with the common toad. The tree-toad, or Hyla, being crepuscular in habits, was found difficult to study, and nothing was determined that bore upon the question of its intellectual capacity. I can but state my impression, which is, that they are not so cunning as the common toad.

On the other hand, I am pained to confess that my many observations and experiments with the several species of true frogs found here, conducted without an intermission for four months, have yielded but little evidence that these creatures possess a particle of intelligence. It almost proved, indeed, to be labor lost, —

'To perch upon a slippery log,
And sit in judgment on a frog.'

[1] Animal intelligence. By George J. Romanes. (Internat. sc. series, no. xliv.) New York, *Appleton & Co.*

Mr. Romanes remarks, that, if frogs are removed to a long distance from water, they will take the shortest route to the nearest pool or brook. Even this, I find, is only usually true. Quite ten per cent of such 'removed' frogs started off, when released, in the direction of the most distant water, rather than that which was nearest. One of my many experiments was as follows: I placed a pail filled with water in a dry, dusty field, burying it to the brim. It was protected by a cap of coarse wire sieving. I then liberated a frog within twenty yards of it. It hopped in the opposite direction, towards water nearly three hundred yards distant. I then placed a frog on the opposite side of the buried pail, so that the distant brook could only be approached by passing near or directly over it, if the frog took a direct course. This the frog did, and less than a score of leaps brought it to the water covered by the sieve. It seemed quite satisfied with the fact that a little water was in sight, although out of reach. Here the frog remained until morning. The following day I removed the pail, and buried it within fifty yards of a running brook. I then took seven frogs of three species, and placed them upon the sieve, which was about half an inch above the surface of the water. Here five of them remained during the whole day, exposed to the glare and heat of a cloudless midsummer day. The evaporation from the water beneath them barely kept them alive; and yet within so short a distance was a running brook, with all the attractive features of ideal frog-life.

I repeated this experiment, with slight modifications, several times, and always with essentially the same results.

In his Travels in North America (Eng. trans., vol. ii. p. 171), Peter Kalm refers to certain habits of the bull-frog (Rana Catesbyana) which seemed to indicate that the frogs of this species occupying the same pond were somewhat governed by a leader. His remarks are, "When many of them croak together, they make an enormous noise. . . . They croak all together, then stop a little, and begin again. It seems as if they had a captain among them: for, when he begins to croak, all the others follow; and, when he stops, the others are silent;" and he adds that the 'captain' apparently gives a signal for them to stop. This, if true, would be evidence of considerable intelligence; but it is only apparently true of them. I have very carefully watched the bull-frogs in a pond near my house, and have found that the croaking of the 'captain' is not always that of the same individual. At times

the initial croak would come from one side of the pond, then the other, and so continue to vary. This shows at once that not any one individual started and stopped the croaking of its companions.

Hoping to find that in the pursuit of prey, which is principally insects, frogs would display some intelligence, I tried several experiments to test their ingenuity; but it was of no avail. Unless the food could be easily reached by making the simple exertion of a single leap, the frogs would go hungry. Subsequently I placed a large fly upon a piece of thin mica, and surrounded it with a circle of fine needles, piercing the plate. The fly thus protected could only be seized by the frog suffering a severe pricking of the jaws. This, I found, a frog would suffer indefinitely, in its attempts to secure the fly. In one instance, the frog, which had been fasting for seventy-two hours, continued to snap at the needle-protected fly until it had entirely skinned its upper jaw. I concluded from this, that the wits of a frog were too limited to be demonstrated.

Some weeks after having completed these experiments, I had the good fortune to capture two fully grown specimens of the bull-frog (Rana Catesbyana); and, noticing their enormously distended sides, I examined the stomach-contents of the two. In one was a full-grown chipmunk (Tamias striata); in the other, a garter-snake (Eutania sirtalis) measuring eighteen inches in length, and also a field-mouse (Arvicola riparia). On close examination, I found that the snake had partially swallowed the mouse; and, while thus helpless, the frog had evidently attacked the snake, and swallowed it.

It is evident, I think, that the frog recognized the helpless condition of the snake at the time, and took advantage of it. If so, it is evidence of a degree of intelligence, on the part of the frog, which the results of my experiments on the frogs generally, had not led me to expect. Certainly a frog, however large, will not attack even a small snake if it is possessed of its usual activity.

The salamanders, on the other hand, by their active movements, wandering disposition, quickness of hearing, and other minor characteristics, give evidence of greater intelligence. This I can state of them, however, as an impression only; for my efforts to prove them possessed of cunning were not successful. The purple salamander, it is true, fights when captured, curving its back, and snapping viciously. This no frog ever does. The common spotted triton (Diemyctelus) becomes quite tame when kept in an aquarium, and, as I found, is soon able to determine the difference between a fly held against the glass and one held over the water. I frequently held a fly against the glass, and very near the triton; but it took no notice of it, after one or two efforts to seize it, but would follow my hand, and, when the fly was held over the surface of the water, the triton promptly leaped at and seized it. This is, indeed, but meagre proof of intelligence, but seems to show, I think, that a salamander is more cunning than a frog.

My observations lead me to conclude, that the habits of an animal have much, if not all, to do with the intellectual capacity it possesses. Frogs, as a class, are not migratory. They frequent a given pond or stream; and, sustained by the insect-life that comes to them but is not sought, they pass an eventless life, trusting, as it were, to luck. Such an existence requires no intellectual exertion, and none is made. The salamanders, on the contrary, are far more wandering and active. They appear to be ever in search of food, and, when lying in wait for it, choose such positions as experience has taught them are best adapted for the purpose: at least, my studies of such specimens as I have kept in confinement lead me to believe so. Intellectually, therefore, the salamanders are in advance of the frogs; but the batrachians as a class, although higher in the scale of life than fishes, are, I believe, inferior to them in intelligence.

CHAS. C. ABBOTT, M.D.

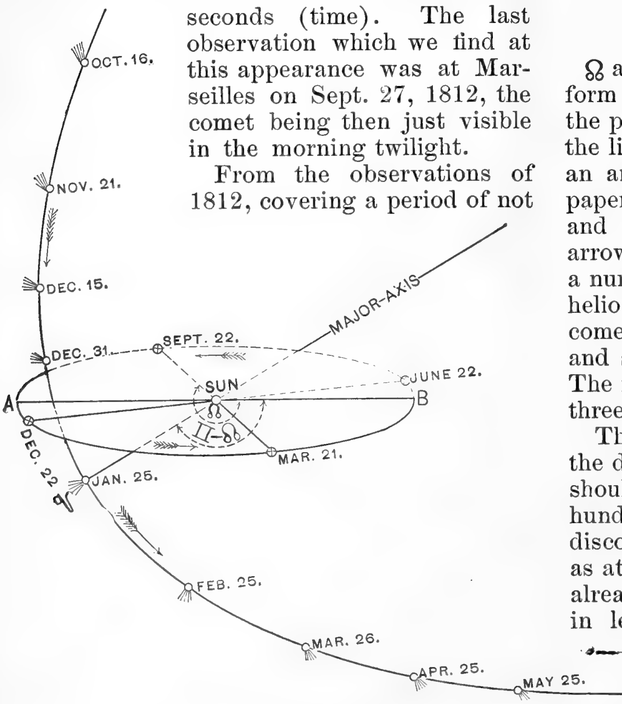
THE PONS-BROOKS COMET.

THE comet which is now being observed at its first predicted return was discovered by Pons, at Marseilles, two hours after midnight of July 20, 1812. Pons was at the time *concierge* at the Marseilles observatory, but afterwards became its director. He died in Florence, Oct. 14, 1831, at the age of seventy, having, between the years 1801 and 1827, discovered no less than thirty-seven comets; this one, according to Zach (*Monatl. corr.*, xxvi. 270), the sixteenth in ten years.

Pons describes the comet at the time of discovery as an irregular, nebulous mass, without coma or tail, and invisible to the naked eye. Having made sure, from the motion, that it was really a comet, he announced his discovery on July 22; and, from July 25 to Aug. 3, it was bright enough to be observed, at lower culmination, with the Marseilles in-

struments. The comet seems to have been discovered independently at Paris by Bouvard, who describes it thus: "Cette comète était très petite. Elle ne fut visible à la simple vue que pendant quelques jours. Le 18 août son noyau, assez brillant, était entouré d'une nébulosité qui offrait l'apparence d'une chevelure et d'une queue d'environ 2° de longueur." Bode reports the comet visible to the naked eye on Sept. 9, 1812, and on Sept. 14 he gives the tail as 1° long; while on the same date, at Seeberg, the tail is given as 2° 17′, and the diameter of the nucleus 5.4 seconds (time). The last observation which we find at this appearance was at Marseilles on Sept. 27, 1812, the comet being then just visible in the morning twilight.

From the observations of 1812, covering a period of not quite ten weeks, several orbits were computed, that of Encke assigning a period of 70.68 years. More recently Messrs. Schulhof and Bossert, from an exhaustive discussion of all the observations available (including some not known to Encke), predicted a return to perihelion about September, 1884, though they pointed out that in their period there was an uncertainty of ±5 years. The comet was actually found by Brooks (Phelps, N.Y.) on Sept. 1, 1883, some time before it had reached the sweeping ephemeris of Schulhof and Bossert; but its identity was soon established.



PATH OF PONS-BROOKS COMET.

The annexed diagram will assist in forming an idea of the path in which the comet is moving. The earth's orbit (the northern side uppermost) is shown orthographically projected upon the plane of the comet's orbit. The data necessary for defining the ellipse in which the comet moves are, the angle ☊ (254°), the longitude of the ascending node; the angle ☊ − ☊ (−161°), the difference between the longitude of the node and the longitude of perihelion (☊); the angle i, the inclination between the earth's orbit and that of the comet; q, the perihelion distance (0.775) expressed in units of the earth's distance from the sun; T, the date of perihelion passage; and e, the eccentricity (0.96), or ratio, —

$$\frac{\text{distance from centre to focus}}{\text{semi-axis major}}.$$

☊ and ☊ − ☊ are shown in the figure; and, to form the complete picture, we are to imagine the plane of the comet's orbit revolved about the line AB, the line of nodes, until it makes an angle of 74° (i) with the plane of the paper. The directions in which the comet and the earth are moving are indicated by arrows. The positions of the two bodies on a number of dates are also given. The perihelion is reached on Jan. 25, 1884, when the comet is seventy million miles from the sun, and sixty-eight million miles from the earth. The nearest approach to the earth, about fifty-three million miles, is upon Jan. 8, 1884.

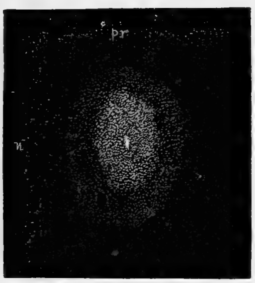
The brightness, as far as depending upon the distance from the sun and from the earth, should reach a maximum about Jan. 11, a hundred and forty-five times as bright as when discovered by Brooks, and five times as bright as at the time of Bode's observation, when, as already noted, the comet had a tail a degree in length. We might expect, then, that it would be visible to the naked eye from the middle of December to the middle of February, equalling, at its best, the brightness of a star of the third magnitude; but unusual and unexplained fluctuations in the brightness have been observed, which render these predictions a little untrustworthy. In the first week in December the comet passed within about seven degrees of the bright star α Lyrae, and continued its motion rapidly towards the south and east.

Since its discovery by Brooks, our visitor has behaved in a most peculiar manner as regards brightness. The theoretical change is given in Professor Boss's article in *Science*, ii. 449. On the following page we find observations made at Harvard college observatory on Sept. 21, 22, 23. The variability remarked at Harvard is confirmed by observations made at about the same time at Paris, Hamburg, and Dresden; so that we find a pretty well defined

maximum of from the seventh to the eighth magnitude, reached between Sept. 22 and 24, falling off suddenly on either side; for on Sept. 21 the comet was 'very faint,' with 'a slight condensation,' and on the 28th it was tenth to eleventh magnitude. Bigourdan says, "It had for some time a brilliancy thirty or forty times what might have been expected, — a fact difficult to explain on the theory that comets have no light of their own."

As regards any variability at its former appearance, the observations of 1812 are not sufficiently precise to furnish conclusive evidence.

A rough sketch of the comet, as seen with the 26-inch equatorial of the Naval observatory, Washington, was made on Sept. 26, 1883; and by permission of the superintendent of the observatory, Rear-Admiral R. W. Shufeldt, it is here given, with the observer's note. "Sept. 26.39, 1883; — observer, Winlock; —



PONS-BROOKS COMET, SEPT. 26, 1883.

26-inch equatorial, magnifying power 183. The comet appeared as an oval, nebulous mass, with a fairly well defined stellar nucleus, somewhat elongated in the *preceding following* direction, the nucleus being situated at about the centre of the nebulosity. The whole mass was some 6′ or 8′ in diameter."

The spectrum of the comet was examined by Konkoly,[1] Sept. 27, 1883. It consisted of three extremely faint bands, — the middle one brightest, the third (from the red end) next, and the one towards the red faintest. The bands ended in points, and were unequal in length. They sometimes lighted up for one or two seconds; and at these times they seemed to be much shorter than ordinarily, — a phenomenon quite new to the observer.

From the similarity of the orbits of the comets of 1812 and 1846, IV., Kirkwood has suggested (*Amer. journ. sc.*, 2d series, xlviii. 255) that they were doubtless members of a cometary system, and were brought into the solar system 695 years before the Christian era by the influence of Neptune. Schulhof and Bossert, in pointing out an error in Kirkwood's calculation, modifying somewhat his conclusion, say that the remarkable resemblance between the orbits of these comets indicates that there was originally some intimate connection between them. Indeed, these two comets, and the comets of 1815, 1847, V. (Brorsen), and 1852, IV. (Westphal), seem to belong to the same family.

As to the proper designation of this comet of Pons and of Brooks, authorities and precedents differ. In *The observatory* for November, 1883, Mr. W. T. Lynn writes, "I presume the designation Pons-Brooks's comet is understood to be only provisional. According to rule, it should be Pons's comet; . . . its permanent name must therefore be 'Pons's long-period comet,' or 'Pons's periodical comet of 1812.'" The shortest designation seems likely to prevail; and doubtless the comet will be known hereafter as the 'Pons-Brooks comet,' or perhaps simply as the 'Comet of 1812,' it being the only comet that was seen in that year.

W. C. WINLOCK.

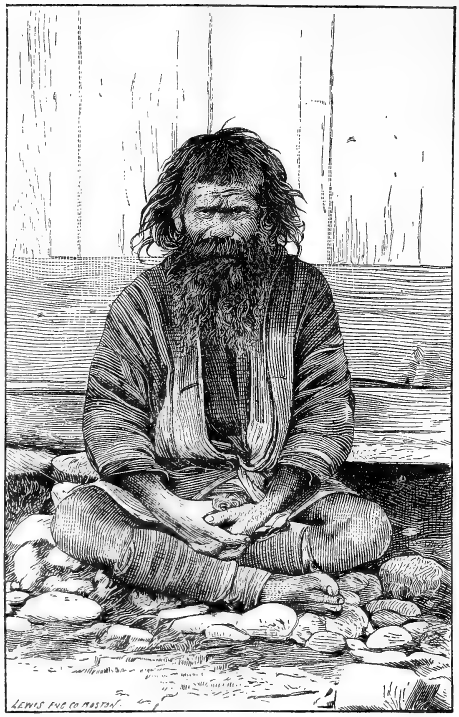
THE AINOS OF YEZO.[1]

ALTHOUGH the literature relating to the Island of Yezo, and the Ainos, — the inhabitants of this island as well as the southern half of Saghalien (or Karafuto), the Kurile Islands, and the southern extremity of Kamtchatka, — has increased much in recent years, still a description of the same, based upon personal observation, may be of use in explaining the many contradictory reports and opinions of ethnologists. Two facts should be borne in mind, — first, that the Ainos are not, even in the most remote way, to be classed with the dark races; and, second, that they are in no way related with their southern neighbors, the Japanese. With regard to their color, I must remark, that I have not found the Ainos of either sex darker than many Europeans: indeed, it is not rare to find in southern and eastern Europe darker individuals than are to be seen among the aborigines of Yezo. The assertion that the Ainos are dark brown, or even black, is sometimes made by those who do not take into consideration the fact that superstition prevents them from washing, and that consequently their complexion appears at times much darker than it really is. The real color, which may be best seen to advantage among the Ainos living on the seashore, is a little lighter, and less reddish, than that of the Japanese. The development of hair is somewhat remarkable: in the case of the men it covers the entire body to about the extent seen in very hairy Europeans. The beard is luxuriant and beautiful: the women imitate it by tattooing. The curly or wavy

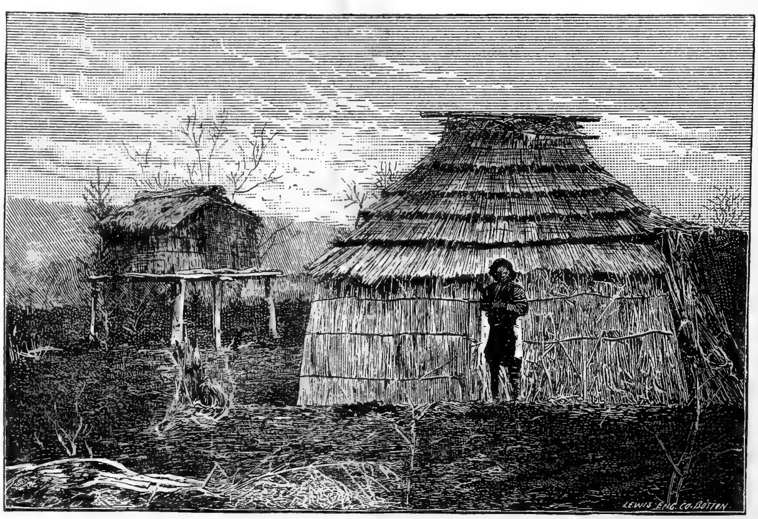
[1] By Professor BRAUNS of Halle. Translated from the memoirs of the Berlin anthropological society.

character of the hair of the head is quite striking. The physique is much better than that of the Japanese; the thigh is not so strikingly shortened; and the muscles are more strongly developed, while there is a weaker development of subcutaneous adipose tissue. The physiognomy and cranial conformation are also very different. The eyes are more deeply set than in the Japanese; and, as with us, they are shaded by heavy brows. The orbits, as shown by the skeleton of the face, are less high; and therefore the lids are horizontal, except in some hybrids. In contrast with the Japanese race, the forehead is straight; prognathism, when present, is very slight; and the nose and chin are generally well developed. The facial expression differs also from that of the Japanese: it indicates a certain fearlessness, joined with ingenuousness and a happy disposition. The intellectual characteristics correspond, as might be expected, to the impression produced by external features.



AN AINO MAN.

As has often been noted, the generous and respectful hospitality of the Ainos never fails to make a more favorable impression on the traveller than is received among the Japanese. In the southwestern parts of the island the character changes somewhat under the influence of the dominant race; and here hybrids are quite numerous. The latter fact has doubtless given rise to erroneous opinions as to the affinities of the two races; for no one would assert a relationship of language, except travellers who knew nothing of the language of either race, and who regarded the Japanese language, which is spoken fluently by the Ainos, as the vernacular of the Ainos. All those who (as Dawidoff, Klaproth, Dobrotworsky, Pfizmaier, v. Siebold, Scheube, Batchelor, Miss Bird) have prepared larger or smaller Aino vocabularies have escaped this error.



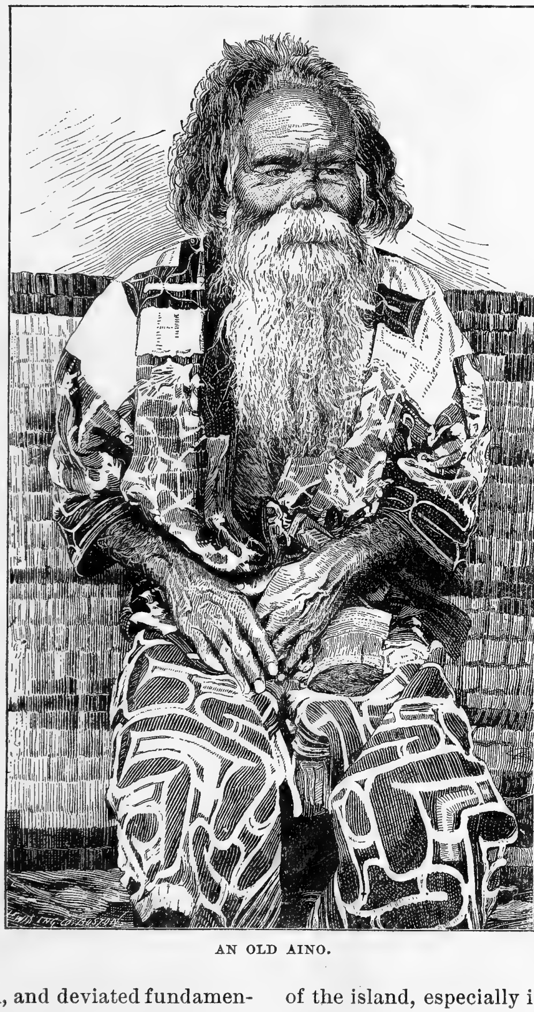
AINO HUT.

These observations were forced upon me on my first acquaintance with the Ainos in and around Sapporo, where I learned to know, also, the Ainos that were brought from Saghalien to Yezo at the time the former island was ceded to Russia. My conclusions were further supplemented and confirmed through a festival instituted by the government of Sapporo (July 9, 1881), in order to show me, as they said, the earlier conditions of the island, as well as the products of modern civilization.

At one end of a large hall, in which we were seated, were seen a number of Saghalien Ainos regaling themselves with saké (rice-wine) under the mellow radiance of oriental lamps. Upon a signal to begin, a young man arose, and led on the women to a round dance, while the older men remained seated. The women, with their faces turned toward the centre of the circle, alternately prostrated themselves and arose, at the same time festively moving onward in the circle. Picturesque as was their costume, consisting of long robes made from the bast of the elm, and metal girdles on which hung carved knife or sickle scabbards, this dance was

of inconsiderable interest, in comparison to the soft, melancholy, but melodious music, with its perfect time, which accompanied it. This singing would not have surprised me in the least in Norway, for example; but here it appeared in the most striking contrast with similar efforts of the Japanese, and indicated quite a different cast of mind.

In the vicinity of Sapporo was Juishikari, an Aino village of especial interest. It was here that I came to know the construction of their huts (great squares with smaller additions, all hung with rushes and reeds), many of their customs, their touching adhesion to their old nature-worship, their worship of the sun by the *Inawo* (a sacred staff frilled with shavings pendent from its upper end, and placed in the eastern window of the hut), and their fear of the dead. Their food consists mainly of millet and salted salmon.



AN OLD AINO.

The intelligence of the Ainos is by no means small. They learn the Japanese language very easily, accustom themselves very readily to all innovations which are not in conflict with their religious conceptions, occasionally make improvements, and are ready to answer questions in a precise manner. They never betray their age, and pretend not to know it. With this exception, I learned every thing I wished from them. I obtained, for example, a detailed account of their terms for different colors. After what I had seen, I was not surprised to find that these terms quite conformed to our own, and deviated fundamentally from those of the Japanese. The Japanese have only one word for *blue* and *green;* while the Ainos have distinct names for both colors, which often appear to be confounded when interpreted by the Japanese.

In Saru (or Sara) I had an opportunity to see all of an ancient state organization that has survived the introduction of a village government. Here I found the seat of the chief among the village elders, which was formerly located somewhat farther in the interior, at Biratori or Piratoru. The chief was regarded by the Ainos as a sort of king. Under Japanese domination his power and rank were lost.

The mode of travelling has been well described by Miss Bird. It is impossible to make any progress without horses; and these, although not of the meanest sort, are most shamefully abused by the Japanese. In this respect the Ainos generally prove useful and agreeable servants, but they are often the too subservient tools of their masters. However, I have never seen the Ainos abuse their horses, their only domestic animals, in the reckless and brutal manner observed among the Japanese: indeed, I have witnessed on many occasions quite the opposite mode of treatment.

In my journeys along the coast, I became convinced that the population of the Ainos had been under-estimated, just as that of the Japanese had been over-estimated. While the number of the latter is certainly less than a hundred thousand, instead of more, as officially reported, the number of the Ainos (said to be eighteen thousand) must be trebled in order to reach approximately accurate figures. The erroneous estimate of the Japanese government is explained by the fact that it takes no account of the large number of Aino villages on the large rivers of remote parts of the island, and particularly along the coast, but is based on the relation of the square surfaces of known and unknown parts. In some of the better known parts of the island, especially in the south-west, the Ainos have been completely dislodged; and in the mixed districts their number has also been much reduced.

From all these observations, as well as from the traditions of the Ainos, in which are ever-recurring laments for a better past, and from many peculiarities in their customs (e.g., loss of the use of really good weapons, the poisoning of the arrows and snares for beasts of the chase, particularly bears), we must conclude that the Ainos are to be classed with those peoples that have earlier been more richly supplied

with the implements of civilization, but have become degraded intellectually through isolation. Prehistoric discoveries, particularly those made in the region of Otaru, on the west coast of the island, favor this view. The pits found there for dwellings indicate that the Ainos came from the north to Yezo. The shell-heaps contain, besides very elegant potsherds, many stone implements, especially obsidian heads of lances and arrows, and ornaments of different kinds, as stone-beads and the like. In all these respects the shell-heaps are distinguished from those found throughout Japan, from latitude 39° north to the southernmost point of the coast of Kiushiu, within which limits the shell-heaps are destitute of ornaments, poor in stone implements, and entirely without obsidian. These facts point to a higher civilization of the Aino race, and at the same time refute the assumption that the Ainos formerly settled a large part of the main island (Nipon), — an assumption erroneously supposed by some to be supported by prehistoric discoveries. As there is no near relationship between the Ainos and the Giljaks of North Saghalien, who are less hairy, more prognathous, and more like the Tchuktchi race, we must assume that the Ainos were displaced by the Giljaks, and that their nearest relatives, judging from important analogies of language, and especially from their 'naturell,' are to be sought among the Kaoli of northern Corea (Oppert's Caucasian type of Koreans). The latter have symmetrical features and luxuriant beards, and are therefore called 'bearded barbarians' by the Japanese. They stand to the inhabitants of southern Corea in many respects as the Ainos to the Japanese. The Kaoli have had, to be sure, a history very different from that of the Ainos; for they became a civilized people, while the Ainos in the primeval forests of Yezo became more and more uncivilized. This fact is not opposed to the assumption of a kinship of the two races; and this assumption is supported not only by the particulars already alluded to, and the undeniable capacity of the Ainos for greater intellectual activity than they now exhibit, but also by the fact, that, notwithstanding the developed culture of the Coreans, certain things (e.g., the lance-shaped turrets on grave monuments) recur which remind one of Yezo. Besides, the traditions of the Kaoli, and certain names of places in the southern part of Amur (on the Sungari and its south-eastern tributaries), point to earlier dwelling-places of the race. From here the Ainos probably spread over the lower part of Amur and Saghalien. Other attempts to bring the Ainos and the North-Coreans into close relationship with other peoples are too hypothetical to require mention here. It is certainly to be hoped, but unfortunately it can hardly be expected, that the silent but eloquent appeal for friendly sympathy which the hearty greeting of the Ainos and the melancholy look given to strangers seem to make clear, may meet with some practical response: at all events, we should not withhold our most cordial good will from these sons of the primeval forests of our temperate zone, who are unquestionably the most peaceful and good-natured of all the so-called 'savages.'

THE HOT BLAST IN MAKING IRON.

At the last few meetings of the Iron and steel institute of Great Britain very important papers have been presented and discussed, showing the direction in which competition has brought about economy in iron-manufacture. These papers, notably those of Messrs. Cochrane, Hawdon, Bell, Cowper, and Howson, give to the technical reader a very good idea of the latest opinions of the foremost iron-makers of England.

The institute held its September meeting in Middlesborough, — the place in which it was organized fourteen years ago. This anniversary naturally led to some general reflections on the progress made in that time, which can be appreciated by the general public. The only drawback to the discussions was the absence, owing to illness, of Mr. I. Lowthian Bell, who has been present at all the previous meetings.

In 1828 Mr. J. B. Neilson patented a process for heating the air before it was blown into the blast-furnace, claiming that a gain in economy of working was the result. The idea was received with disbelief in most quarters. A little later Mr. Neilson proved conclusively to all that one hundred pounds of coal burned in heating the air for the blast were able to save three hundred to four hundred pounds of the fuel used within the furnace. The first step was made, and the iron-makers had to accept the consequences.

From this small beginning the tide of invention and enterprise went on, until the air used for blast was no longer heated by coal burned for the purpose, but by the combustion of what were formerly waste gases issuing from the top of the furnace. One improvement after another was introduced, until the temperature of the blast was raised to 900° F., and even to 1000° F. At this point it seemed that the metal pipes used in the stoves for heating had reached their limit of endurance; and a portion of the iron-making world made up their minds that greater heat than this could not be economically maintained, and that, even if the question of obtaining the heat was solved, there was still a balance of chemical reactions within the furnace which would prevent the greater heat from being advantageous.

Meanwhile, by the use of the Siemens regenerator principle, two different inventors, Cowper and Whitwell, each manufactured stoves which contained fire-brick chambers, within which the waste gases burned for a period, until the fire-bricks were at a red heat. The gases were then turned off to the alternate stove, and the air for the blast-furnace was driven in through the heated stove until the other one had become sufficiently heated. The interchange was again made, and so on. These various devices have resulted in the production of a blast of air for the furnace heated up to 1600° F., or even to 1700° F.

Now let us see what has been the result of this change. The blast-furnaces of 1869 produced, on an average, a little over 180 tons of iron per week. To-

day they produce, on an average, upwards of 300 tons per week, in some cases 800 or 900 (and in one of the Pittsburg furnaces the enormous output of 1,800 tons has been reached). Mr. Charles Cochrane, an advocate of the hottest hot blast, stated, that, at the works at Ormsby, they began in 1855 with a furnace of 7,000 cubic feet capacity, and with a temperature of air between that of molten lead and molten zinc, using 39.64 cwts. of coke to the ton of pig. In 1857 they used 33.87 cwts.; in 1867 it was only 29.66; in 1877 it had become reduced to 22.64; and in 1882, 21.18 cwts. was the average for all furnaces, small and large, while the larger furnace of 34,000 cubic feet capacity worked the whole year through on 19.38 cwts. per ton of pig. Hence from 1855 to 1883 the saving was 20.34 cwts. of coke per ton of iron; and, in Mr. Cochrane's opinion, fully half this saving was due to the use of the Cowper fire-brick stoves.

Mr. Cochrane has recounted some of the theoretical calculations that have been made. In 1879 he ventured to predict that a ton of iron could be made with 17.90 cwts. In 1881 he had made iron with 18.40 cwts. Another iron-master stated that a furnace has run for eight weeks on less than 18 cwts.

Mr. Hawdon claims that heating the blast from 990° F. to 1400° F. resulted in a saving of 1.5 cwts. of coke to the ton of iron, and that a further heating to 1550° F. was followed by a total saving of 2.5 cwts., bringing the coke down to 21.3 cwts.

In the discussions which took place at the meetings referred to, the prominent iron-manufacturers generally took the ground that the hotter the blast the better the result, up to the temperature of melting iron. Mr. I. Lowthian Bell, however, dissents from this view, and thinks, that, in real ultimate economy, 1000° F. will prove to be about the limit of heat for the blast which it is worth while to strive for.

R. H. RICHARDS.

MODERN PHYSIOLOGICAL LABORATORIES: WHAT THEY ARE AND WHY THEY ARE.[1] — I.

A LITTLE more than seven years ago I announced from this platform that the old biological laboratory was ready for use, — that set of rooms in the third story of this building, which, inconvenient in many respects as they were, will, I trust, always be remembered by some of us with affection, and mayhap with a little pride.

This night on which we have met to celebrate the completion of the new laboratory is, however, an occasion for looking forward rather than backward. But before proceeding to speak in detail of the new building, I feel sure I do but what every one of the members of the biological department present would think me remiss to omit, in pausing a moment to express our gratitude to those to whom we owe it, — first to our founder, Johns Hopkins, for his munificence; and next to his trustees. Probably very few present realize how much time and thought the trustees spent on the building before a stone of its foundation was laid, and during its erection. No one but myself knows how often I have been put in good heart by the cheering words, "Well, Dr. Martin, let us get it right when we are about it." In this connection I cannot refrain from saying, that, though we owe all so much, we owe a special debt of gratitude to Mr. Hall Pleasants, the chairman of the building committee. Throughout the whole summer there was hardly a morning on which he did not visit the building, and that not merely for a glance, but far more often to spend an hour or two hours about it, and make sure that all was going right.

[1] An address delivered on the occasion of the formal opening of the new biological laboratory of the Johns Hopkins university, Jan. 2, 1884. By H. NEWELL MARTIN, M.D., Dr. Sc., M.A., professor of biology in the university.

The material result of this liberality, forethought, supervision, and care, is that stately building on the top of the hill. Handsome though not ostentatious, comfortable but not luxurious, pleasant to work in without unnecessary finery, it stands there, for its purpose unrivalled in the United States, and not surpassed in the world.

Substantial, solid, well thought out, suited to its ends, and with no frippery about it, it is now for us to see that our work agrees in character with the building.

There are many here to-night, who, not being biologists, may desire to know what such laboratories are for, and why there is any need of them. I shall perhaps best begin my attempt to answer these questions by stating briefly what our own laboratory is.

It is a building constructed primarily to afford facilities for instruction and research in physiology; and, secondarily, similar opportunities in allied sciences, as comparative anatomy and botany, some training in which is essential (and the more the better) to every one who would attain any real knowledge of physiology. As so many distinct branches of biological science are pursued in it, we call it in general the biological laboratory; but it is a biological laboratory deliberately planned that physiology in it shall be queen, and the rest her handmaids. If, therefore, you visit the building prepared to see a great zoölogical museum or an extensive herbarium, you will be disappointed. I do not underrate, and no one connected with this university can, — bearing in mind the brilliant anatomical researches of Dr. Brooks and others, made among us, — the claims of morphology; and in time I trust we may see a sister building specially designed for study of the structure, forms, and development of plants and animals. But one or the other had to be first chosen, unless we were to do two things imperfectly instead of one well, and there were strong reasons for selecting physiology. In the first place, I think even the morphologists will admit that hitherto, and especially in the United States, they have had rather more than their fair share; innumerable museums and many laboratories have been built for their use; while physiology, if she got any thing, was usually allotted some out-of-the-way room in an entirely unsuitable building, if

no one else wanted it, and was very glad to get even that. A second and still stronger reason is, that as medicine is slowly passing out of the regions of empiricism and rule-of-thumb treatment, or mal-treatment, it has become evident that sound physiology is its foundation; and this university will at no distant day have a medical school connected with it.

As you walk presently through the rooms of the new building, and see the abundance of instruments of precision for teaching and research — the batteries, galvanometers, induction-coils, and spectroscopes; the balances, reagents, and other appliances of a chemical laboratory; the microscope for every student; the library of biological books and journals; the photographic appliances; the workshop for the construction and repair of instruments — when you see these things, it may interest you to recall that sixty years ago there was not a single public physiological laboratory in the world; nor was there then, even in any medical school, a special professor of physiology. So late as 1856 Johannes Müller taught in Berlin, human anatomy, comparative anatomy, pathological anatomy, physiology, and embryology.

DuBois-Reymond, now himself professor in Berlin, has graphically described the difficulties of the earnest student of physiology, when he attended Müller's lectures in 1840.[1]

"We were shown (he says) a few freshly prepared microscopic specimens (the art of putting up permanent preparations being still unknown), and the circulation of the blood in the frog's web." So much for the histological side.

"We were also shown the experiment of filtering frog's blood to get a colorless clot, an experiment on the roots of the spinal nerves, some reflex movements in a frog, and that opium-poisoning was not conducted along the nerves. There were some better experiments on the physiology of voice, — a subject on which Müller had recently been working; and there was finally a demonstration of the effect upon respiration of dividing the pneumogastric nerves."

In all, you see six experiments, or sets of experiments, in the whole course, in addition to the exhibition of some microscope slides; and all these mere demonstrations. It was hardly thought of, that a student should use a microscope, or make an experiment, himself. If he desired to do so, the difficulties in his way were such as but few overcame.

"He must experiment in his lodgings, where on account of his frogs he usually got into trouble with the landlady, and where many researches were impossible — there were no trained assistants to guide him — no public physiological library — no collection of apparatus. We had to roll our own coils, solder our own galvanic elements, make even our own rubber tubing, for at that time it was not an article of commerce. We sawed, planed and drilled — we filed, turned, and polished. If through the kindness of a teacher a piece of apparatus was lent to us, how we made the most of it — how we studied its idiosyncrasies — above all, how we kept it clean!"

Of course certain men, the men who were born to become physiologists, and not mere attendants on lectures on physiology, surmounted these difficulties.

[1] Emil DuBois-Reymond. *Der physiologische unterricht, sonst und jetzt.* Berlin, 1878. The quotations from this pamphlet, while giving, I trust, a true idea of the substance of DuBois-Reymond's statements, have been curtailed, and are not to be regarded as literal full translations of the original. — H. N. M.

One has only to recall the names of DuBois-Reymond himself, and of such of his contemporaries as Brücke, Helmholtz, Ludwig, Vierordt, Donders, and Claude Bernard, to realize that fact; and undoubtedly there was a good side to it all. Triflers, at any rate, were eliminated; and the class of individuals was unknown who sometimes turn up at modern laboratories (and, judging from a good deal of current physiological literature, sometimes get admitted to them) with a burning desire to undertake forthwith a complicated research, though they would hardly know an ordinary physiological instrument if shown to them, much less how to handle it. They never can wait: they must begin the next morning, believing, I presume, that modern laboratories are stocked with automatic apparatus, — some sort of physiological sausage-machines, in which you put an animal at one end, turn the handle, and get a valuable discovery out at the other.

With one exception, Berlin was not in 1840 worse off than other German universities, so far as facilities for physiological study were concerned, and certainly better off than any university in England or the United States. The exception was in Breslau, where the celebrated Purkinje, single-handed, had founded a physiological institute. It has usually been supposed that in this he followed the example given by Liebig, who founded at Giessen the first public chemical laboratory; but this, *pace* my colleague Professor Remsen, can hardly have been the case. It is to Purkinje that the honor belongs of founding the first public laboratory. Liebig undoubtedly conceived the plan when working in Paris in Gey Lussac's private laboratory, but it was not until 1826 that he began to put it into execution; and at that date Purkinje had already, largely at his own cost, started a physiological laboratory at Breslau, open to students, — on a very small scale, it is true, but still the germ of all those great laboratories of physics, chemistry, and biology, which are now found in every civilized country, and to which, more than to any thing else, modern science owes its rapid progress. Of these there must be at least forty now organized for physiological work; and almost every year sees an increase in their number. How has this come about in the fifty odd years which have passed since the origination of Purkinje's ill-equipped and little known workrooms?

First and foremost, because of the improvement in philosophy which took place as men began to break loose from the trammels of Greek and mediaeval metaphysics, and to realize that a process is not explained by the arbitrary assumption of some hypothetical cause invented to account for it. So long as the phenomena exhibited by living things were regarded, not as manifestations of the properties of the kind of matter of which they were composed, but as mere exhibitions of the activity of an extrinsic independent entity, — a pneuma, anima, vital spirit, or vital principle which had temporarily taken up its residence in the body of an animal, but had no more essential connection with that body than a tenant with the house in which he lives, — there was no need for physiological laboratories. Dissection of the dead body might, indeed, be interesting as making known

the sort of machine through which the vital force worked, — just as some people find it amusing to visit the former abode of a great author, and see his library and writing-table and inkstand; and there might be discussions as to the locality of the body in which this vital force resided; to carry out our simile, as to what was its favorite armchair. Various guessers placed it in the heart, the lungs, the blood, the brain, and so forth. Paracelsus, with more show of reason, located it in close connection with the stomach, on the top of which he supposed there was seated a chief vital spirit, Archaeus, who superintended digestion. It is mainly to Descartes,[1] who lived in the earlier half of the seventeenth century, that physiology owes the impulse which set it free from such will-o'-the-wisps. Putting aside all consciousness as the function of the soul, he maintained that all other vital phenomena were due to properties of the material of which the body is composed; and that death was not due to any defect of the soul, but to some important alteration or degeneration in some part or parts of the body.

The influence of Descartes, and in the same half-century the demonstration of the circulation of the blood by Harvey, gave a great impulse to experimental physiology. Both Harvey and Descartes, however, still believed in a special locally placed vital spirit or vital *force*, which animated the whole bodily frame as the engine in a great factory moves all the machinery in it. What a muscle did, or a gland did, depended on the structure and properties of the muscle or gland; but the work-power was derived from a force outside those organs, — on vital spirits supplied from the brain along the nerves, or carried to every part in the blood. As the pattern of a carpet will depend on the structure and arrangement of the loom, — which loom, however, is worked by a distant steam-engine, — so the results of muscular or glandular activity were believed to be determined by the structure of muscle and gland; but the moving-force came from some other part of the body.

The next essential advance was made by Haller, about the middle of the eighteenth century. He demonstrated that the contracting-power of a muscle did not depend on vital spirits carried to it in nerve or blood, but on properties of the muscle itself. Others had guessed, Haller proved, that the body of one of the higher animals is not a collection of machines worked by a central motor, but a collection of machines each of which in itself is both steam-engine and loom; leaving aside, of course, certain of the purely mechanical supporting and protecting apparatuses of the skeleton. This was the death-blow of the 'vital force' doctrine. Extensions of Haller's method showed that it was possible to destroy the brain and spinal cord of an animal, and separate its muscles, its heart, its nerves, its glands, and yet keep all these isolated organs working as in life for many hours. The life of an animal could be no longer regarded as an entity residing in one region of the body, from which it animated the rest; and the word gradually became simply a convenient phrase for expressing the totality or *resultant* of the lives of the individual organs. Physiologists began to see that they had nothing to do with seeking a vital force, or with essences or absolutes; that their business was to study the phenomena exhibited by living things, and leave the noumena, if there were such, to amuse metaphysicians. Physiology thenceforth became more and more a study of the mechanics, physics, and chemistry of living organisms and parts of organisms.

[1] See Huxley: *The connection of the biological sciences with medicine* (*The lancet*, Aug. 13, 1881).

Progress at first was necessarily very slow; physics and chemistry, as we now know them, did not exist; galvanism was not discovered; osmosis was unknown; the conservation of energy was undreamed of; while modern chemistry did not take its rise until the discovery of oxygen by Priestly, and the extension and application of that discovery by Lavoisier towards the close of the last century. Physiology had to wait then, as now, for its advance upon the development of the sciences, dealing with simpler forms of matter than those found in living things. But little by little, step after step, so many once mysterious vital processes have been explained as merely special illustrations of general, physical, and chemical laws, that now the physiologist scans each advance in these sciences in full confidence that it will enable him to add another to the phenomena of living bodies, which are in ultimate analysis not peculiar or 'vital,' but simply physico-chemical. Apart from the phenomena of mind, whose mysterious connection with forms of matter he can never hope to explain, if a modern physiologist were asked what is the object of his science, he would answer, "not the discovery or the localization of a vital force, but the study of the quantity of oxidizable food taken into the stomach, and the quantity of oxygen absorbed in the lungs; the calculation of the energy or force liberated by the combination of the food and oxygen; and observation of the way in which that force has been expended, and the means by which its distribution may be influenced."

Once it was recognized that at least the great majority of physiological problems were problems admitting of experimental investigation, the necessity for special collections of apparatus suitable for experiment on living plants and animals, and for affording students an opportunity to study the play of forces in living organisms, had not long to wait for recognition. Physiological laboratories were organized at first in such rooms as could be spared in buildings constructed for other purposes; later, in structures built for this special end. The first laboratory specially erected for physiological work was built for Vierordt, in Tübingen, less than twenty years ago. So far as I know, our own is the first such building in the United States.

There is still another reason which has combined with the recognition of the independence of physiology as a science to make the modern laboratory, open to all properly prepared students, a possibility; and physiology owes it to this country. I do not forget how Brown-Sequard in Philadelphia clinched and completed Bernard's great discovery of the vaso-motor

nerves; nor the researches of Weir Mitchell on the functions of nerve-centres, and the action of snake-poisons; nor, in later years, the researches of Wood on the physiology of fever; and on various subjects by Bowditch, Arnold, Flint, Minot, Sewall, Ott, Chittenden, Prudden, Keyt, and others. But speaking with all the diffidence which one, who, at least by birth, is a foreigner, must feel in expressing such an opinion, I say, that considering the accumulated wealth of this country, the energy which throbs through it, and the number of its medical schools, it has not done its fair share in advancing physiological knowledge, *but for one thing*, which makes the world its debtor. I mean the discovery of anaesthetics. When Morton, in 1846, demonstrated in the Massachusetts general hospital that the inhalation of ether could produce complete insensibility to pain, he laid the foundation-stone of our laboratory, and of many others. No doubt the men whose instincts led them to physiological research, and who realized that by the infliction of temporary pain on a few of the lower animals they were discovering truths which would lead to alleviation of suffering, and prolongation of life, not only in countless generations of such animals themselves, but in men and women to the end of time, would have tried to do their work in any case. But the men who can steel their hearts to inflict present pain for a future greater gain are few in number. The discovery of anaesthetics has not only led to ten physiological experimenters for each one who would have worked without them, but by making it possible to introduce into the regular course of physiological teaching, demonstrations and experiments on living animals, without shocking the moral sense of students or of the community at large, has contributed incalculably to the progress of physiology.

On the occasion of the opening of the old laboratory I used these words:[1] —

"Physiology is concerned with the phenomena going on in living things, and vital phenomena cannot be observed in dead bodies; and from what I have said you will have gathered that I intend to employ vivisections in teaching. I want, however, to say, once for all, that here, for teaching purposes, no painful experiment will be performed. Fortunately the vast majority of physiological experiments can nowadays be performed without the infliction of pain, either by the administration of some of the many anaesthetics known, or by previous removal of parts of the central nervous system; and such experiments only will be used here for teaching. With regard to physiological research, the case is different. Happily here, too, the number of necessarily painful experiments is very small indeed; but in any case where the furtherance of physiological knowledge is at stake — where the progress of that science is concerned, on which all medicine is based, so far as it is not a mere empiricism — I cannot doubt that we have a right to inflict suffering upon the lower animals, always provided that it be reduced to the minimum possible, and that none but competent persons be allowed to undertake such experiments."

Those words were a declaration of principle and a pledge given to this community, in which I was about to commence my work. That the work has been carried on for seven years among you, without a murmur of objection reaching my ears, is sufficient proof that Baltimore assents to the principle; and, gratifying as the building of our new laboratory is to me from many points of view, there is none so grateful as its witness, that, in the opinion of our trustees and of my fellow-citizens, I have carried out my pledge. There has been no hole-and-corner secrecy about the matter: the students in the laboratory have been no clique living isolated in a college-building, but either your own sons, or boarders scattered among dozens of families in this city; and no room in the laboratory has ever been closed to any student: what we have done has been open to all who cared to know. On this occasion, when we formally make a fresh start, I desire to re-assert the principle, and repeat the pledge.

(To be concluded.)

BERTHELOT'S EXPLOSIVE MATERIALS.

Explosive materials, a series of lectures delivered by M. P. E. BERTHELOT; *translated by* MARCUS BENJAMIN. *A short historical sketch of gunpowder, translated from the German of* KARL BRAUN *by* Lieut. JOHN P. WISSER, U.S.A. *A bibliography of works on explosives; reprinted from Van Nostrand's magazine*, No. 70. N.Y., *Van Nostrand*, 1883. (Van Nostrand's science series.) 180 p. 24°.

THE lectures of Berthelot, which form the more important part of this collection, are devoted to a popular exposition and amplification of the theories which he has from time to time advanced, concerning the constitution and mode of action of explosive substances. The principal topics treated are, the force of explosives; the origin, duration, and speed of propagation of the explosive reactions; inflammation and detonation as modes of inducing explosions; and explosions by influence.

The force of an explosive may be understood in two ways: it may be considered either as the pressure developed or as the work accomplished. The pressure depends principally upon the nature of the gases formed, their volume, and their temperature. The work, on the other hand, is principally dependent upon the amount of heat given off in consequence of the chemical decomposition. In practice, as, for instance, in guns, the transformation of this heat into useful work is never complete, since heat is absorbed by the gun, gases, and projectile, and a portion of the work produced is lost in moving the gases and air projected. Taking all these facts into consideration, it has yet been difficult to explain the great differences which result from the different methods employed for inducing explosions. Berthelot holds that this diversity depends upon the rapidity with which the explosive reaction propagates itself, and the more or less intense pressures which result from it, and he illustrates it as follows: —

Let the case be the simplest one, such as an explosion caused by the fall of a weight from a certain height. At first one would suppose the effects observed to be due to the heat developed by the pressure of the suddenly arrested weight. But calculation shows that the arresting of a weight of several kilograms, falling .25 to .50 of a metre, would not be capable of raising the temperature of the explosive mass more than a fraction of a degree, if the resulting heat were dispersed uniformly throughout the entire mass: while for a body such as nitroglycerine, for instance, it is necessary to heat it to 190° to induce explosion.

It is by another process that the mechanical energy of the weight, which is transformed into heat, becomes the originator of the observed effects. It is sufficient to assume, that, as the pressures which arise from the shock exerted on the surface of the nitroglycerine are too rapid to become uniformly dispersed throughout the entire mass, the transformation takes place locally among the layers first reached by the shock. If it is sufficiently violent, they may thus be rapidly heated to the necessary temperature; and they will be immediately decomposed, and produce a large quantity of gas. This production of gas is in its turn so violent that the shocking body has not time to displace itself; and the sudden expansion of the gases of explosion produces a new shock, probably more violent than the first, on the layer situated below. The mechanical energy of this shock is changed into heat in the layers which it reaches, and produces an explosion; and this alternation between a shock developing mechanical energy which changes into heat, and a production of heat which elevates the temperature of the layers up to the degree necessary for a new explosion capable of reproducing the shock, propagates the reaction, molecule by molecule, through the entire mass. The propagation of the deflagration takes place in this way in consequence of phenomena comparable to those which produce a sonorous wave; that is to say, by producing a real explosion which advances with a rapidity incomparably greater than that of a simple burning provoked by the contact of a body in ignition, and operating under conditions where the gases expand freely in proportion to their production.

The reaction started by the first shock in a given explosive material is propagated with a rapidity which depends upon the intensity of the first shock; and this intensity may vary considerably, according to the method by which it is produced. Marcel Duprez has shown that the effect of a blow from a hammer may vary in duration from the hundredth to the ten-thousandth of a second, according as one strikes with a hammer having a flexible handle or with a block of steel. From this it follows that the explosion of a solid or liquid mass may develop itself according to an infinite number of different laws, each one of which is determined, all other things being equal, by the original impulse. The more violent the initial shock, the greater will the resulting violence of the decomposition be, and the greater will be the pressures which are exerted during the entire course of this decomposition. One and the same explosive substance may hence produce very different effects, according to the method of ignition.

Among these methods of ignition, by far the most curious and inexplicable is the determining of the explosion of one mass by the explosion of another mass near by, but not in contact with it, which is termed by Berthelot 'explosion by influence.' Abel has offered his theory of *synchronous vibrations* to explain this phenomenon, and the theory seemed to be confirmed by the interesting experiments of Champion and Pellet; but Berthelot regards them as inconclusive, or else directly opposed to Abel's theory, and he offers a theory of his own, which is but an expansion of that of shocks explained above.

Working, as Berthelot is, under the direct auspices of the French government, he has had the best of facilities for the study of explosive substances and the phenomena of explosions; and no one has probably engaged in a more critical or extended physical and chemical examination of these bodies, and hence he speaks with authority. Yet some of his theories have failed to find general acceptance, especially that concerning the influence of dissociation upon the force of explosives; and it is noticeable that this theory finds no place in these lectures.

Karl Braun's sketch is bright and entertaining but iconoclastic, and, while wresting the honor of the discovery of gunpowder from Berthold Schwartz, intimates that the knowledge of its manufacture was brought from the orient to Augsburg in 1353 by a Greek Jew named Typsiles.

Of the 'Bibliography of explosives' the best that can be said is, that it is an unsystematized collection of titles, that it is filled with errors of the grossest kind, and that it is unworthy of both compiler and publisher. In fact, it must be said the book throughout is marred by printers' errors.

HOUSTON'S ELEMENTS OF CHEMISTRY.

The elements of chemistry; for the use of schools, academies and colleges. By EDWIN J. HOUSTON. Philadelphia, *Eldredge*, 1883. 444 p., illustr. 8°.

HOUSTON'S 'Elements of chemistry' is a brief compilation of the latest facts in regard to the science, arranged for the use of schools, academies, and colleges. Its use will be confined to the first named, or at least to institutions where the rudiments of chemistry are taught. The work is divided into three parts, — theoretical, descriptive or experimental, and organic, — and the arrangement is in most respects good. In the first part the fundamental laws are clearly and concisely stated, and present the subject in a form as well adapted to beginners as we have seen in any text-book. A short description of the different systems of crystallography concludes this portion. In the descriptive part the elements are discussed under the head of non-metals and metals in an order based upon their quantivalence; but the division of the metals into perissad and artiad is not one which most text-books follow. A brief outline is given, in the seventy-five pages of the third part, of the chemistry of the carbon compounds; and the author has succeeded in condensing into this space many important facts; there are, however, several erroneous statements and a general lack of completeness. The division of the carbon compounds into single link, double link, etc., is simply investing an old classification with a new name, and there is no gain in point of clearness.

A large portion of the book, nearly one-fourth, is repetition in the form of a syllabus and questions for review, at the end of each chapter, and, at the close of the book, questions for examination. This seems to be for the purpose of aid, in case the teacher should have had insufficient training in the subject. Indeed, so great is the help afforded, that with it any one with little or no knowledge of chemistry could assume the instruction of a class. We cannot but deplore the introduction of such a system of teaching at a time when it is all-important that chemistry should be scientifically taught in our elementary schools. Instruction in chemistry, to be thorough, should depend upon the teacher, and not upon the text-book. Only a good instructor can impress upon a beginner the necessity for observation, which is the prime requisite for successful work; and a text-book intended to be crammed tends to destroy the sense of observation. The space devoted to this system could have been profitably devoted to increasing the number of experiments and illustrations of experiments; which last are few and illy executed, and often do not show the best method of conducting the experiment. We object to the use of the Fahrenheit scale and English measures as causing a needless confusion, inasmuch as the centigrade scale and metric system are the accepted scientific notation.

BESANT'S HYDROMECHANICS.

A treatise on hydromechanics. Part i., hydrostatics. By W. H. BESANT, F.R.S., mathematical lecturer of St. John's college, Cambridge. 4th ed. *Deighton Bell & Co.*, 1883. 288 p. 8°.

THIS is "a reproduction, with considerable alterations and additions, of the first part of a treatise on hydrostatics and hydrokinetics, the third edition of which was published in 1877," and is intended as a text-book upon this subject, for those preparing for the mathematical tripos examinations at Cambridge, England. The principal heads treated are, the general conditions of fluid equilibrium; surfaces ot equal pressure; resultant pressures; the equilibrium, stability, and oscillations of a floating body (metacenter); the pressure of the atmosphere; the tension of flexible surfaces, and their relation to capillary phenomena; and, finally, the figure of equilibrium of a mass of rotating fluid, acted on by the mutual attraction of its parts. This work requires, as do most of the Cambridge mathematical text-books, that the reader shall have perfect facility in the employment of the differential and integral calculus. There is a plentiful list of examples, selected from previous examination papers, at the end of each chapter. It is perhaps superfluous to speak of the important place which the subject of hydromechanics has occupied in modern mathematical physics since the labors of Helmholtz, Maxwell, and Thomson, in reducing the mathematical treatment of electricity and magnetism to that of the motion of incompressible fluids. This volume is put forth as an introduction to the discussion of fluid motion or hydrokinetics, of which the elements will be given in part ii., which the author hopes to have in readiness early in 1884.

It is a matter of great regret that the state of mathematical training among our colleges is of such elementary character, that there are comparatively few of them where the excellent text-books of this grade can be profitably used by the undergraduates.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

American philosophical society.

The Proceedings of the society, vol. xxi., No. 114, from April to December, 1883, to be distributed to the members and correspondents of the society in January, contains: 1. A memoir on the migration of the Tutelo tribe of Indians, by Horatio Hale (with a map); 2. Medieval sermon-books, etc., by Prof. I. F. Crane of Cornell university; 3. The latitude of Haverford college, by Isaac Sharpless; 4. A crinoid with movable spines, by H. S. Williams (with a plate); 5. The *rôle* of parasitic photophytes, by W. N. Lockington; 6. The reversion of series, and its application to the solution of numerical equations, by J. G. Hagen, S.J.; 7. The conversion of chlorine into hydrochloric acid in the deposition of gold from its solutions by charcoal; 8. A brief account of the more important public collections of American archeology in the United States, by Henry Phillips, jun.; 9. Photodynamic notes, No. viii., by Pliny E. Chase; 10. Introduction to a study of the North-American Noctuidae, by A. R. Grote; 11. Revision of the Lysiopetalidae, by A. S. Packard, jun.; 12. The Perry county fault, by E. W. Claypole; 13. Seeds sprouting in ice, by Joseph Lesley; 14. A relic of the native flora of Pennsylvania, by E. W. Claypole; 15. The Portage rocks in Perry county, by the same; 16. The genus Rensselaeria, by the same; 17. A large Catskill crustacean, by the same (with a plate); 18. Obituary notice of Henry Seybert, by Monclure Robinson; 19. The zone of asteroids and ring of Saturn, by Daniel Kirkwood; 20. Obituary notice of Dr. John F. Meigs, by Dr. William Pepper; 21. Kintze's fire-damp indicator, by Charles A. Ashburner; 22. Obituary notice of Oswald Heer, by Leo Lesquereux; 23. Obituary notice of Dr. John L. LeConte, by Dr. George H. Horn; 24. Aerial ships, by Russell Thayer, C.E.; 25. Section of Chemung rocks at Le Roy, Bradford county, Penn., by A. T. Lilley; 26. Distribution of Loup Fork formation in New Mexico, by E. D. Cope; 27. Second addition to the knowledge of the Puerco epoch, by the same; 28. The trituberculate type of tooth in the mammalia, by the same; 29. Delaney's synchronous multiplex telegraph, by Edwin J. Houston; 30. The microscopic examination of timber with regard to its strength, by Frank M. Day (with a plate). Several papers requiring illustrations are left over to be published in No. 115, as it is the custom of the society to publish its two annual numbers of its proceedings as nearly on the 1st of January and June as possible. No. 114 includes pp. 1 to 350 of the current vol. xxi.

The society has also published, as part i. of vol. xvi. of its transactions, a Dictionary of Egyptian hieroglyphics, by Edward Y. McCauley, U.S.N. (240 p., 4°), printed from relief-plates photographed from Commodore McCauley's manuscript.

The society is printing the last pages of its library catalogue, the fourth and last part of which will be published in February or March. The whole catalogue (three parts of which have been distributed in previous years) will make about fifteen hundred pages octavo. There will be subsequently published an alphabetical index of author's names, and a supplement of books received since a certain date.

The society is also printing, as a volume of about five hundred pages octavo, a succinct transcript of its minutes from 1744 to 1837, made by the secretary in 1882. Its proceedings were first published in 1838, and subsequently in one series up to the current No. 114. The possible destruction of the minute-books, by fire or otherwise, has always been a cause of anxiety. When this volume from 1744 to 1837 is printed, a complete history of the society will be secured. Already proof-reading has reached p. 288 (minutes of 1800), and the volume will probably be published in May next.

Cincinnati society of natural history.

Jan. 8. — Dr. Walter A. Dun read a paper on some recent explorations of mounds in the Scioto valley. The paper gave a detailed description of the mound, a large one, its dimensions being thirty-three feet in height, and a hundred and fifteen feet in diameter. The shaft sunk from the top showed several intrusive burials, and that the mound was constructed of successive layers of sand and clay. At the depth of twenty-five feet a vault constructed of logs was found, in which was a large quantity of root-like fibres, with a skeleton in a fair state of preservation. The skull was saved almost entire, and was described in detail by the doctor, who found it to compare closely with the figures of mound-builder skulls in Squier and Davis's 'Monuments,' and Morton's 'Crania americana.' A number of flint arrow-points, shell beads, and a small octagonal piece of sandstone, were also found in the 'vault.' The vault was eight feet high, five feet and a half long, and four feet wide.

The discovery of an authentic mound-builder's skull was regarded as important, and worthy of record. Dr. Dun also read a detailed description of the teeth and jaw of the skull, prepared at his request by Dr. E. G. Betty. Mr. Joseph F. James remarked that a skull found near Memphis, Tenn., associated with some earthen pots bearing dates of 1654–1708, showed the same remarkable flattening of the occipital region shown in Dr. Dun's specimen.

Mr. J. R. Skinner said that he had lately observed that the symbol of the Aztec god, Itzcoatl (), was the same as a marking upon what is known as the Richardson tablet from Wilmington, O.

Society of arts, Massachusetts institute of technology.

Dec. 27. — Mr. John Ritchie, jun., exhibited and explained a model showing the orbit of the comet of 1812, and Mr. J. R. Robinson described his safety-seam steam-boiler. Mr. Robinson's first invention consisted in reaming out the edges of the rivet-holes in the plates on the inside, or where they come in contact, making them conical for a short distance.

When the rivet is put in, it flows out and fills the space thus formed, becoming, therefore, of greater diameter at the middle than at the ends. When the plates are under tension, the rivet will cant, and the ring-like projection around its centre will pry the plates slightly apart, as Mr. Robinson has satisfactorily demonstrated by experiment, thus allowing the escape of the steam in the case of a boiler, and avoiding an explosion; while, on the removal of the stress, the plates come tightly together again, provided the strain on the rivet were adapted not to exceed its elastic limit. The simple conical reaming-out of the holes, however, was not found to be just what was wanted; as it was possible for the metal of the rivet to be forced out between the plates farther than was wished, preventing their coming together tightly at all, even at first. To obviate this objection was the object of Mr. Robinson's second invention, which consists in cutting out a small hemispherical ring in each plate around the rivet-hole, and reaming out to this ring, so that when the plates are put together the conical enlargement of the hole at the centre is followed by a chamber in the shape of a circular ring; and into this 'relief-chamber' the metal of the rivet can flow out. But, as the amount of metal to be so forced out is never to be great enough to fill this chamber, the plates are brought closely together in the process of riveting, while the action of the rivet under great pressures is the same as has been described.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Geology. — Prof. L. C. Johnson reports that the Ripley group of the cretaceous in Alabama and Mississippi presents some curious and interesting features. It is an interrupted formation. Beginning in Mississippi, north-west of the Corinth group, it runs southward one hundred miles, and there runs out. It also appears in the extreme south-east, on the Chattahoochee River, in Barbour county, Ala., and extends westward to a point undetermined, but not reaching the Alabama River. It also occurs as a wedge between the elder cretaceous and the great lignitic A.

Chemistry. — The chemical division of the survey is at work on analyses of alkaline and saline waters from the Great Basin, collected by Mr. G. K. Gilbert and I. C. Russell; notably, the waters of Humboldt River, Walker Lake, Pyramid Lake, Mono Lake, Lake Tahoe, etc. There are also on hand, awaiting analysis, specimens of water from Helena hot-springs, Montana, from warm springs of Emigrant Gulch and from Livingston, in the Yellowstone valley, in Montana, collected by Dr. A. C. Peale during the past summer.

Prof. F. W. Clarke is also engaged upon a complete revision of his specific-gravity tables, which form part i. of the Smithsonian Constants of nature.

A white porcelain-like clay from the Detroit coppermine, near Mono Lake, California, proves, upon analysis by Professor Clarke, to be a very pure halloysite, thus adding another to the list of localities for this mineral.

A mineral sent in from Big Springs, Texas, said to occur there in abundance, proves to be a mixture of gypsum and sulphur, the latter predominating.

Miscellaneous. — The topographical parties have all returned to the office in Washington. The total area surveyed during the season amounts to fifty-one thousand square miles.

Early in September, while attempting the ascent of the 'Three Sisters,' a group of peaks in the Cascade range in Oregon, Ensign Hayden, who accompanied Mr. J. S. Diller in his reconnaissance of the Cascade range, was thrown from the edge of a cliff by the crumbling of the rocks, and seriously injured. As a result of the accident, he has recently had to suffer an amputation of one of his legs. The operation was performed at Portland, Or. Mr. Diller, in rescuing Mr. Hayden, was also hurt, but not seriously, by the falling rocks.

The library of the survey has just secured a copy of the 'Codex Cortesianus,' by Léon de Rosny, of which eighty copies have just been published in Paris (1883). The line of Mexican manuscripts for the study of the Maya alphabet, in the library of the survey, is now complete, with the exception of a manuscript in the possession of Señor D. Alfredo Chavero, in the city of Mexico. It is entitled 'A MS. explanation in Italian of the Codex Borgiana, by Fabregat.' Steps are being taken to secure a copy of it for publication.

The manuscript for two survey bulletins has been sent to the government printer: viz., No. 3, 'On the fossil faunas of the upper Devonian, along the meridian of 76° 30′, from Tompkins county, N.Y., to Bradford county, Penn.,' by H. S. Williams; and No. 4, 'Lists of elevations,' by Henry Gannett.

Five volumes of the monographic publications of the Hayden survey are still unpublished. The general direction of the completion and publication of these quarto reports has been put in charge of the director of the geological survey. Two of these volumes are almost wholly in type, and will be issued shortly.

The London *Graphic* of Nov. 17 has a double-page illustration of the Transept in the Kaibab Grand Cañon of Colorado River, which is an engraving reduced from plate xviii. of the atlas accompanying Capt. Dutton's 'Tertiary history of the Grand Cañon' (vol. ii. of the monographs of the survey).

PUBLIC AND PRIVATE INSTITUTIONS.

Massachusetts institute of technology.

The new photographic laboratory. — Since the recent invention of the gelatine dry-plate, photogra-

phy has been advancing rapidly in the number of its applications to the arts and to the industrial and applied sciences. The Institute of technology has not been behindhand in recognizing this fact; and in the new building, now nearly completed, a large room in the south-west corner of the basement has been appropriated to the establishment of a photographic laboratory, perhaps the first ever constructed in connection with a scientific institution, for the especial instruction of students in photographic manipulations, and for purposes of original research, in this most interesting department of applied science.

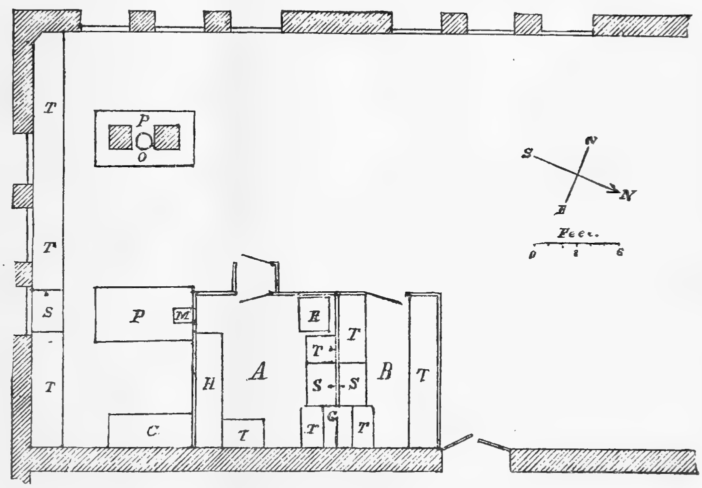
The following plan shows the arrangement of a portion of the room, which measures sixty feet in length by thirty in breadth.

P, *P*, are two brick piers surmounted by solid stone slabs, and constructed on foundations entirely independent of the building, in order to avoid all possibility of shock or jarring. Upon one of these, brick columns are built, which pass through the ceiling into the 'fourth-year' physical laboratory, which occupies the room above. The other one reaches a height of three feet, and forms a solid foundation for the support of a heliostat, microscope, spectroscope, or other instrument. *A* and *B* are the two dark rooms, entirely separated from one another by a partition, and by a wooden frame containing the gas-jet *G*, which is partially surrounded on three sides by sheets of Carbutt's ruby paper. *S*, *S*, *S*, are soapstone sinks, the two former of which are supplied with vacuum pipes for the purpose of accelerating filtration. *T*, *T*, *T*, represent tables, the one in the window being used for printing purposes, while the others are to support photographic apparatus and accessories. Gas will be introduced into the dark rooms over the sinks for lighting when they are not in photographic use. It will also be supplied at the small square table in the larger dark room for heating purposes, such as boiling emulsions. *C* is a case of shelves and drawers to contain books, paper, and apparatus. *H* is a series of shelves for the storage of plates and chemicals. *M* is a square wooden box resting on the pier, but connecting by an aperture measuring ten inches by twelve with the interior of the larger dark room. This is to contain a microscope for researches in photomicrography, the light coming from the heliostat through a small hole in the box. The image is thence projected upon a screen placed inside the dark room, where the operator can examine it at his leisure. This screen is supported upon the focusing table *R*, which rolls upon a track, and may be placed at any distance less than three metres (ten feet) from the aperture at *M*. The dark room is thus converted into a large camera, inside of which the operator stands and exposes his plate, while he may at the same time be developing another one previously taken. The greatest efficiency, convenience, and economy of time are thus combined by this arrangement.

Both dark rooms are constantly ventilated by a system of double walls, with openings at the ceiling and floor, whilst the draught of the lamp *G* is utilized to increase the circulation. The light thus becomes a source of health, instead of vitiating the atmosphere, as is the case in most dark rooms. The room *A* is provided with double doors, so that the operator may leave the room at any time during an exposure, without the slightest fear that even the most sensitive plate could possibly be fogged by a chance ray of stray light. This arrangement, though convenient at all times, will be particularly so when working with long exposures of two or three hours in length; and, indeed, it is only by some such arrangement that these exposures become possible. Besides the aperture at *M*, a smaller one six inches square is made through the wall of the dark room. This is intended for spectroscopic and astronomical work. Either window may be closed by a sliding shutter when the other is in use.

Between the brick columns of the pier *P* is placed a shelf, on which will be kept a large carboy containing a saturated solution of potassium oxalate, from which the developer bottles may constantly be replenished by means of a siphon permanently attached. We thus avoid the trouble of continually making up fresh solutions, and at the same time do not require to have the developer bottles inconveniently large. The hyposulphite-of-soda and sulphate-of-iron solutions will be similarly provided for, the latter being covered with a thin film of oil to prevent oxidation from the air.

The routine work of the department will be arranged somewhat as follows. Only those students at the institute taking the courses in mechanical and electrical engineering, architecture, chemistry, natural history, physics, and the general courses, will



PLAN OF PHOTOGRAPHIC LABORATORY.

receive photographic instruction. Each of them will be required to perform at least ten hours' work, divided into five days of two hours each.

Some experience has already been attained in teaching photography upon a small scale (last year this department had sixteen students); but, should the present venture prove a successful one, it is hoped it may be adopted by other colleges, and that photography may in the future come to be regarded as a necessary portion of every professional man's college education. WM. H. PICKERING.

NOTES AND NEWS.

IT is generally known that Williams college secured a table early last year at Dohrn's international station at Naples. The table may be occupied by any American scientific scholar recommended by the faculty of the college. Any one wishing to use the table should send an application to President Carter, and the application should be accompanied by evidence of ability to improve the unrivalled facilities for original investigation afforded at Naples.

Each occupant is expected, soon after his return, to give a brief course of lectures at Williamstown on some subject connected with zoölogical work. The lectures by the first occupant, Dr. Edmund B. Wilson, formerly fellow in the Johns Hopkins university, are to be given in January and February.

In assigning the table, any regular graduate of Williams college will be recognized as entitled to precedence; but, in case no graduate of the college worthy of the honor is an applicant for the position, the appointment will be determined as far as possible by distinction already attained. The successful applicant will be at once informed of his appointment, and his name communicated to *Science* and the *American naturalist* for publication.

The table is at present used by Dr. Samuel F. Clarke, professor of natural history in Williams college, but will probably be vacated on or before April 1, 1884.

— The department of the interior, at the request of the Italian government, has issued a circular, calling attention to the Bufalini prize of five thousand lire for an essay on the experimental method in science, and giving the conditions under which writers must compete. The character of the essay may be gathered from the following extract from Bufalini's will: —

"Let the learned consider, therefore, whether they can pardon me for daring to appeal to them ten years after my death, and after that every twenty years, to solve the following problem: the necessity of the experimental method in arriving at the truth and the relation of all the sciences being assumed, it is required to demonstrate in a first part how far the said method is to be used in every scientific argument, and, in a second part, to what extent each of the sciences has availed itself thereof during the time that has elapsed since the last competition for a prize, and how they may be brought to a more faithful and complete observance of the method itself."

— According to *Nature*, a meeting was recently held in Sheffield for the purpose of carrying out, in connection with Firth college, a proposed technical department having reference to the trade of the district. Among those who spoke were Mr. Mundella and Dr. Sorby; and all agreed as to the desirability of establishing such a department, and the necessity of educating the captains as well as the privates of industry in the principles of their crafts. For that, Mr. Mundella insisted, is the true technical education. He gave the experience of a friend who has just been visiting the United States, and inspected the means for technical education existing there. The distinct conclusion was, "that there is more skill and intelligence in American industrial pursuits than there is in our English industrial pursuits."

— At the meeting of the Institution of civil engineers, Nov. 27, the paper read was on 'The new Eddystone lighthouse,' by Mr. William Tregarthen Douglass.

The necessity for the construction of a new lighthouse on the Eddystone rocks had arisen in consequence of the faulty state of the gneiss rock on which Smeaton's tower was erected, and the frequent eclipsing of the light by heavy seas during stormy weather. The latter defect was of little importance for many years after the erection of Smeaton's lighthouse, when individuality had not been given to coast-lights; but, with the numerous coast and ship lights now visible on the seas surrounding this country, a reliable distinctive character for every coast-light had become a necessity. The tower of the new Eddystone is a concave elliptic frustum, with a diameter of 37 feet at the bottom, standing on a cylindrical base 44 feet in diameter and 22 feet high, the upper surface forming a landing platform 2 feet 6 inches above high water. The cylindrical base prevents in a great measure the rise of heavy seas to the upper part of the tower, and has the further advantage of affording a convenient landing-platform, thus adding considerably to the opportunities of relieving the lighthouse. With the exception of the space occupied by the fresh-water tanks, the tower is solid for 25 feet 6 inches above high-water spring-tides. At the top of the solid portion the wall is 8 feet 6 inches thick, diminishing to 2 feet 3 inches in the thinnest part of the service-room. All the stones are dovetailed both horizontally and vertically, as at the Wolf Rock lighthouse. Each stone of the foundation-courses was sunk to a depth of not less than 1 foot below the surface of the surrounding rock, and was further secured by two Muntz-metal bolts 1½ inches in diameter, passing through the stone and 9 inches into the rock below, the top and bottom of each stone being fox-wedged. The tower contains nine rooms, the seven uppermost having a diameter of 14 feet and a height of 10 feet. These rooms are fitted up for the accommodation of the light-keepers and the stores necessary for the efficient maintenance of the lights. They are rendered as far as possible fireproof, the floors being of granite covered with slate. The stairs and partitions are of iron, and the windows and shutters of gun-metal. The oil-rooms contain eighteen wrought-iron cisterns capable of storing 4,300 gallons of oil; and the water-tanks hold, when full, 4,700 gallons. The masonry consists of 2,171 stones, containing 62,133 cubic feet of granite, or 4,668 tons. The focal plane of the up-

per light is 133 feet above high water, its nautical range is 17½ miles, and in clear weather it overlaps the beam of the electric lights from the Lizard Point. The lantern is of the cylindrical helically-framed type adopted by the Trinity House. The light is derived from two six-wick 'Douglass' burners, the illuminant being colza-oil. With a clear atmosphere, and the light of the Plymouth breakwater lighthouse (10 miles distant) distinctly visible, the lower burner only is worked at its minimum intensity of 450 candles, giving an intensity of the flashes of the optical apparatus of 37,800 candles; but, whenever the atmosphere is so thick as to impair the visibility of the breakwater-light, the full power of two burners is put in action, with the aggregate intensity of 1,900 candles for the lamps, and an intensity of the optical apparatus of 159,600 candles. This intensity is about 23.3 times greater than that of the fixed light latterly exhibited from Smeaton's tower, and about 3,282 times that of the light first exhibited in the tower from tallow candles. The new tower was built at a distance of 130 feet from Smeaton's lighthouse, a large portion of the foundation being laid below the level of low-water spring-tides. The estimate for the work was £78,000, and the cost £59,255. The first landing at the rock was made in July, 1878, and the work was carried on until December. Around the foundation of the base of the tower a strong coffer-dam of brick and Roman cement was built for getting in the foundations. By June, 1879, the work was sufficiently advanced for the stones to be laid in the lower courses, and every thing was arranged for H.R.H. the Duke of Edinburgh to lay the foundation-stone on the 12th of the month; but, the weather being stormy, the ceremony was postponed until the 19th of August. On the 17th of July, 1880, the cylindrical base was completed, and the 38th course by the early part of November. On the 1st of June, 1881, the Duke of Edinburgh, when passing up the Channel in H.M.S. Lively, landed at the rock, and laid the last stone of the tower. On the 18th of May, 1882, the Duke of Edinburgh completed the work by lighting the lamps and formally opening the lighthouse. The edifice was thus erected and fitted up within four years of its commencement, and one year under the time estimated. The whole of the stones, averaging more than 2 tons each, were landed and hoisted direct into the work from the deck of the steam-tender Hercules, by a chain-fall working between an iron crane fixed at the centre of the tower, and a steam-winch on the deck of the Hercules, which was moored at a distance of 30 fathoms from the rock.

The town council and inhabitants of Plymouth having expressed a desire that Smeaton's lighthouse should be re-erected on Plymouth Hoe, in lieu of the Trinity House sea-mark thereat, the Trinity House made over to the authorities at Plymouth the lantern and four rooms of the tower. After the removal of the structure to the floor of the lower room, the entrance-doorway, and well-staircase leading from it to the lower room, were filled in with masonry, and an iron mast was fixed at the centre of the top of the frustum.

— The U. S. naval institute offers a prize of a gold medal, one hundred dollars, and a life membership, to the writer of the best essay offered on the subject of 'The best method for the reconstruction and increase of the navy.' The judges selected to adjudge the prize are Dr. D. C. Gilman, Admiral C. R. P. Rodgers, Senator J. R. Hawley.

— E. & F. N. Spon announce the publication at an early date of a book on 'Sorghum, its culture and manufacture economically considered,' by Peter Collier; also 'Electricity, magnetism, and electro-telegraphy,' by D. T. Lockwood.

— Professor Gustavus Hinrichs, director of the Iowa weather-service, has again issued an attractive annual pamphlet, entitled this year 'The seasons in Iowa, and a calendar for 1884,' with appropriate illustrations, and much valuable meteorological information. The notable weather features of the several months are given in detail; so that observers may judge at any time whether an occurrence is normal and probably to be continued, or abnormal and likely soon to disappear. The chief peculiarity of the climate is its variability, common to interior stations on the track of frequent cyclonic storms, and of which several striking examples are given; and there is found to be much probability of a cold snap late in January, a snow-storm at the close of April, a cold spell in May, tornadoes in June, squalls in July, heavy local rains in August, and frost early in September. Since 1875, tornadoes have occurred in Iowa on the following dates: April 8, 18, **21**, 23; May 9, 13, 18, 19; June 1, 4, **9**, **11**, 12, 14, **17**, 24; July 2; Oct. 8, 15, 28, 30 (the more severe ones in bold type). June is the month most disturbed by these storms; and directly after it a three-month period, July 3 to Oct. 8, has no record of tornadoes. It is said that the danger from tornadoes in Iowa has been greatly exaggerated. The rainfall maps for every month and for the year are repeated from last year. Precipitation is almost three times as great in summer as in winter. Professor Hinrichs hopes next year to illustrate his annual from home sources exclusively, and asks for sketches and photographs of halos, hail stones, destructive effect of wind and lightning, meteors, cloud-forms, or any other phenomena. Drawings of Iowa scenery, as well as detailed maps of storms, hail, and floods, will all be welcome. We wish the director success in his excellent work.

— The publications of the census office so long expected are now being issued in rapid succession by the Government printing-office. Thus far, three quarto volumes, besides the compendium, have appeared, and several others are very near completion. The three which have been issued are those upon population, manufactures, and agriculture. The first, which saw the light some two months ago, comprises 'Population, part 1,' as issued by the census office a year and a half ago, with, as additions, the tables relating to race, nativity, age, sex, parentage, occupations, illiteracy, the defective, dependent, and delinquent classes, and the newspaper and periodical press. The tabular matter is preceded by a somewhat full discus-

sion of the progress and movement of population, which is illustrated by numerous colored charts relating to the progress of settlement, and the distribution of the different elements of the population. Other subjects, such as inter-state migration, immigration and nativity of the population, and occupations, are ably discussed by the late superintendent, Gen. Walker, in remarks introductory to the tables relating to these subjects. The volume is a bulky one, contianing, with its full index, 1,050 pages. It contains, also, forty-two colored maps, of which twenty-eight are double-page maps, and thirty other full-page illustrations.

The volume upon manufactures, which has but recently appeared, is an equally bulky tome, comprising 1,248 pages. The opening discussion, by Gen. Walker, is brief, comprising but thirty-five pages; and, while it is suggestive rather than exhaustive, it skims the cream from the whole body of statistics. The tables present: 1°. General statistics regarding manufactures, by states and territories, in 1880, 1870, 1860, and 1850; 2°. The statistics for the whole country, of certain specified industries, some three hundred and fifty in number; 3°. Similar statistics for each state and territory; 4°. General statistics by counties; 5°. Statistics regarding selected branches of manufactures by counties; 6°. The manufactures of a hundred leading cities; and 7°. Special statistics regarding certain leading industries. The statistical portion of the volume occupies four hundred and seventy-six pages. The report of Mr. Hollerith upon 'Power' consists of tables, showing by states the amount of steam and of water power in use, and also the power applied to certain leading industries in the several states. The statistics are prefaced by a few pages of discussion, in which the leading points are brought out. The report is accompanied by four colored charts of the eastern part of the United States, showing, by shades of color, the total power in use, the steam-power, and the water-power, each in proportion to area, and the local excess of steam and of water power. There are also three sheets of diagrams, illustrating the proportions of power in different industries and in the several states and territories. In his able treatise upon the Factory system of the country, Col. Wright sketches the origin and history of that system; treats of its evil effects, both moral and physical, particularly upon women and children, of its influence upon wages, prices, and production; and summarizes the legislation of the several states in regard to factory operatives. To the houses of factory operatives he devotes much attention, illustrating his text with plans and elevations of many houses for operatives, selected from foreign and American examples. This paper is a very instructive one, both economically and socially. The report of Mr. Fitch, upon Interchangeable mechanism, treats of the manufacture of fire-arms, ammunition, sewing-machines, locomotives, watches, clocks, and agricultural implements. He sketches the history and progress of these branches of manufacture in this country, and details the most recent improvements. This report, as well as that by the same author upon hardware and cutlery, is fully illustrated with cuts. The report upon Iron and steel production, by James M. Swank, secretary of the American iron and steel association, is here reprinted. It was first issued by the census office as a separate publication, being the first complete report published by that office. Mr. Swank precedes the statistics of production by a very full discussion, and closes the report with an extremely interesting and valuable history of the iron and steel industry, not only in this country, but in the civilized world; beginning with Tubal Cain, in the seventh generation after Adam. The report is illustrated with six double-page charts, showing the iron-producing regions of the country, and the production, by counties, of pig-iron, rolled iron, wrought-iron blooms, and steel. The report upon Silk manufacture, by Mr. Wyckoff, consists of a summary of its history, and a very full sketch of its present condition in this country. That upon Cotton manufacture, by Mr. Atkinson, is extremely brief, comprising only sixteen pages: it opens with a summary of the cotton-producing countries of the globe, the sources of supply of the staple, and goes on to discuss the methods of manufacture, and the relative qualities of the product of this and European countries, and the facilities offered by different parts of this country for this industry. The report of Mr. Bond consists entirely of statistics relating to the industry of wool manufactures, prefaced by a few introductory remarks. The report upon Chemical products treats of the production of soda, manufactured manures, phosphates, sulphur and sulphuric acid, potassium bichromate, potash, phosphorus, borax, bromine, nitro-glycerine, acetate of lime and salt. The volume closes with Mr. Weeks's report upon Glass manufacture. In addition to full statistics regarding this industry, Mr. Weeks summarizes and discusses the statistics fully. This portion of the report is followed by a treatise upon glass, the materials used in its manufacture, and the methods employed both in manufacture and in working. The report closes with a history of the industry from the earliest historic times. An admirably full and complete general index is given, in addition to the indices to the several reports. Probably with a view to a separate publication of each special report, each is paged by itself on the top, while at the bottom the paging runs consecutively through the volume.

— S. E. Cassino & Co. desire us to state that they have bought the interest of Estes & Lauriat in the 'Standard natural history,' and are now the sole publishers of that work.

Mr. J. H. Emerton, whose name was given as a contributor to this work, writes that he is only so in so far as a part of the chapter on spiders is quoted from what he had published elsewhere.

— *La Nature*, Dec. 15, 1883, apologizes for an error in stating that Mr. Ferry crossed the English Channel on the water-tricycle figured in *Science*, Dec. 14, and gives illustrations of the tricycle, convertible into a boat, in which the passage was actually made.

SCIENCE.

FRIDAY, JANUARY 25, 1884.

COMMENT AND CRITICISM.

Mr. A. Graham Bell's recent communication to the Washington philosophical society, discussing various common fallacies as to the dumbness of deaf children, is a clear and convincing presentation of the arguments for teaching deaf children with no defects in their vocal organs to speak, though they cannot learn as other children do, being unable to hear. To teach lip-reading is certainly practicable in many such cases, if not in all; and therefore it would seem that the attempt ought to be made in every case, to the exclusion of a purely conventional language of signs. Mr. Bell points out the real nature of the problem and its difficulties, indicating, among other things, the importance of the context to the deaf lip-reader in distinguishing words which look alike to his eye, such as *pat*, *bat*, *mat*, because he cannot see the workings of all the organs of speech, and laying emphasis on the fact that even very imperfect speech, if intelligible, is far better than no speech at all.

After reading his communication and the discussion which followed, especially his answer to objections and to arguments for the use of signs in teaching the deaf, we must give full assent to all the essentials of his arguments. Any student of linguistic science realizing the importance of a clear conception of the nature of language, and the value of careful phonetic analysis, will find this paper of interest, and must hope for the spread of such views as those here expressed, in the interest of his own studies as well as of the deaf-mutes, who may yet be taught to speak.

There is an entertaining field for some linguistic geographer to cultivate in this country by mapping out the distribution of the various kinds of town, county, river, and other names according to their origin and derivation. The great bulk of newer names has no significance in this regard, being purely local, personal, and commonplace; but places of older date often give an interesting clew to the former homes of their first settlers. Distinctively English names have but a slight penetration beyond the Atlantic coast, except in Canada. The French follow a well-marked line up the St. Lawrence and down the Mississippi. Dutch and German names give local color to the Hudson valley and parts of eastern Pennsylvania; and the Spanish have a broad occurrence in the far south-west. Indian names occur everywhere, from the euphonious Minnesota to the doubtful Tuscaloosa and the abrupt Oshkosh. The proper sorting-out of these last would require a rarer knowledge, as it would give more valuable results than the rest of the work; but all might be graphically shown with great clearness.

The hydrographic office of the U. S. navy department has issued the Pilot chart of the North Atlantic for January, on which are given the latest reported positions of floating wrecks. The number of such wrecks which were reported as seen from Nov. 22 to Dec. 25, and of which the positions are charted, is twenty-two. Nine of them were along the eastern coast of the United States, from Maine to Cape Hatteras; seven were on the Atlantic, in the track of vessels going from the United States to England; two were near the West Indies; and three off the coast of Spain. Some months ago the more or less impracticable suggestion was made, of employing naval vessels to chase these dangerous obstructions, and blow them to pieces. The navy department has done good work in locating their positions; but, on account of the winds and ocean-currents, the results can only have value for a short time. It is desirable that some

way should be invented of doing away with this additional danger of ocean travel.

It is not uncommon to hear complaints of the methods of teaching geography in our lower schools. The faults most frequently mentioned are, that the beginning is not made properly; that there are too many lists of places committed to memory; and that the teaching is too lifeless, and is not made real enough by illustration and description apart from the text-book. The first error can be easily corrected by adopting the German method of instruction, where, instead of beginning with the definitions of meridians and parallels, that are so often found misplaced on the opening pages of our text-books, the pupils first study the arrangement of the schoolroom, then of the playground, next the geography of the town and of the surrounding country, and thus learn the meaning of the maps from which they afterwards study about the more distant parts of the world.

But this does not go very far. After laying the proper foundation, is there any way of learning geography, except by committing to memory the names and relative positions of the many mountains, rivers, capes, bays, lakes, cities, and towns, that give features to the earth? Detail may, of course, be carried too far, if a precise knowledge of distant, and to us unimportant, countries be required; but for the average scholar of this country, who should become well acquainted with the geography of North America and Europe, there is no easy path, no royal road, over the broad, rough field of fact that he must cross. We fancy, therefore, that the second criticism touches, not a fault, but a difficulty inherent in the study. Names and positions of places must be learned; but, as books of moderate cost can give very little more than the barest mention of them, the study is apt to become lifeless, and to degenerate into the learning of dull words from a dead map, unless the teacher averts this unfortunately common result, and enlivens the work by instruction beyond the text-book. This, however, is more than we have a right to expect from the overworked and underpaid teachers in the lower schools, for it is no easy task. It demands much reading in many books; it requires illustration by numerous maps, photographs, and diagrams, far beyond the reach not only of the teacher, but of the school board as well. In short, the desirable, the ideal teaching of even so commonplace a subject as elementary geography is an expensive art, requiring much study, high skill, and an extensive outfit.

It is now recognized that the successful teaching of chemistry, physics, and natural science, needs that the teachers of these branches shall know them by practical, experimental, observational work. A fair application of the same principle would require that the teacher of geography should have travelled; but how far are we now from so desirable an end! It is safe to say, that, of all the teachers of our common schools, not one-quarter have seen an ocean, a harbor, or a high mountain, and not one-twentieth of them have had any personal acquaintance with the foreign countries that they have to describe. Under these conditions, it is certainly no wonder that the study of geography becomes so often a tiresome exercise of unintelligent memory; and it cannot be otherwise, without a cost that few school boards can allow.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Naval officers and the coast-survey.

In your issue of the 11th you refer editorially to the proposition contained in the report of the secretary of the navy for 1883, to transfer all national work connected with the ocean, and conducted by other departments, to the control of the navy department; and in a subsequent paragraph you make some criticisms upon the character of the work performed by navy officers in the coast-survey. The question as to whether the navy or the treasury department shall control the work, I do not propose to discuss; but I must enter my protest against the assertion in a journal like *Science*, which goes forth to the world as authority, that the "work which these [navy] officers perform is routine, the plans and methods for which have been devised and developed by civilian experts," and to the assertion contained in the phrase, "the present method of employing our superfluous navy, under the intelligent supervision of

civilian experts."— To answer these points in order, I will say, first as a matter of history, that the 'plan' of the coast-survey was compiled over forty years since by a mixed board composed in part of navy officers. This plan was legalized by Congress in 1843–44, and has been mainly in force ever since; though some modifications have necessarily been made by the judgment and experience of the eminent men who have held the offices of superintendent and principal assistants. By the plan referred to, it was made the *legitimate* duty of officers and men of the navy to execute the hydrographic part of the work; and to them has ever since been assigned the bulk of that work, except during the few years when the civil war and the subsequent scarcity of officers made it impossible to do so. That period (i.e., from 1861 to 1871) developed a good many civilian hydrographers who have no superiors in the world, but nearly all of these resumed their more legitimate work upon the return of navy officers to the survey. The *methods* of hydrography are the growth of hundreds of years, and have been contributed to by the seamen of all maritime nations; and, while the inventors of a good many instruments and special methods are known, it would be exceedingly difficult to trace the *system* to its source. The 'tricks of the trade,' so to speak, have been handed down from one to another with gradual improvement, — as a rule, too slow to give any definite point from which that improvement can be shown, though during the forty years of its existence the coast-survey has vastly improved the character of its work; but probably the improvement in its means (i.e., the introduction of steam-propelling power, etc.) deserves a good deal of the credit for improved methods. While civilians have had a share in the development, it is a long way from the fact, to ascribe all to them, as it is to assume that hydrography is a work which does not require skill, judgment, and care. Those who think the last have never worked in intricate waters. The officers engaged upon the coast-survey have been so assigned because it was a part of their regular duty, and not because 'superfluous.' Having had for five years the privilege of nominating the officers to be employed upon the coast-survey, I can speak with some authority. Officers were chosen strictly for their qualifications; and often, had it not been for the great interest taken in the coast-survey by the successive chiefs of the bureau of navigation, the officers selected would not have been spared from other duties. That all work of the coast-survey is supervised by the superintendent, an expert of high order, is an undoubted fact; but his instructions to hydrographers, unless he has some special object in view, simply assign geographical limits, but do not prescribe methods, a general printed manual covering all that is required in the latter. The work, after completion, has of course to pass the rigid scrutiny of the superintendent; but the same is the case with all other work. To this extent the work of navy officers may be said to be 'supervised by civilian experts,' but no farther. In 1873 several navy officers, who without previous experience were ordered to the coast-survey, placed themselves for a short time under the instructions of civil assistants, who had been doing their work for some years; and all of them freely and gratefully acknowledge the assistance they received. I am free to acknowledge obligations of a similar character,— of many a *point* received from my valued civil associates during the Darien Canal expedition of 1870. Nautical surveying has always been taught theoretically at the Naval academy; and as much practice as possible has generally, though not always, been given. Furthermore, nautical surveying and navigation are very near cousins, so that all the instruction needed to make a navigator a surveyor is to give him what I have called the 'tricks of the trade;' and these are being handed down by officers as they have been by their predecessors. EDWARD P. LULL,

Captain U.S. navy, late hydrographic inspector U.S. coast geodetic survey.

[The plan of organization of the coast-survey and the plan of work of the survey are quite different things. It is the duty of the chief of the survey to arrange and supervise the latter. That the scope and character have been extended since its organization in accordance with the views of the chief is beyond question. While from the above letter it might be inferred that the nautical work of the coast-survey is confined to marine surveying in its older sense of locating rocks and shoals, and determining the boundaries of courses of the navigable waters by time-honored methods, yet from the publications of the coast-survey, and from other sources, we had gathered that the study of ocean physics, and of the conformation and character of the ocean bottom, together with the different forms of marine life, had formed, of recent years, an important part of the work of the survey, and that it was carried out in accordance with the plans of the chiefs of the survey, and by the methods devised and developed by them and by the two Agassizs, Pourtales, Thompson, Milne-Edwards, and many other eminent specialists, modified in minor details by the circumstances of each case.

It is an error to suppose we regard the employment of naval officers in this work unfavorably; for, on the contrary, we think it highly desirable that they should be employed in this routine work of collecting data and material for discussion and study by specialists; and their skill, judgment, and care, their knowledge of organization and discipline, and their close adherence to instructions, render them extremely useful. It is wise, also, that, in the present reduced condition of the navy as to ships, and its overcrowded condition as to officers, the secretary should find employment for this superfluity in the coast-survey, the fish-commission, the geological survey, the national museum, as instructors in our colleges, and as assistants in special researches. Such employment cannot but result in benefit to the navy, and assist in the advancement of science.

Yet we have still to be persuaded that it will promote the efficiency or the economy of the scientific organizations of the government if they are transferred from the supervision of the present expert civilian heads to that of the officers of the navy.]

Italics for scientific names.

I agree with the editorial remarks under this heading in *Science*, No. 49, that the proper mission of italics is for 'emphasis, or as catch-words;' and their use for scientific names of animals and plants is, it seems to me, — contrary to the opinion conveyed editorially, — of great practical utility, especially in indexing, or in searching the pages of an article or memoir for references to particular species that may be under treatment. Italicizing such words makes them 'catch-words,' and gives great facility in discovering incidental reference to species, the eye quickly catching the italicized name, and as quickly recognizing whether it is the one sought. Considering scientific names as 'a simple convenience,' and as having no higher value, their use is so necessary as

a 'handle to facts,' or as names of objects of which we have to speak, it seems desirable to have them so typographically distinguished that their presence on a printed page will quickly catch the eye as guide-posts to the subject of the immediate context.

J. A. ALLEN.

Cambridge, Mass.

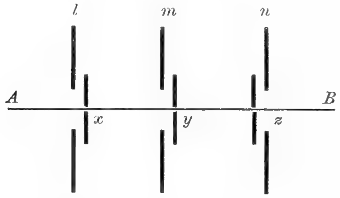
[The editor has yet to be convinced that typography should be moulded to suit the purposes of an indexer.]

Eating horns.

Indians eat the horns of the deer when in the velvet. One day on the Sioux Reservation, in Dakota, a deer was killed near camp, and brought in entire. At sight of it, Pahlani-ote, a Minneconjon of some fifty years, dropped his usual statuesque attitude, knocked off the horns, and, seating himself by the fire, began at the points to eat them, velvet and all, without cooking, as if they were most delicious morsels. The others of the party looked on as if they envied him. They said they always ate them so. S. GARMAN.

Radiant heat.

In a letter to *Science* of Dec. 21, 1883, Dr. Eddy has endeavored to show that I was mistaken in thinking that his proposed arrangement for proving that radiant heat is not subject to the second law of thermodynamics would not work.



I can most easily explain how Dr. Eddy is again mistaken by referring to my diagram which he reproduces in his letter. Dr. Eddy says that *every* time the door z is opened two quantities of heat pass into the region B, one of which had originally come from A, and the other from B. I had assumed that the occasions when it opened to let heat that had come from A pass were different occasions from those when it opened to let that from B pass. I assumed this, because I could see no way of getting the heat that had come from B back again through z in the same direction as it had come out, except by a reflection from the back of y; and of course that required y to be shut at the time of reflection, so that this heat could not reach z at the same time as any heat that had originally come from A. I have been unable to think of any method of getting the heat from A and what had come from B to travel *simultaneously* in the same direction; and I am inclined to think, that, if this were possible, Dr. Eddy's doors, etc., would not be required to enable A to radiate more heat to B than B does to A. This supposed arrangement might, as far as I can see, go on working continuously, returning the heat to B, and simultaneously transmitting that from A; for this seems to me to be what Dr. Eddy postulates as possible.

If the two quantities pass into B through z in two different directions, then two other quantities will escape from B in these two directions, and B will be in exactly the same condition as it would be according to my hypothesis that they passed into B at different times.

Dr. Eddy confesses to being unable to see how to accomplish what he postulates with my arrangement of screens and apertures; and I believe that the only reason he is unable to do so, and imagines that his own proposed whirling tables would do so, is because my arrangement is so much simpler than his, that it is almost impossible to be misled as to where and when the heat comes in and goes out; while, with his arrangement, he has so many holes that it is almost impossible to keep before one's mind all that is supposed to be going on. I cannot see how my simple arrangement is less general than Dr. Eddy's complicated one, as it seems to me that a multiplicity of holes cannot be of any real use, while they produce very serious complication; and, except in the number of holes, I think Dr. Eddy's arrangement only differs from mine in that his supplies a mechanism for opening the apertures, which, of course, has nothing to do with the question. If Dr. Eddy will explain how he manipulates so as "to bring the heat coming from A into a position such that it would be in readiness to pass into B at the same time," *and in the same direction*, "as the heat which originally came from B is returned to B," and does not rest upon the authority of Professor Gibbs that his arrangement does so, then I will agree that he has invented an arrangement by which the second law of thermodynamics may be cheated. GEO. FRAS. FITZGERALD.

40 Trinity college, Dublin,
Jan. 7, 1884.

Professor De Volson Wood makes statements in his letter published in your issue of Jan. 11 which appear to me unsupported by facts. Were your columns open to a lengthy discussion, I should like to show this in detail. Suffice it to say, that in his reference to Mr. Fitzgerald's construction he entirely overlooks the difference between radiant heat, which must be moving along given lines in a determinate direction, and other heat. The heat referred to as 'entangled in the space $m\ n$' is radiant heat alone. I have definitely traced its path, and shown that it does not move as Professor Wood states. Instead of regarding this fact, he has attributed to it the properties of heat as ordinarily existing in matter.

Professor Wood also refers to his papers in the *American engineer*, etc. The only point in that somewhat lengthy and personal discussion upon which I understand Professor Wood to finally insist, he republished in the *Journal of the Franklin institute* for May, 1883. In my reply in the same journal for June, 1883, I showed the fallacy of his objection. So far as I know, Professor Wood has taken no notice of that reply, and now completely ignores it. I may say that the proof he relied upon was of this nature. He proposed a certain construction or process (differing essentially from mine) for dealing with radiant heat, and one which would not accomplish the end sought. He then showed that his construction was a failure, and concluded that mine would therefore fail also, — a method of reasoning which seems to me inconclusive, to say the least. And now Professor Wood says that Mr. Fitzgerald's construction is 'conclusive.' All it is conclusive of is, that it will not accomplish the end which I have proposed: we all agree that it will not. I have shown, however, that my proposed construction differs from both in just those particulars necessary to make it accomplish the end sought.

It is unfortunate that the velocity of radiant heat is such as to render experimental verification a matter of great difficulty. H. T. EDDY.

A NEW VOLCANO ISLAND IN ALASKA.

RECENTLY the newspapers have contained references to the rise of a new volcanic island near Bogosloff Island in the Aleutian chain. Bogosloff itself is believed to be a recent development. Possessing some unpublished material and some sketches bearing on this topic, it has been suggested that a *résumé* of the subject would not be without interest for the readers of *Science*.

The island of Ioanna Bogoslova (St. John, the theologian), or Agáshagok of the Aleuts, is commonly known by the shorter name of 'Bogosloff' to the white residents of the region. Owing to its isolated and remote situation, it has been rarely visited, and hence is less widely known than other modern volcano-islands. It is, however, one of the few instances of the sudden and violent formation of land in the sea which have been witnessed in historic times. It is situated in latitude 53° 58′, and longitude 168° west, approximately some forty-two miles west of the northern corner of Unalashka Island of the Aleutian chain. At the

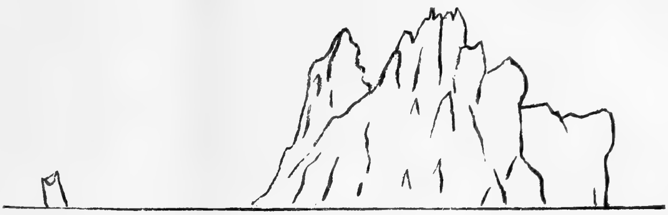
FIG. 1.

NOTE.—'S' is Ship Rock.

time when it was observed by us it formed a sharp serrated ridge, about eight hundred and fifty feet in height, very narrow, the sides meeting above in a very acute angle, where they are broken into a number of inaccessible pinnacles. There is no crater, nor appearance of a crater. The shore-line formed a tolerably regular oval, pointed at the south-east end, having its longitudinal axis trending N. W. ¼ W. and S. E. ¼ E. by compass, and reaching about three-quarters of a nautical mile in length. The shores are mostly precipitous; but at the south-eastern extremity the waves have accumulated a small spit or pointed bit of beach, of talus, on which in perfectly favorable weather a landing may be had. With the least swell a heavy surf is formed here. Seen through a strong glass at a distance of four miles, it appeared of a light pinkish-gray color, devoid of vegetation or water, and covered with myriads of birds. Less than half a mile north and west from the island is a perpendicular square-topped pillar, about one hundred and fifty feet high, called on modern charts 'Ship Rock.' Less than half a mile north and east from the island is a small rock rising only a few feet above the water. North, east, and south, and



S North, 4 miles.

FIG. 2.

especially east-south-east from the point of the island, scattered breakers were observed, extending less than three-quarters of a mile from shore. The crags of the main island afford the most secure refuge to thousands of sea-parrots, puffins, auks, and divers; and sea-lions (Eumetopias Stelleri) often rest on the talus point. It is visited in spring, if weather permits, by native egg-hunters from Unalashka; but in 1873 several years had passed since any one had been able to make a landing at the proper season. My own party attempted it unsuccessfully in 1872 and 1873.

Such was the condition and appearance of the island in 1873. The outline sketches here given are facsimiles of those taken on the spot as we approached the island from the south-west, and passed south of it eastward toward Unalashka. Their proportions were corrected by horizontal and vertical angles. The wind

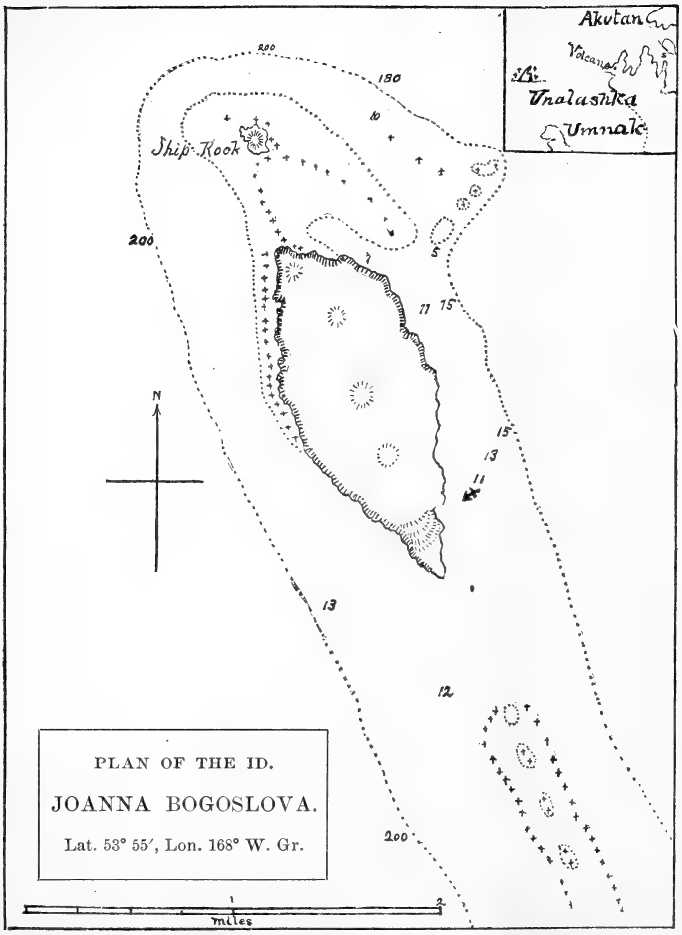
was light; but there was a heavy ground-swell, which broke on the rocks and the little spit at the south-east end, rendering a landing imprac-

ticable. On the line of the supposed reef, which has ornamented the charts for so many years as connecting Bogosloff and Umnak, three miles from the island, we sounded in eight hundred fathoms without touching bottom. With the exception of a small reef near the north-east end of Umnak, and the rocks within a short distance of Bogosloff, there is water more than eight hundred fathoms deep



PLAN FROM KRUSENSTERN'S ATLAS, 1826.

on all sides of the island. The supposed reef was probably taken for granted by those who saw the white water of a tide-rip which eddies southward toward Umnak Pass on the ebb, in the wake of Bogosloff, as we ourselves observed to occur in a small way. Ship Rock is seen on several of the sketches, standing off to the northward. The earliest information in regard to this island is derived from the map of Krenitzin and Levasheff, prepared from surveys made in 1768–69. No reference to it appears in the abstract of their report which has been preserved for us by Coxe; but a little profile surrounded by rocks is represented off the end of Umnak on their chart, which evidently represents the rock which existed before the present peak was raised. A facsimile of this part of their map appears in the corner of the Krusenstern map on this page.

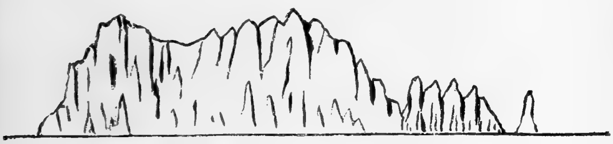
The next information is given by Cook's voyage in 1778, when an elevated rock, like a tower, was seen Oct. 29, at a distance of twelve miles: 'The sea, which ran very high, broke nowhere but against it.' On Cook's chart it is called Ship Rock, but its identity with what is now known as Ship Rock is uncertain; and at that distance there might have been a number of adjacent rocks or breakers not visible.

We learn from Langsdorff, who visited this region from 1804 to 1806, that, previous to the appearance of the present peak of Bogosloff, a rocky islet had long stood in the same situation, which the Aleuts declared from the time of their forefathers had been a notable resort of seals and sea-lions. This could not have been the present Ship Rock, which is a huge perpendicular pillar.

In 1795 the islanders marked a local appearance, as of fog, in the neighborhood of this rock, which did not disperse even when the rest of the atmosphere was perfectly clear. This created much uneasiness, since the natives of Umnak and Unalashka had been used to regard this rock as one of their great sources of food-supply. After a long time, in the spring of 1796, one of the more courageous natives visited the locality, and returned immediately in great terror, saying that the sea all about the rock boiled, and that the supposed fog was the steam arising from it. It was then supposed to have become the abode of evil spirits, and was avoided by every one without exception. The disturbances were accompanied by volcanic activity in the craters of Makushin on Unalashka and others on Umnak Island. The account given by Baranoff and Veniaminoff of what followed may be

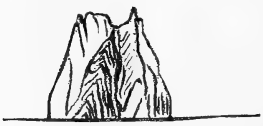
summarized, it being remembered that the island is over thirty miles from the nearest land, and about forty from the nearest habitations on Unalashka.

On the 1st of May (old style), 1796, according to one Kriukoff, then the Russian American company's agent at Unalashka, a storm arose near Umnak, and continued for several days. During this time it was very dark, and low noises resembling thunder were continually heard. By daybreak on the 3d of May the storm ceased, and the sky became clear. Between Unalashka and Umnak, and northward from the latter island, a flame was seen arising from the sea, and smoke was observed for ten days about the same locality. At the end of this time, from Unalashka, a rounded white mass was seen rising out of the sea. During the night, fire arose in the same place, so that objects ten miles off were distinctly visible. An earthquake shook Unalashka, and was accompanied by fearful noises. Stones, or pumice, were thrown from the new volcano as far as Umnak. With sunrise the noises ceased, the fire diminished, and the upraised island was seen as a sharp black crag. It was named after St. John the theologian, though it does not appear for what reason. It did not rise, according to the above account, on his day. A month later it was appreciably higher, and emitted flames constantly. It continued to rise, but steam and smoke took the place of fire. In 1800 the smoking appeared to cease, and in 1804 a party of hunters visited the island. They found the sea warm about it, and the surface, in some places at least, too hot to walk upon, even if the distorted fragments of lava, which formed its base, were accessible to a landing. It was said to be two miles and a half in circumference, and three hundred and fifty feet high.



Pinnacle Island, W. S. W., 10 miles.

FIG. 7.



Pinnacle Island, N. N. W., 6 miles.

FIG. 8.

In 1806 fissures appeared, lined with crystals of sulphur. According to Langsdorff, who saw it in this year,[1] it did not exhibit any special activity, though steam and smoke arose more or less constantly. In this year three baidars visited the island. On the north side soft lava flowed into the sea, and it was too hot to approach closely; but on the southern end a landing was effected. The peak was too sharp and rugged to be ascended, and the rock was very hot. A piece of seal meat suspended in a crevice was thoroughly cooked in a short time. There was no soil nor fresh water.

The only map or survey of Bogosloff and vicinity known by us to exist is that of Krusenstern, published in 1826, a facsimile of which is here given, except that the evidently formal hachuring has been omitted. Since 1823, and up to the present year, the island has remained tranquil, and its form has not changed. The close similarity to our own, of Lütké's profile taken in 1827, confirms this view. The widely differing estimates of its height and area given by Grewingk illustrate the futility of unchecked guessing rather than any change in the island itself; and even the map, which could have had no base-line except one measured by log on the water, though relatively correct, represents, according to our observations, a scale about one-quarter too large, the island being about a mile and a quarter long, instead of a mile and three quarters, as the map gives it.

We have not space here to discuss the detailed process by which our conclusions have been reached, but will briefly state them.

The site of Bogosloff was a low islet or cluster of rocks not identical with the present Ship Rock, and which were long known to the Aleuts, and mapped by Levasheff. In 1795–96 a series of progressive disturbances occurred by which, in May, 1796, a considerable mass of material was upheaved and the major part of the present island formed. The reports of exactly what occurred, as well as the dates assigned, are discrepant and all unsatisfactory, when we recollect the distance from which the alleged observations were made, and that they were not noted down until several years after-

[1] In 'Alaska and its resources,' by an accident in the historical chapter, the item relating to the rising of this volcano from the sea was misplaced ten years, and appears under 1806, though properly dated in the geological chapter. An agent of the census by the name of Petroff, believing apparently that a little imagination would enliven his statistics, and misled by this erroneous date, gives in his report an account of an eye-witness of the phenomenon, 'born in 1797,' and 'who was one of the individuals who first noted' it, and with such terror 'that his trembling knees could scarce carry him back to report!' (H. R. ex. doc. No. 40, p. 19, 1881.)

ward. The reef shown on most charts extended only a short distance from Umnak or Bogosloff, and was never continuous between them.

Other islands of exactly similar origin are to be found in this region, notably Koniúgi and Kasátochi in the western Aleutians, and Pinnacle Island near St. Mathew Island. Of the last, sketches are reproduced here, showing it 'end on' and from the side. It differs from Bogosloff in having the crest deeply channelled; and it has been reported, that within a few years light has been seen in this fissure by navigators passing at night, though there is no record of smoke or lava being ejected.

Of the latest addition to the list of Aleutian volcano-islands, we are not in a position to say much. The facts reported seem in brief to be these: —

During the past season, Bogosloff has been in a state of eruption, as was observed by Capt. Hague, of the steamer Dora, on two occasions, when passing it at a distance of a mile and a half. He describes it as entirely enveloped in smoke and flame, with red-hot lava issuing from its central portion, and great quantities of softer lava running down to the sea. This has continued up to the time of the latest reports. The natives state that the eruption began about six months ago, and has continued in an intermittent manner ever since. Makushin volcano, on Unalashka Island, remained quiet. On the 16th of October a dark cloud of indescribable appearance covered the sky northward from Unalashka, and hung very near the earth for some time, completely excluding the light of the sun, and accompanied by a rise of temperature in the air. In about half an hour this cloud collapsed, and covered the earth with dull gray, cottony ashes of extreme lightness. This was ascribed to the Bogosloff eruption which had been heard of, though not visible from Iliuliuk harbor, where these observations were made. Another account says the fall of ashes occurred Oct. 24, and that the amount has been exaggerated.

Subsequently Capt. Hague passed again in the vicinity of Bogosloff, and, to his astonishment, observed a new island which had appeared above the sea since his previous visit, and in a spot which he had previously sailed over. In the month of September Capt. Anderson, of the schooner Mathew Turner, had observed the new island, which was then a mass of fire and smoke, apparently not having taken shape. Capt. Hague reports the new peak to be situated half a mile north-north-westward from Bogosloff, to be cone-shaped, with an irregular outline, rising five to eight hundred feet above the sea, and about three-quarters of a mile in diameter.

It is stated that no further information was obtained; and none is likely to be obtainable until next spring, as communication with Unalashka is not kept up during the winter months. To examine it, a special expedition from Unalashka would be necessary; as it cannot be much less than forty-five miles from Iliuliuk harbor, in the open sea, and would be little more than visible from the nearest land. I would suggest for it the name of Grewingk Island, in honor of the celebrated geologist who monographed in 1850 all that was known of Alaskan geology and mineralogy.[1]

Since the above news was received, further intelligence has come to hand in regard to volcanic activity in Alaska, from an unexpected locality. From the entrance of Port Graham, sometimes called English Bay, at the mouth of Cook's Inlet on its eastern shore, may be seen the rounded summit of Augustin or Chernobour Island. It presented in 1880 the appearance of a low rounded dome without a peak, and measured about thirty-eight hundred feet in height by angles from different stations. The island of which it is the summit is about fifty miles from Port Graham in a south-west by west direction, is rounded and about eight miles in diameter, bluff to the north-west, and sloping to the south-east. There are many rocks about it, and it has been a noted haunt of sea-otters. It was known to be volcanic, but no description of it as active is on record so far as I can discover. According to information received from Capts. Cullie and Sands, and summarized for the press by Prof. George Davidson at San Francisco, the following observations were made at the Alexander Village at Port Graham. Smoke first arose from the peak in August. On the morning of Oct. 6 the inhabitants heard a heavy report, and saw smoke and flames issuing from the summit of the island. The sky became obscured, and a few hours later there was a shower of pumice-dust. About half-past eight o'clock the same day an earthquake wave, estimated at thirty feet in height, rolled in upon the shore, deluging the houses on the lowland, and washing the boats and canoes from the beach. It was followed by others of less height. The ash fell to a depth of several inches, and the darkness required lamps to be lighted. At night flames were seen issuing

[1] Capt. Hague proposed to name it New Bogosloff; but the derivation of the word 'Bogosloff' is such that a different name would be preferable.

from the summit, and the snow had disappeared from the island. After the first disturbances were over, it was found that the northern slope of the summit had fallen to the level of the cliffs which form the shore, and the mountain appeared as if split in two. Two previously quiet volcanoes on the peninsula of Aliaska began simultaneously to emit smoke and dust; and in the ten-fathom passage between Augutin Island and the mainland a new island, seventy-five feet high and a mile and a half in extent, has made its appearance. It is stated that subterranean noises had previously been heard by a party of hunters, some of whom are reported missing.

The volcano has not been approached nearer than ten miles since the eruption, at which distance the new island was distinctly seen north-west from Augustin Island. Its dimensions, therefore, are merely approximate. The morning of the eruption was perfectly clear, with a light south-west wind, and the tide extremely low. Three days before, all the fish are said to have disappeared from Port Graham. At last accounts smoke was arising from a point on Augustin Island, south from the cleft above mentioned, which crosses the island from east to west.

It would seem as if these events were local manifestations of an awakening of volcanic energy nearly world-wide. WM. H. DALL.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1]—IX.

TORNADOES differ from the storms thus far mentioned in their excessive violence over a very restricted area, and their visibly rapid advance. After a great deal of theorizing, it is now possible to explain them very satisfactorily and simply as whirls in the air, a little above the ground, into the vortex of which the surface-winds are drawn up with great velocity. Electricity has no essential share in their action.

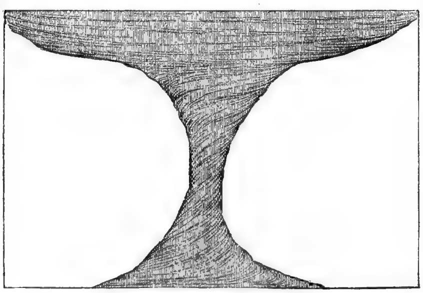
Recent studies, especially the reports by Mr. Finley of the signal-service, have done much to show us the regions of, and general conditions preceding, tornadoes. They are most numerous in Kansas, Missouri, and Illinois, although they have been recorded throughout the states east of the Mississippi, except in the far north-east and on the central Alleghanies. So they have occurred in all the months, and at nearly all hours of the day; but their time of greatest frequency is in the afternoons of June and the months adjoining. Where most fully studied, they seem to occur along the contact-line of warm southerly winds and cooler north-westerly or westerly winds. Local quiet and rather excessive warmth commonly precede them, and chilly winds come after their passage. Rain and hail fall in their neighborhood, but usually at a moderate distance away from the destructive wind-centre. Their advance is nearly always to the north-east, at about thirty miles an hour.

When first perceived, the tornado is generally described as a dark, funnel-shaped mass, hanging from heavy, dark, agitated clouds (fig. 23). Its roaring sound is heard as it comes nearer; and the whirling funnel is often seen to swing from side to side, and to rise and fall. Within its dark column, various objects snatched from the ground may be seen rising and turning round and round in the eddying winds: pine-trees appear like bushes, and barn-doors are mistaken for shingles. At a certain height these fragments are thrown laterally out of the power of the ascending current, and then fall to the ground, often with violence, from their lofty flight. If such a cloud appear in the west or south-west, one should make all possible haste to the north or south of its probable track; but there is seldom time to escape. The rapidity of the storm's approach, the noise of its roaring, the fear that its darkness and destruction naturally inspire, too often serve to take away one's presence of mind; and, before there is time for reflection, the whirl has come and passed, and the danger is over for those who survive. The force of the wind is terrific. Heavy carts have been carried, free from the ground, at such a velocity, that, when they strike, the tires are bent and twisted, and the spokes are broken from the hubs. Iron chains are blown through the air. Large beams are thrown with such strength that they penetrate the firm earth a foot or more. Children, and even men, have often been carried many feet above the ground, and sometimes dropped unhurt. A velocity of wind exceeding one hundred miles an hour is required to produce such effects. Strange examples of the wind's strength are found in the treatment of small objects: nails are found driven head first firmly into planks; a cornstalk is shot partly through a door, recalling the firing of a candle through a board. More than this, the wind shows signs of very unequal motions in a small space: bedding and clothing are torn to rags; harness is stripped from horses. Nothing can withstand the awful violence of the tornado's centre; and yet, at a little distance one side or the other, there is not only no harm

[1] Concluded from No. 50.

done, but there is no noticeable disturbance in the gentle winds. The track of marked disturbance averages only half a mile, and the path of great destruction is often only a few hundred feet wide.

The whirling at the centre is evident enough, in many cases, from the rotary motion of the funnel-cloud: it is, in all reported cases, from right to left, like the cyclones of this hemisphere. At a little distance from the centre, the wind is probably nearly radial, as is shown fully enough by the direction in which fences or trees are blown over, or houses and other loose objects carried. On the right side of the track the winds are more violent, and their destructive effect consequently reaches farther from the whirl than on the left. This is evidently because, on the right, the motion of the wind and the advance of the storm are combined, as has been explained under cyclones. Here are several examples from the Kansas tornadoes of May, 1879, as described in Finley's report, showing the opposed currents of air.



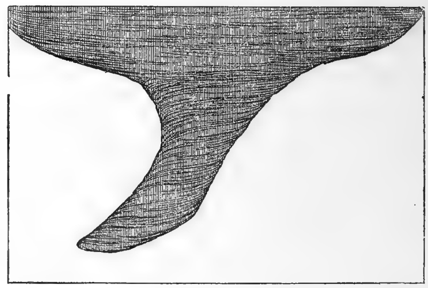


FIG. 23.[1]

Fig. 24 shows the fence on the right blown to the east; the fences on the left, to the west and south; and the hay from a stack, scattered in a curved line. When fences are not blown over, rubbish often collects on their windward side.

Fig. 25 illustrates, by arrows, the direction of the wind, by which several buildings were more or less injured; but most peculiar is the track of a man, who, on coming out of the east side of a barn, was caught up by the winds and carried half way around the building, and there set down very dizzy, but unhurt. At the same time, two horses near by were killed, their harness stripped off and torn to pieces. A scantling four inches square and ten feet long was found driven three feet and a half into the ground, only forty-five feet from its starting-point. A large board sixteen feet long was found two miles to the north-east, where it was identified by the color of its paint.

Fig. 26 shows a more disastrous case. The house was swept away, and its fragments filled the creek to the south-east. The trees west of the house were not hurt; but those in the grove on the track were blown over to the north-east, their bark and leaves stripped off, and their south-western side blackened as if burnt. In such position, branches have been found twisted from right to left about the trunks. As the storm came on, the family occupying the house ran out, turning to the north and west. One by one they were blown away, — first a little girl, who was found dead; then a girl and boy, not seriously hurt; next the mother was thrown against a tree and killed; and last, the father, carrying the baby, and becoming confused in the rushing wind, turned back from his safe flight to the west, was caught up and thrown over one hundred yards to the north-east, and killed. The accounts of tornadoes only too often give a record like this. In six hundred and odd tornadoes, forty are recorded as fatal to the people on their track. In these forty, four hundred and sixty-six lives were lost, and six hundred and eighty-seven persons were injured.

In addition to the violence of the whirling winds, an explosive effect is often noted in buildings where the windows and doors are closed. Doubtless this is one reason why roofs are so generally carried away. Doors

[1] Figs. 23, 24, 25, and 26 are from Finley's Report on tornadoes of May 29 and 30, 1879.

and windows have been blown outward. The four walls of a house have fallen outward from the centre. Still more definite is the account of a railroad-agent who had barred the window-shutters and locked the door of his station after a train had gone by. A tornado passed over it, and burst the window open outwards. Evidently the air of ordinary density within the building suddenly expands as the outside pressure of the atmosphere is taken off when the storm-centre passes. Possibly this action may aid in the plucking of poultry in tornadoes: the unfortunate chickens that are caught near the centre are nearly always stripped of their feathers. So with the remarkable penetration of mud into clothing, which cannot be cleansed by repeated washings: perhaps the air is drawn out as the storm passes, and then the mud is forced closely into the fabric by the returning atmospheric pressure. The ground

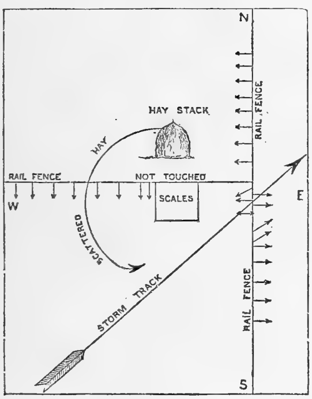

FIG. 24.

is sometimes said to look as if heavily washed on the central path: it may be that the expansion of air in a loose soil aids such a result.

Nothing can be better proven than the existence of a continuous and violent updraught at the centre of the whirl. An observer far enough from the track of the tornado to watch it composedly, and yet near enough to see it with some distinctness, seldom fails to note the rapid rising of *débris* and rubbish in the vortex, whirling as it rises; and a current of air strong enough to lift boards and beams must ascend with great energy. Most of the fragments thus captured by the wind are thrown to one side, and allowed to fall after a short flight; but smaller, lighter objects, such as hats, clothes, papers, shingles, are often carried several miles through the clouds, and dropped far away from home. But observers often report, also, that the extremity of the funnel-clouds is seen to descend, and from hanging aloft it suddenly darts downward to the ground. How can these two contradictory motions be reconciled? Simply enough: for the last is purely an apparent motion. It is simply the downward extension of the cloud-forming space faster than the cloud-particles

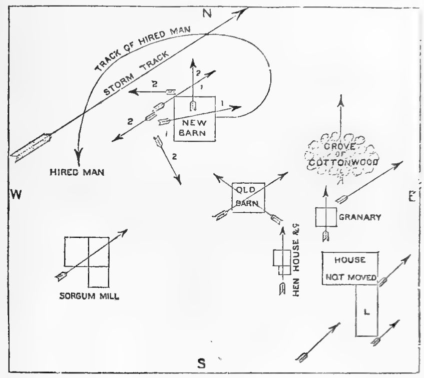

FIG. 25.

are carried upward. The same style of apparent motion against the wind may be seen in some thunder-showers where a cloud forms faster than the wind blows, and so eats its way to windward. There has been much needless mystification here, for the point was neatly explained by Franklin a century and a quarter ago. He wrote, that "the spout appears to drop or descend from the cloud, though the materials of which it is composed are all the while ascending;" for the moisture is con-

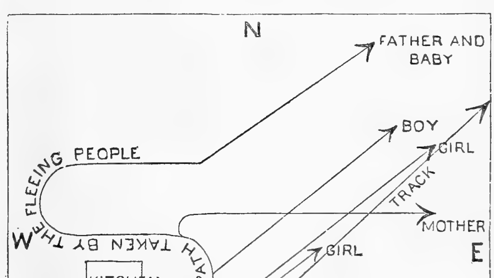

FIG. 26.

densed "faster in a right line downwards than the vapors themselves can climb in a spiral line upwards" (Franklin's Works, Sparks's ed., vi. 153, 154; letter dated Feb. 4, 1753).

Now let us look for the explanation of these varied effects, and discover, if possible, the reason of the extremely local development of such intense motions.

The explanation given for sand-whirls in the desert fails to provide for the excessive force of the tornado. A thin, warm surface-stratum of air would be prevented by friction with the ground from attaining any very excessive velocity; and, moreover, it is often excessively hot without tornadoes following, and tornadoes often happen when the air is not perfectly still. Yet, as they occur most frequently on warm or hot afternoons, surface-warmth very probably re-enforces other causes up to the point of violent storm development.

The existence of conflicting winds, as already noted, gives us more aid. So long as the cold wind passes under the warm, there will be no great disturbance, for the equilibrium will remain stable; but, if the warm wind advances under the cold, an unstable equilibrium may result. We have already seen that warm saturated air requires the smallest vertical difference of temperature to destroy its stability; and also that the saturated condition may often be met in the cloud-stratum, although absent below it. For these two reasons we may infer that a tendency to upset will be more frequently reached a few hundred or thousand feet above the earth than closer to the ground. Suppose that such a condition is reached when a mass of warm southerly wind has pushed itself below the colder north-westerly stratum: the surface-air will often rest quiet and become warm below such a meeting, for the same reason that calms occur along the equator at the meeting of the trades; and a change must soon relieve this unnatural arrangement. The warm wind, feeling about for a point of escape through its cold cover, soon makes or finds a vent where it can drain away upwards; and then the entire warm mass, even a mile or more in diameter, and often more than one thousand feet in thickness, begins the rotary motion already described in whirls and cyclones, rises at the centre, and passes away. Before describing the peculiar tornado features, let us contrast the storm as now developed with the two other kinds of storms already explained. The desert-whirl arises from a thin layer of hot dry air, warmed at the place where the whirl begins, ascending in a small column through a considerable thickness of colder air. Friction with the ground prevents the attainment of an excessive velocity; and the ascending current can lift only sand and light objects. As soon as the bottom-air is drained away, the whirl stops. The cyclone is fairly compared, on account of its great horizontal extension, to a broad, relatively thin disk, with a horizontal measure several hundred times greater than its thickness, having a spiral motion of much rapidity, inward below and outward above, but a central ascending component of its motion so gentle that raindrops can ordinarily fall down through it. Its continuance depends largely on heat derived from vapor condensation: it is therefore self-acting after it has once begun, and goes on drawing in new air long after the original supply is exhausted. The tornado is like a cylinder, with a height equal to or greater than its diameter. Its warmth is chiefly imported to the point where its action begins, partly as sensible, partly as 'latent' heat; but, unlike the cyclone, its action ceases as soon as the original mass of warm air escapes upward through its warm cover. On apprehending these peculiarities, we may better appreciate its farther development.

The tornado has two motions to be considered, in addition to its general progression,— the spiral rotation, and the central updraught. The latter cannot, except under special conditions yet to be mentioned, become very rapid, for it depends primarily, simply on differences of temperature insufficient to produce very active motion; but the former attains a great velocity near the centre in virtue of the mechanical principle already quoted,—the 'preservation of areas.' When a whirling body is drawn toward the centre about which it swings, its velocity of rotation will increase as much as its radius of rotation decreases; the centrifugal force will also increase, and with the square of the velocity, or inversely as the square of the radius. This law claims obedience from air, as well as from solid bodies: hence, if the air of a tornado mass have a gentle rotary velocity of twenty or thirty feet a second at a thousand yards from the centre, this velocity will increase as the central air is drained away and the outer particles move inward; so that, when their radius is only one hundred yards, they will fly around at the rate of two or three hundred feet a second, or over one hundred and fifty miles an hour. It must be understood, however, that this requires that there should have been no loss of motion by friction, and hence can be true only for the air at a distance above the ground; and, further, that, in spite of the great horizontal rotary motion, there is still only a moderate vertical current. And consequently we have not yet arrived at the cause of the violent central and upward

winds that distinguish the tornado from other storms, but this cause is close at hand.

Admit for a moment that there is no friction between the air and the ground. We should then have a tall vertical cylinder of air, spinning around near the centre at a terrific speed, at the base as well as aloft, and consequently developing a great centrifugal force. As a result, the density of the central core of air must be greatly diminished. Most of the central air must be drawn out by friction into the whirling cylinder, and prevented from returning by the centrifugal force. The core will be left with a feeling of emptiness, like an imperfect vacuum. If there were any air near by not controlled by the centrifugal force, it would rush violently into the central core to fill it again. Now consider the effect of friction with the ground. The lowermost air is prevented from attaining the great rotary velocity of the upper parts, and consequently is much less under the control of the centrifugal force, which is measured by the square of the velocity. The surface-air is therefore just what is wanted to fill the incipient vacuum: so it rushes into the core and up through it with a velocity comparable to that of the whirling itself; and *this inward-rushing air is the destructive surface-blast of the tornado.*

This explanation, first proposed by Mr. Ferrel a few years ago, is most ingenious and satisfactory. Moreover, he has followed its several parts by close mathematical analysis, and shown that the moderate antecedent conditions are amply sufficient to account for all the violence of the observed results.

There are still several points to be considered. The whirling motion has been described as corresponding in nearly all cases with that of northern cyclones; and yet it cannot be supposed that the indraught winds of a tornado are drawn from sufficient distances to show the effect of the earth's deflective force: it is more probable that the tornado is to be regarded as a small whirl within a larger one, for the warm and cold winds are probably part of a large cyclonic system in which differential and rotary motions are established; and, when such winds form a small local whirl of their own, it will rotate in the same direction as they do, from right to left. For a like reason the planets rotate on their axes in the direction in which they revolve around the sun. The constant direction of rotation in tornadoes may therefore, by itself, be taken as evidence that their cause is not in a stagnant atmosphere, like that of the desert-whirls, but is connected with the conflicting currents of a large, gentle cyclone.

The progressive motion of the tornado-centre is so constant in its direction to the north-east or east, that it cannot depend on local conditions within itself, but must rather result from its bodily transportation by the prevailing winds, with which the tornado-tracks agree very well in direction and rate. It will last till the lower warm air, which constituted the original unstable mass, is exhausted. This generally happens in about an hour, when it has traversed a distance of nearly thirty miles.

The tornado thus constituted may be likened to a very active air-pump, carried along a few hundred feet above the ground, sucking up the air over which it passes. It is for this reason that the surface-winds are so nearly radial. For this reason an enclosed mass of air, as in a house, suddenly explodes as the vacuum is formed over it; and as the air rushes to the centre, and there expands and cools, its vapor becomes visible in the great funnel, or spout, pendent from the clouds above. No rain can fall at the centre. Bodies much heavier than rain are lifted there, instead of dropped: so the rain must rise through the central core, and fall to one side of the storm, or before or behind it. If the expansion be very great, and the altitude reached by the drops rather excessive, then they will be frozen to hailstones before falling. Hail-storms and tornadoes commonly go together: they mutually explain each other. Electricity has no important part to play in the disturbance.

It was stated under cyclones that their central barometric depression had two causes, — the overflow caused by the central warmth, and the dishing-out of the air by centrifugal force. The first of these is ordinarily regarded as the effective cause of the wind's inward blowing. It has already been pointed out that the second and greater part of the depression is also effective in drawing in the winds when friction decreases their rotary velocity. We may now call attention to a third cause of centripetal motion in the cyclone already alluded to, in which it is like the tornado. The upper winds move with great rapidity, and cause a strong barometric depression at the centre of their whirling; but at the base of the storm, where friction with the sea, or still more with the land, reduces the lower wind's motion, and so diminishes their centrifugal force, we may have an indraught of the tornado style, in which the centrifugal diminution of central pressure in the upper winds is an effective cause of centripetal motion in the lower winds. While this is not the principal cause of surface-

winds in a cyclone, it may be an important aid to central warmth.

Water-spouts are closely allied to tornadoes: but when seen in small form they approach the character of simple desert-whirls; that is, they then depend merely on air warmed at the place where they occur, and not on the running together of warm and cold winds from other regions. A probable cause for the excess of their strength above that of the sand-whirls lies in the smoothness of the water-surface on which they spring up, which will allow a long time of preparation; and in the moisture in the air, which will cause the warming of a greater thickness than if the air were very dry. The greater the thickness, the more their action will resemble that of a typical tornado. The appearance of the downward extension of the funnel-shaped cloud to meet the rising column of water is almost certainly only an appearance, and has the explanation already quoted from Franklin's ingenious writings.

We have relied largely, in the preceding explanations, on deductions from general principles, checked by the results of observation. The writings of many investigators have been examined, and in a few cases their names have been given; but the literature of the subject is now so extensive that full reference has been deemed unadvisable. Little attention has been paid to the older theories, in which conflicting winds and electricity were looked on as the chief causes of storms. The latter is regarded as an effect rather than a cause; and, while the former has much importance when rightly considered in connection with the earth's rotation, it is of small value as originally stated, and is then limited to the production of short-lived storms in mountainous districts. The more important factors of the modern theory of storms are the consideration of the conditions of stable and unstable equilibrium of the atmosphere, the true measure of the action of condensing water-vapor, the full estimation of the effect of the earth's rotation, and the recognition of the necessary increase in the wind's velocity as it is drawn in toward the storm-centre.

W. M. DAVIS.

THE CRITICAL STATE OF GASES.

THE *Philosophical magazine* for August, 1883, contains a letter from Dr. William Ramsay which refers to observations upon the critical state of gases, published in the Proceedings of the London royal society, 1879–80. The chief observations that had previously been made upon this interesting subject are those of Cagniard de la Tour (*Annales de chimie*, 2ème série, xxi. et xxii.), Faraday (*Phil. trans.*, 1823 and 1845), Thilorier (*Annales de chimie*, 2ème série, lx.), Natterer (*Pogg. ann.*, xciv.), Andrews (*Phil. trans.*, 1869). Andrews found that when a gas was compressed in a closed space, and was maintained at a temperature below a certain limit, the pressure of the gas increased up to a fixed point, beyond which condensation occurred. The pressure at which condensation takes place increases rapidly with the temperature of the gas. At and beyond a certain temperature — the critical temperature — no amount of pressure can produce any of the usual phenomena of condensation. The isothermal lines below the critical temperature are apparently discontinuous, one portion representing no change of pressure corresponding to a change of volume. Above the critical temperature the isothermals are continuous.

The experiments of Dr. Ramsay were made upon benzine and ether, and a mixture of equal weights of benzine and ether. In one experiment a closed glass tube, somewhat in the shape of an hourglass, was used. One end of the tube was partly filled with ether, and was heated in an inclined position. The liquid expanded until, at the moment the meniscus disappeared, it nearly filled the lower half of the tube. On cooling, the liquid all condensed in the lower half.

The experiment was varied by inverting the tube after the meniscus had disappeared. On cooling, the liquid condensed in the upper half of the tube. The tube was next maintained for some time at a temperature above that at which the meniscus disappeared. On cooling, an equal quantity condensed in each division of the tube. It was observed, that, after the meniscus had disappeared, the part of the tube containing liquid had a different index of refraction from the other part.

The conclusion to be drawn from these results is, that, at and above the critical point, the density of the liquid is the same as that of its saturated vapor: consequently, after a sufficient time, the liquid and its vapor will become mixed. Above the critical point, the surface tension of a liquid disappears.

This conclusion is confirmed by the experiments of M. Cailletet (*Comptes rendus*, Feb. 2, 1880). He found that when the lower part of his experimental tube was filled with liquid carbonic anhydride at a temperature of 5°.5, and the upper part was filled with air and gaseous carbonic anhydride, a pressure of a hundred and fifty to two hundred atmospheres was necessary to cause the liquid to mix with the gas. At the suggestion of Mr. Jamin (*Comptes rendus*, May 21, 1883), hydrogen was substituted for the air in the upper part of the tube, and it was then found that a greater pressure was necessary to produce the mixture. This result would necessarily follow if we suppose that the mixture takes place when the densities of the liquid and the gas become equal. We cannot say that the liquid is converted into gas by pressure.

Though the densities of a liquid and its saturated vapor are equal, above the critical point, the two states of matter are still distinguished by other physical properties. Their indices of refraction are differ-

ent: the liquid is capable of dissolving solids which are insoluble in the vapor. The latter fact is proved by the experiments of Hannay and Hogarth (*Proc. roy. soc.*, Oct., 1879), and also by similar experiments of Dr. Ramsay. A small piece of potassium iodide was placed in the lower part of the experimental tube, which was partly filled with anhydrous alcohol. The upper part of the tube was free from alcohol, but its sides were covered with a film of crystalline potassium iodide. When the tube was heated and the meniscus disappeared, the salt in the lower part of the tube was dissolved, while that in the upper part remained unchanged. Similar observations were made on eosine.

Dr. Ramsay's second paper contains the isothermal lines for benzine, ether, and a mixture of benzine and ether, below and above the critical temperatures. The apparatus used resembled that of Andrews. The most remarkable feature of these lines is, that, below the critical temperature for benzine, there appears to be a diminution of pressure corresponding to a diminution of volume, immediately before complete condensation takes place. This phenomenon appears very slightly in a mixture of benzine and ether, but is not apparent in ether alone. It has been suggested by James Thomson (*Proc. roy. soc.*, 1871) that the isothermals for all gases might have somewhat this form below the critical temperature. Dr. Ramsay explains the fact by supposing that the molecules, when the gas has been compressed to a certain extent, begin to exert mutual attraction and relieve the pressure. The fact may be connected with the observed phenomenon that the meniscus of benzine remains easily distinguishable until it vanishes, whereas the meniscus of ether soon becomes hazy. At the part of the isothermal under consideration the substance is evidently in a condition of unstable equilibrium, and it is difficult to see how this part of the curve could have been detected experimentally.

The critical temperature and pressure of a mixture of benzine and ether were found to be not far removed from the mean of the critical temperatures and pressures of the components.

No direct experiments have yet been made to ascertain whether heat is evolved when a gas is converted into liquid by pressure at temperatures above its critical temperature. Mr. Jamin concludes that at and beyond the critical point there is no latent heat. This conclusion, however, does not seem probable; since the molecular constitution of a liquid and its vapor are probably different, even above the critical temperature.

The conclusions which Ramsay draws from his experiments are summed up as follows: —

"1°. A gas may be defined as a body whose molecules are composed of a small number of atoms.

"2°. A liquid may be regarded as formed of aggregates of gaseous molecules, forming a more complex molecule.

"3°. Above the critical point, the matter may consist wholly of gas if a sufficient volume be allowed, wholly of liquid if the volume be sufficiently diminished, or of a mixture of both at intermediate volumes. That mixture is, physically speaking, homogeneous in the same sense as a mixture of oxygen and hydrogen gases may be termed homogeneous."

C. B. PENROSE.

COLORED SKIES AFTER AN ERUPTION OF COTOPAXI.[1]

THE remarkable sunsets which have been recently witnessed upon several occasions have brought to my recollection the still more remarkable effects which I witnessed in 1880 in South America, during an eruption of Cotopaxi; and a perusal of your highly interesting letter in the *Times* of the 8th inst. has caused me to turn to my notes, with the result of finding that in several points they appear to have some bearing upon the matter which you have brought before the public.

On July 3, 1880, I was engaged in an ascent of Chimborazo, and was encamped on its western side at 15,800 feet above the sea. The morning was fine, and all the surrounding country was free from mist. Before sunrise we saw to our north the great peak of Illiniza, and twenty miles to its east, the greater cone of Cotopaxi; both without a cloud around them, and the latter without any smoke issuing from its crater, — a most unusual circumstance: indeed, this was the only occasion on which we noticed the crater free from smoke during the whole of our stay in Ecuador. Cotopaxi, it should be said, lies about forty-five miles south of the equator, and was distant from us sixty-five miles.

We had left our camp, and had proceeded several hundred feet upwards, being then more than 16,000 feet above the sea, when we observed the commencement of an eruption of Cotopaxi. At 5.45 A.M. a column of smoke of inky blackness began to rise from the crater. It went up straight in the air, rapidly curling, with prodigious velocity, and in less than a minute had risen 20,000 feet above the rim of the crater. I had ascended Cotopaxi some months earlier, and had found that its height was 19,600 feet. We knew that we saw from our station the upper 10,000 feet of the volcano, and I estimated the height of the column of smoke at double the height of the portion seen of the mountain. The top of the column was therefore nearly 40,000 feet above the sea. At that elevation it encountered a powerful wind blowing from the east, and was rapidly borne for twenty miles towards the Pacific, seeming to spread very slightly, and remaining of inky blackness, presenting the appearance of a gigantic inverted ⌊_ drawn upon an otherwise perfectly clear sky. It was then caught by a wind blowing from the north, and was borne towards us, and appeared to spread rapidly in all directions. As this cloud came nearer and nearer, so, of course, it seemed to rise higher and higher in the sky, although it was actually descending. Several hours passed before the ash commenced to intervene between the sun and ourselves; and, when it did so, we witnessed effects which simply amazed us. We saw a green sun, and

[1] From *Nature*, Dec. 27. A letter sent to Mr. Norman Lockyer.

such a green as we have never, either before or since, seen in the heavens. We saw patches or smears of something like verdigris-green in the sky; and they changed to equally extreme blood-reds, or to coarse brick-dust reds, and they in an instant passed to the color of tarnished copper or shining brass. Had we not known that these effects were due to the passage of the ash, we might well have been filled with dread instead of amazement; for no words can convey the faintest idea of the impressive appearance of these strange colors in the sky, seen one minute and gone the next, resembling nothing to which they can be properly compared, and surpassing in vivid intensity the wildest effects of the most gorgeous sunsets.

The ash commenced to pass overhead at about midday. It had travelled (including its détour to the west) eighty-five miles in a little more than six hours. At 1.30 it commenced to fall on the summit of Chimborazo, and, before we began to descend, it caused the snowy summit to look like a ploughed field. The ash was extraordinarily fine, as you will perceive by the sample I send you. It filled our eyes and nostrils, rendered eating and drinking impossible, and reduced us to breathing through handkerchiefs. It penetrated everywhere, got into the working-parts of instruments and into locked boxes. The barometer employed on the summit was coated with it, and so remains until this day. That which ssed beyond us must have been finer still. It travelled far to our south, and also fell heavily upon ships on the Pacific. I find that the finer particles do not weigh the twenty-five thousandth part of a grain, and the finest atoms are lighter still. By the time we returned to our encampment, the grosser particles had fallen below our level, and were settling down into the valley of the Chimbo, the bottom of which was 7,000 feet beneath us, causing it to appear as if filled with thick smoke. The finer ones were still floating in the air, like a light fog, and so continued until night closed in.

In conclusion, I would say that the terms which I have employed to designate the colors which were seen are both inadequate and inexact. The most striking features of the colors which were displayed were their extraordinary strength, their extreme coarseness, and their dissimilarity from any tints or tones ever seen in the sky, even during sunrises and sunsets of exceptional brilliancy. They were unlike colors for which there are recognized terms. They commenced to be seen when the ash began to pass between the sun and ourselves, and were not seen previously. The changes from one hue to another, to which I have alluded, had obvious connection with the varying densities of the clouds of ash that passed; which, when they approached us, spread irregularly, and were sometimes thick and sometimes light. No colors were seen after the clouds of ash passed overhead and surrounded us on all sides.

I photographed my party on the summit of Chimborazo whilst the ash was commencing to fall, blackening the snow-furrows; and, although the negative is as bad as might be expected, it forms an interesting souvenir of a remarkable occasion.

Edward Whymper.

MODERN PHYSIOLOGICAL LABORATORIES: WHAT THEY ARE AND WHY THEY ARE.[1] — II.

We have seen that Haller laid the foundation of the knowledge that the body of one of the higher animals was essentially an aggregation of many organs, each having a sort of life of its own, and in health coöperating harmoniously with others for the common good. In the early part of this century, before scientific thought had freed itself from mediaeval guidance, this doctrine sometimes took fantastic forms. For example: a school arose which taught that each organ represented some one of the lower animals. DuBois-Reymond relates that in 1838 he took down these notes at the lectures of the professor of anthropology: —

> "Each organ of the human body answers to a definite animal, is an animal. For example, the freely movable, moist, and slippery tongue is a cuttlefish. The bone of the tongue is attached to no other bone in the skeleton; but the cuttlefish has only one bone, and consequently this bone is attached to no other. It follows that the tongue is a cuttlefish."

However, while Professor Steffens and his fellow-transcendentalists were theorizing about organs, others were at work studying their structure; and a great step forward was made in the first year of our century by the publication of Bichat's 'Anatomie générale.' Bichat showed that the organs of the body were not the ultimate living units, but were made up of a number of different interwoven textures, or *tissues*, each having vital properties of its own. This discovery paved the way for Schwann and Schleiden, who laid the foundation of the cell-theory, and showed, that, in fundamental structure, animals and plants are alike, the tissues of each being essentially made up of aggregates of more or less modified microscopic living units called cells. Our own generation has seen the completion of this doctrine by the demonstration that the essential constituent of the cell is a peculiar form of matter named protoplasm, and that all the essential phenomena of life can be manifested by microscopic lumps of this material; that they can move, feed, assimilate, grow, and multiply; and still further, that, wherever we find any characteristic vital activity, we find some variety of protoplasm. Physiology thus became reduced, in its most general terms, to a study of the faculties of protoplasm; and morphology, to a study of the forms which units or aggregates of units of protoplasm, or their products, might assume. The isolation of botany, zoölogy, and physiology, which was threatened through the increased division of labor, brought about by increase of knowledge, necessitating a limitation of special study to some one field of biology, was averted; and the reason was given for that principle which we have always insisted upon here, — that beginners shall be taught the broad general laws of living matter before they are permitted to engage in the special study of one department of biology.

If I be asked, what have biological science in general, and physiology in particular, done for mankind

[1] Concluded from No. 50. Address by Dr. H. Newell Martin.

to justify the time and money spent on them during the past fifty years, I confess I think it a perfectly fair question; and fortunately it is one very easy to answer. Leaving aside the fruitful, practical applications of biological knowledge to agriculture and sanitation, I will confine myself to immediate applications of the biological sciences to the advance of the theory, and, as a consequence, of the art, of medicine.

So long as the life of a man was believed to be an external something apart from his body, residing in it for a while, diseases were naturally regarded as similar extrinsic essences or entities, which invade the body from without, and fought the 'vital force.' The business of the physician was to drive out the invader without expelling the vital spirits along with it, — an unfortunate result, which only too often happened. To the physicians of the sixteenth century a fever was some mysterious, extraneous thing, to be bled, or sweated, or starved out of the body, much as the medicine men of savages try to scare it off by beating tomtoms around the patient. Once life was recognized as the sum total of the properties of the organs composing the body, such a theory of disease became untenable, and the basis of modern pathology was laid. Disease was no longer a spiritual, indivisible essence, but the result of change in the structure of some one or more of the material constituents of the body, leading to abnormal activity. The object of the physician became, not to expel an imaginary, immaterial enemy, but to restore the altered constituent to its normal condition.

The next great debt which medicine owes to biology is the establishment of the cell-doctrine, — of the fact that the body of each one of us is made up of millions of little living units, each with its own properties, and each in health doing its own business in a certain way, under certain conditions, and no one cell more the seat of life than any other. The activities of certain cells may, indeed, be more fundamentally important to the maintenance of the general life of the whole aggregate than that of others; but these cells, which, by position or function, are more essential than the rest, were, in final analysis, no more alive than they. Before the acceptance of the cell-doctrine, pathologists were practically divided into two camps, — those who believed that all disease was primarily due to changes in the nervous system, and those who ascribed it to alteration of the blood. But with the publication of Virchow's 'Cellular pathology' all this was changed. Physicians recognized that the blood and nerves might at the outset be all right, and yet disease originate from abnormal growth or action of the cells of various organs. This new pathology, like the older, was for a time carried to excess. We now know that there may be general diseases primarily due to changes in the nervous system, which binds into a solidarity the organs of the body, or of the blood, which nourishes all; but we have also gained the knowledge that very many, if not the majority, of diseases have a local origin, due to local causes, which must be discovered if the disease is to be successfully combated. An engineer, if he find his machinery running imperfectly, may endeavor to overcome this by building a bigger fire in his furnace, and loading the safety-valve. In other words, he may attribute the defect to general causes; and in so far he would resemble the old pathologists. But the skilled engineer would do something different. If he found his machinery going badly, he would not jump forthwith to the conclusion that it was the fault of the furnace, but would examine every bearing and pivot in his machinery, and, only when he found these all in good working-order, begin to think the defect lay in the furnace or boiler; and in that he would resemble the modern physician instructed in the cell-doctrine.

A third contribution of biology to medical science is the germ-theory as to the causation of a certain group of diseases. To it we owe already antiseptic surgery; and we are all now holding our breath in the fervent expectation that in the near future, by its light, we may be able to fight scarlet-fever, diphtheria, and phthisis, not in the bodies of those we love, but in the breeding-places, in dirt and darkness, of certain microscopic plants.

From one point of view the germ-theory may seem a return to the idea that diseases are external entities which attack the body; but note the difference between this form of the doctrine and the ancient. We are no longer dealing with immaterial, intangible hypothetic *somethings*; and the modern practitioner says, "Well, show me the bacteria, and then prove that they can cause the disease: until you can do that, do not bother me about them."

It is worth while, in passing, to note that these three great advances in medical thought were brought about by researches made without any reference to medicine. Haller's purely physiological research into the properties of muscles laid the foundation of a rational conception of disease. The researches of Schwann on the microscopic structure of plants, and since then of others on the structure of the lowest animals, led to the cellular pathology. Antiseptic surgery is based on researches carried out for the sole purpose of investigating the question as to spontaneous generation. My friend Dr. Billings has described "the languid scientific swell, who thinks it bad style to be practical, and who makes it a point to refrain from any investigations which lead to useful results, lest he might be confounded with mere practical men." Well, I am sorry for the swell; because, for the life of me, I cannot see how he can make any investigations at all. The members of his class must anyhow be so few in number that we need not much grieve over them. Personally I never have met with an investigator who would not be rejoiced to find any truth discovered by him put to practical use; and I feel sure that in this day and generation the danger is rather that disproportionate attention will be devoted to practical applications of discoveries already made, to the exclusion of the search for new truth. So far as physiology is concerned, it has done far more for practical medicine, since it began its own independent career, than when it was a mere branch of the medical curriculum. All the history of the physical sciences shows that each of them has con-

tributed to the happiness and welfare of mankind in proportion as it has been pursued by its own methods, for its own ends, by its own disciples. As regards physiology, this is strikingly illustrated by a comparison of the value to medicine of the graduation theses of Parisian and German medical students. As probably you all know, a candidate for the doctorate of medicine in those countries, as in many schools here, must present a graduation thesis on some subject connected with his studies. Every year a certain number select a physiological topic. The French student usually picks out some problem which appears to have a direct bearing on the diagnosis or treatment of disease, while the German very often takes up some physiological matter which on the surface has nothing to do with medicine. Now, any one who will carefully compare for a series of years the graduation theses in physiology, of German and French candidates, will discover that even the special practical art of medicine itself is to-day far more indebted to the purely scientific researches of the German students than to those of the French, undertaken with a specific practical end in view. Situated as we shall be here, in close relation to a medical school, and yet not a part of it, I believe we shall be under the best possible conditions for work. Not under too direct pressure of the influence of the professional staff and students, on the one hand, on the other we shall be kept informed and on the alert as to problems in medicine capable of solution by physiological methods.

I must find time to say a few words as to the connection of physiology with pathology and therapeutics. The business of the physiologist being to gain a thorough knowledge of the properties and functions of every tissue and organ of the body, he has always had for his own purposes to place these tissues under abnormal conditions. To know what a muscle or a gland is, he has to study it not merely in its normal condition, but when heated or cooled, supplied with oxygen or deprived of it, inflamed or starved, and see how it behaves under the influence of curari, atropine, and other drugs. From the very start of physiological laboratories, a good deal of the work done in them has necessarily been really experimental pathology and experimental therapeutics. I suppose to-day that at least half of the work published from physiological laboratories might be classed under one or other of these heads. And what has been the fruit? I can here refer only to one or two examples. It is not too much to say, that, though inflammation is the commonest and earliest recognized of pathological states, we really knew nothing about it until the experimental researches of Lister, Virchow, and Cohnheim; and that all we really know as to the nature of fever is built on the similar researches of Bernard, Haidenhain, Wood, and others. As to therapeutics, so far as giving doses of medicine is concerned, it, still in its very infancy, had its birth as an exact science in physiological laboratories. Every modern text-book on the subject gives an account of the physiological action of each drug. What the future may have in store for us by pursuit of these inquiries it is hard to limit. The work of Bernard, — showing that in curari we had a drug that would pick out of the whole body, and act upon, one special set of tissues, the endings of the nerve-fibres in muscle, — and the results of subsequent exact experiments as to the precise action of many drugs upon individual organs or tissues, hold out before us a hope that perhaps at no very distant day the physician will know exactly, and in detail, what every drug he puts into his patient is going to do in him.

Pathology and therapeutics, while almost essential branches of physiological inquiry, have nevertheless their own special aims; and, now that the physiologists have proved that it is possible to study these subjects experimentally, special laboratories for their pursuit are being erected in Germany, France, and England. These laboratories are stocked with physiological instruments, and carry on their work by physiological methods. Those who guide them, and those who work in them, must be trained physiologists: if not, the whole business often degenerates into a mere slicing of tumors and putting up of pickled deformities: pathological anatomy is a very good and important thing in itself, but it is not *pathology*. Looking at the vast field of pathological and therapeutic research open to us, and bearing in mind the certainty of the rich harvest for mankind which will reward those who work on it, I regard as one of my chief duties here to prepare in sound physiological doctrine, and a knowledge of the methods of experiment, students who will afterwards enter laboratories of experimental pathology and pharmacology immediately connected with our medical school.

If the relations of the biological sciences to medicine be such as I have endeavored to point out, what place should they occupy in the medical curriculum? That men fitted for research, and with opportunity to pursue it, should be trained to that end, is all well and good; but how about the ninety per cent who want simply to become good practitioners of medicine? What relation is this laboratory to hold to such men, who may come to it, intending afterwards to enter a medical school? As a part of their general college-training, of that education of a gentleman which every physician should possess, it should give them specially a thorough training in the general laws which govern living matter, without troubling them with the minutiae of systematic zoölogy or botany; it should enable them to learn how to dissect, and make them well acquainted with the anatomy of, one of the higher animals; it should teach them how to use a miscroscope, and the technique of histology, and finally, by lectures, demonstration, and experiment, make known to them the broad facts of physiology, the means by which those facts have been ascertained, and the sort of basis on which they rest. The man so trained, while obtaining the mental culture which he would gain from the study of any other science, is specially equipped for the study of medicine. Trained in other parts of his general collegiate course to speak and write his own language correctly, having acquired a fair knowledge of mathematics and Latin, able to read at least French and German, having learned the

elements of physics and chemistry, and, in addition, having studied the structure and properties of the healthy body, he can, on entering the technical school, from the very first turn his attention to professional details. Knowing already the anatomy of a cat or dog, he knows a great part of human anatomy, and need do little but acquaint himself with the surgical and medical anatomy of certain regions. Knowing normal histology, he can at once turn his attention to the microscopy of diseased tissues. Well instructed in physiology, he can devote himself to its practical applications in the diagnosis and treatment of disease. The demand for an improvement in medical education, which has been so loudly heard in England and this country for some years, is (the more I think of it, the more I feel assured) to be met, not, as has been the case in England, by putting more general science into the medical-school curriculum, but by confining *that* more strictly to purely professional training, and by providing, as we have attempted to do here, non-technical college-courses for undergraduates, which, while giving them a liberal education, shall also have a distinct relation to their future work. Personally I regard it as the most important of my duties, to prepare students to enter medical schools in this city or elsewhere.

To advance our knowledge of the laws of life and health; to inquire into the phenomena and causes of disease; to train experimenters in pathology, therapeutics, and sanitary science; to fit men to undertake the study of the *art* of medicine, — these are the main objects of our laboratory. I do not know that they can be better summed up than in the words of Descartes, which I would like to see engraved over its portal: "If there is any means of getting a medical theory based on infallible demonstrations, that is what I am now inquiring."

THE CLOSING REPORT OF HAYDEN'S SURVEY.

Twelfth annual report of the U. S. geological and geographical survey of the territories: a report of progress of the exploration in Wyoming and Idaho for the year 1878. Washington, *Government printing-office*, 1883. 2 vols. 8°. With portfolio of maps and panoramas.

IN two stout octavo volumes, with an accompanying portfolio of maps, Dr. Hayden presents the twelfth and last annual report of the Geological survey of the territories. While the late reorganization and consolidation of the surveys which have been occupied in the scientific exploration of the west is indubitably a very marked step in advance, it is not without a measure of regret that we realize that Dr. Hayden's familiar and always welcome annual report now reaches us for the last time. It is perhaps only those having some experience of similar work who can fully appreciate the energy and maintained scientific enthusiasm necessary for the conduct of an organization such as that which under Dr. Hayden has built so broad a foundation for our geological knowledge of the western part of the continent.

The volumes now issued constitute the report for 1878, the concluding season of field-work. Great care has evidently been given to the editing and printing of the report; and the number and good quality of the illustrations and maps are noteworthy features. Of plates alone, in the two volumes, there are over two hundred and fifty; and most of them are excellent specimens of lithographic art.

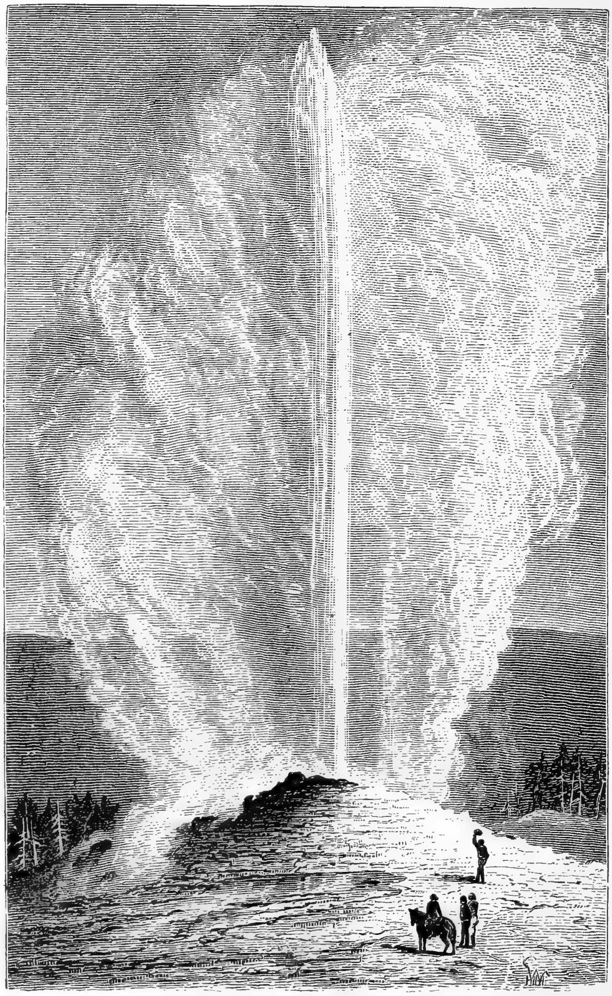
The first volume is devoted chiefly to paleontology and zoölogy, while the second may be regarded as a memoir on the Yellowstone national park. Dr. C. A. White, in his report, under the title of 'Contributions to invertebrate paleontology, No. 2,' presents the second part of his descriptions and illustrations of cretaceous fossils. This is followed (as parts 4 to 8 of the contributions) by papers on tertiary, Laramie, Jurassic, triassic, and carboniferous fossils. The article on the Laramie, including, besides the descriptions and plates of a number of forms, a systematic enumeration of the invertebrate fossils of the group, assumes the character of a synopsis of its fauna invaluable to the student of this period of geological history. Mr. Orestes St. John's very comprehensive and systematic report on the Wind River district could be done justice to only in a separate note of some length.

Mr. S. H. Scudder's report on the tertiary lake-basin of Florissant is next in order. From this place a number of fossil plants and a few fishes and birds have been obtained: but it is specially remarkable for the wonderfully numerous remains of insects which it affords; "having yielded in a single summer more than double the number of specimens which the famous localities at Oeningen, in Bavaria, furnished Heer in thirty years." The fossils occur in fine-grained volcanic ash-beds, which, together with coarser materials of the same origin, constitute the deposits of the old lake-basin. The age of the beds is apparently about that of the oligocene, and the climatic conditions may have resembled those of the northern shores of the Gulf of Mexico at the present day. A complete description of the insects will be awaited with much interest. Mr. Packard's monograph of the phyllopod Crustacea of North America, having been already noticed in *Science*,[1] need only be mentioned. In the latter part of the first volume, Dr. R. W. Shufeldt treats of the osteology of the Cathartidae

[1] Vol. ii. p. 571.

and North-American Tetraonidae, the burrowing owl, horned lark, and shrike.

On the Yellowstone national park, or reservation as it may perhaps more fitly be called, much has already been written, both of a scientific and popular character; but the second volume of the present report is the first proximately complete account of its physical and geological features. The first scientific exploration of this wonderful region was that of the survey of the territories in 1871 and 1872; and it is largely due to the personal efforts of Dr. Hayden that the district was set apart as a national park. Though reports more or less garbled, of its geysers and hot-springs, were from an early period in circulation in the west, they were not generally credited; and it is a remarkable fact, that this region, in the midst of so much active exploration of the west, continued so long practically unknown. It remained for the ubiquitous western 'prospector' to afford some intelligible account of its character between 1863 and 1869; and Dr. Hayden's first exploration followed not long thereafter.



OLD FAITHFUL GEYSER IN ACTION, 1871.

The reservation is situated mainly in north-western Wyoming, but embraces also portions of Idaho and Montana. It is about 65 by 53 miles in extent, with a computed area of 3,312 square miles, of which nearly 200 square miles are occupied by lakes. To the north and east are bounding ranges of lofty and rugged mountains; but, apart from the cañons of the rivers, the region itself does not abound in grand scenery, consisting chiefly of high rolling plateaus covered with dark coniferous forest, but, along the borders of the streams, opening out into the attractive park-like country characteristic elsewhere of many of the sub-alpine valleys of the Rocky Mountains. The mean elevation, being about eight thousand feet, renders it subject to frosts throughout the summer, and quite unfit for agriculture: indeed, the frequent reference to snow-storms as interfering with the operations of 1878 would alone be sufficient to indicate the sub-arctic character of the climate.

The geology of the park is reported on by Mr. W. H. Holmes, who carries with him throughout a clear appreciation of the bearing of observed facts on the causes and history of the remarkable events of which this portion of the 'great divide' has been the theatre. While most of the formations known in the north-west are represented in the park, a glance at the map shows that those of volcanic origin cover by far the greatest area; and it is in connection with these that its special features have been developed. Volcanic conglomerates of tertiary age are particularly prominent, and attain in some places a very great thickness. Rhyolite preponderates, but basalts also frequently occur; and the existence of large masses of obsidian or volcanic glass is a point both of mineralogical, and, from the use made of it by the Indians, ethnological interest.

From the deeply eroded valley of the Yellowstone, almost all the facts as to the pre-tertiary history of the park are drawn; and the line of this river appears to have been determined by a great fault for which a minimum estimate of the displacement is given at 15,000 feet. This fault was probably synchronous with the general Rocky Mountain uplift, and is presumed to be in more or less direct causal connection with the subsequent remarkable history of the district. It is not a simple fissure, but a break along which the edges of the strata have been much dragged and contorted, particularly on the dropped side; appearing, in fact, to have the character of a great flexure pushed to fracture. On its northern side rises the Yellowstone Range; while to the south, in the depressed area, are found the evidences of that prodigious volcanic activity of which the actual thermal phenomena are the last lingering stages.

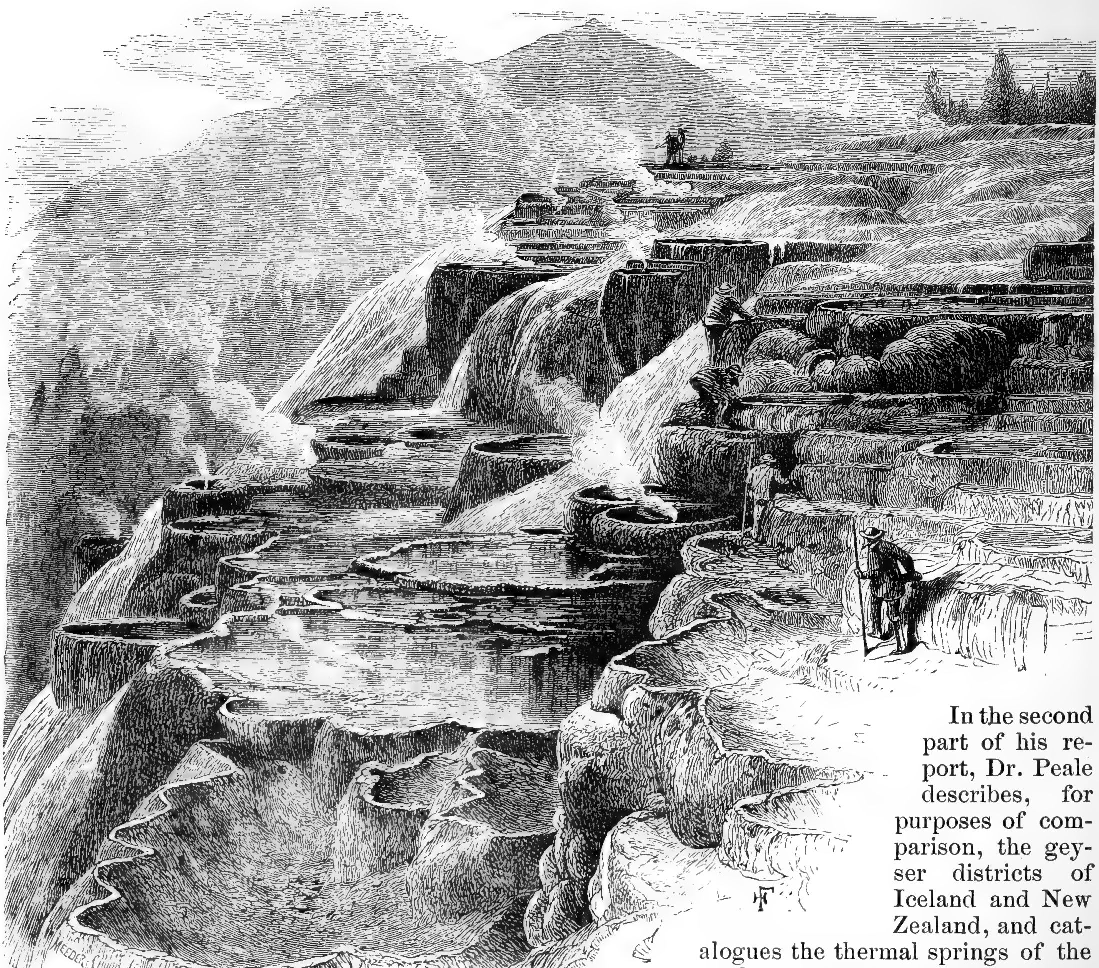
From the older tertiary rocks of the park have been collected a number of plants which Professor Lesquereux refers to the Fort Union group; but, before the inauguration of the volcanic periods, these beds, together with the paleozoic rocks, had been deeply scored by erosion. The earlier flows of trachyte and rhyolite poured into the then existing valleys till they were, in many cases at least, entirely obliterated, and the successors of these first rivers forced to cut new channels having little or no reference to the position of the old. Subsequent lava-flows again filled these later valleys, and, through the succeeding basaltic and conglomeritic epochs of activity, this process appears to have been repeated many times. The entire period of volcanic activity must have been of extremely long duration, and may have lasted through a great part of the tertiary. From the volcanic conglomerates of Amethyst Mountain, plants of upper miocene or lower pliocene age have been identified. Very much yet remains, however, to be discovered in the history of this prolonged period, which, in its succession of volcanic outbursts alternating with epochs of quiet river-work, much resembles that of the classic tertiary volcanic region of central France, and may, when fully disclosed, tell as interesting a story. In Amethyst Mountain some of the latest stages are well exemplified, and we have, perhaps, the finest series of buried erect forests ever discovered. The volcanic rocks, here characteristically conglomeritic, show a thickness of five thousand feet, and are charged almost throughout with the silicified remains of ancient forests. The lower layers are comparatively fine grained, but are followed by conglomerates which become coarser and more breccia-like in ascending, but are throughout interbedded with sandstones, and shaly layers largely tufaceous in character, and appear to be partly water-bedded and partly sub-aerial. The intervals between successive eruptions have been sufficient to allow the surface to become clothed again and again by a heavy forest-growth, each of which has been destroyed and buried in turn.

GRAND CAÑON OF THE YELLOWSTONE.

There can be little doubt that the hot-springs have been continuously in existence since the volcanic period; and actual evidence of their great antiquity is found in the occurrence of fragments of the characteristic calcareous deposit in some of the higher river-terraces, since the formation of which the Yellowstone has cut for itself a cañon a thousand feet in depth.

For an account of the hot-springs and geysers as found at the present day, we must, however, turn to the second section of the report, in which Dr. Peale treats the subject in an exhaustive manner, tabulating over two thousand springs and seventy-one

geysers. The springs show some evidence of linear arrangement, but dispose themselves for purposes of investigation in a series of groups, which are systematically described, mapped, and illustrated. The eruptions of the principal geysers are tabulated with the purpose of investigating the regularity, or otherwise, of the eruption periods ; and, in collecting and reviewing all that has already been observed on this point, Dr. Peale has had by no means a light task. So many accounts have already appeared of the more remarkable geysers and springs, that their main features have become more or less familiar to all, in so far as they can be made so by description. The Giant, Castle, Grand, Old Faithful, Giantess, Bee-Hive, and others of the best known geysers, are included in the upper geyser basin of the Fire-Hole River; and the flow of heated water is here so great as to notably affect the temperature of the stream itself. In this area alone, not quite four square miles in extent, 440 springs are known, of which 26 are veritable geysers, some, during these paroxysms of eruption, producing columns of 150 to 250 feet in height.



BASINS AT MAMMOTH HOT-SPRINGS OF GARDINER'S RIVER.

In the second part of his report, Dr. Peale describes, for purposes of comparison, the geyser districts of Iceland and New Zealand, and catalogues the thermal springs of the world. In the third, under the title of 'Therma-hydrology,' the general features of hot-springs are discussed : their physical and thermal conditions, formations and deposits, and geyseric phenomena, are reviewed, bringing out many points of interest. The geysers of all parts of the world are essentially similar in character. Those of the park are remarkable for the development of chimneys, or cones, at their orifices, — a fact attributed to the greater antiquity of the now existing vents, but which, it appears

equally probable, may arise from the greater dryness of air in the park region as compared with that of Iceland and New Zealand.

The chemical investigation of the Yellowstone springs is not yet sufficiently complete for their satisfactory classification; but they are broadly divided by Dr. Peale into those of calcareous, siliceous, and aluminous character. The so-called aluminous springs, being those highly charged with mud, or matter in a state of suspension, will doubtless eventually be relegated to one or other of the first-named classes. The possible therapeutical value of the springs is as yet practically untested; and it is to be remarked in this connection, that the climate is such as in any event to be unfavorable to those suffering from debilitating diseases. A few experiments on the color of the waters are recorded; but these, it must be confessed, are unsatisfactory, as the samples had been long in bottle; and, apart from this, it is doubtful whether the waters of the park offer peculiarities so marked as to throw any important light on a subject which has already been elaborately studied by physicists and chemists.

The older theory of geyser action requiring a steam-chamber which blew off, from time to time, through a water-trap connecting with a tubular orifice, and implying a quite exceptional co-ordination of circumstances, became virtually untenable when geysers were discovered in such considerable numbers in different regions. Bunsen's explanation, depending on the superheating of water under pressure in fissures, or more or less tubular receptacles, seriously modified in action by local circumstances, is considered sufficient to account for the observed phenomena.

Appended to this report, is a valuable bibliography of the park, and of the literature treating of geysers and hot-springs generally.

In the latter part of the volume, Mr. Gannett reviews the geographical work on which the excellent maps accompanying the report are based.

Notwithstanding the amount of precise information now made available on this region, much yet evidently remains to be discovered. The field-work on which the report on the park is based extended over about two months only; and the observations have too often been of what Mr. Holmes regretfully describes as the 'twenty-five-mile-a-day kind.' Armed with the present report, embodying the results so far obtained, each scientific visitor for a long time to come may well hope to add some important new facts. The definition of the catchment areas from which the various groups of springs are supplied, and the circulation of the underground waters, may be specially noted as an important point scarcely yet touched.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Princeton science club.

Nov. 8.—Dr. L. W. McCay reported that the Perrot method for estimating P_2O_5 can only give accurate results providing chlorine be absent. This, however, is seldom the case in apatites, superphosphates, etc. He therefore proposes a modification,—dissolving the tri-argentic phosphate from the filter-paper with dilute nitric acid, thereby leaving the chloride, and proceeding at once to titrate the silver according to Vallhardt. He reserves for himself the privilege of developing the subject.

Jan. 10.—Dr. Halsted opened a discussion as to whether Euclid was a suitable text-book for elementary geometrical instruction;—Mr. Fine read a paper on Synthetic solution of a class of problems in maxima and minima on the partition of a segment of a circle;—Professor Macloskie, Notes on biological articles in recent scientific serials;—Dr. McCay, Analysis of beer made in state of New Jersey;—Mr. McNeill, Determination of co-ordinates of certain stars by the meridian circle;—Professor Scott, The lamprey (the peculiar flattened shape of the spinal cord in the lamprey arises late in larval life, and is an acquired peculiarity. In the embryo the dorsal roots of the spinal nerves are all connected by a commissure, which also connects the tenth, ninth, and seventh nerves together, and with the spinal nerves. This commissure apparently forms the lateral nerve. The third nerve arises independently, and would seem to be of segmental value);—Professor Osborn, A method of double injection of anatomical specimens (by first injecting the veins through the arteries with blue gelatine, then injecting the arteries with plaster of paris, which is stopped at the capillaries, the veins and arteries can be readily distinguished);—Professor Young, The cause of the unusual sunsets, On the spectrum of the Pons-Brooks comet.

Ottawa field-naturalists' club.

Jan. 17.—The paper of the evening was by Mr. E. Odlum, M.A., of Pembroke, 'On the sand-plains and changes of water-level of the Upper Ottawa;' the portion of the river specially referred to being a stretch of some forty miles opposite the town of Pembroke, and extending from the head of the Coulonge Lake to the entrance of the reach known as the Deep

River. The district thus included lies along latitude 45° 50′, between longitudes 76° 40′ and 77° 40′; the town of Pembroke being 77° 10′, with an elevation above sea-level of 423 feet. At the upper end of the district the Ottawa divides its waters, and encircles the large Allumette Island; the Culbute Channel on the north being narrow, while the southern one expands so as to be known as the Upper and Lower Allumette Lakes. On the Quebec shore the land rises precipitously; the Laurentian Mountains seldom receding more than a mile, and at times rising sheer from the water's edge in towering cliffs of trap. On the Ontario side the land is comparatively undulating, and rises by a succession of plateaus separated by ridges of rock, or by ranges of hills gradually increasing in height. After a graphic description of the beauties of this district, the writer outlined the principal sand-plains which constitute a large portion of the steppes of the southern shore, and pointed out that their levels coincided with the well-marked terraces found on Allumette Island and at other points along the river. The formation of these sand-plains was then fully discussed; and it was claimed that they had undoubtedly been formed from the *débris* transported by flowing water from the rock ranges that bound and intersect them, and toward which the surface gradually changes from fine sand (or occasionally clay), through coarser sands, pebbles, etc., to bowlders. The principal plain is that called the Chalk-river sand-plain, extending from near Pembroke, twenty miles westward. It is interrupted toward the lower end by broken ridges, which harmonize in position with the rapids, and which formed parts of barriers between a higher level westward and a lower level eastward. Occasional sand-ridges occur, which lie between the ancient mouths of rivers, of which some are now extinct, and others, as the Petawawa and Muskrat, still flow in greatly diminished volume. The two principal levels of this plain correspond with two terraces boldly marked on the Laurentians near the head of Coulonge Lake, fully thirty miles away. A lake as large as, or larger than, Superior must in the past have hidden in its great depths Allumette Island, the entire Pembroke district, and adjacent sand-plains, as well as thousands of the now arable acres lying toward Renfrew. As indicated by the terraces, there had been two distinct periods, in the first of which the water had been 200 feet deeper, and in the second 100 feet deeper, than the present level. After describing the constitution of the soils derived respectively from the granite or trap ridges, and their relative capacities for agriculture, the writer very lucidly and interestingly explained the changes, as witnessed by him, which are still going on in the district, and the manner in which, by the incessant weathering and denudation of the rocks, sand-plains on a smaller scale are still being formed. The present barriers which cause the rapids interrupting navigation were explained to be of varying degrees of hardness, so that change proceeds more rapidly at certain points. Thus the channel rocks at the foot of the river-reach in question are composed of fine sandstones (Potsdam) compacted with bluish clay, and are being rapidly eroded; and at a not excessively remote date the channel will be so lowered that the upper and lower lakes will form one navigable level, while the channel to the west, having a much harder bed-rock, will be changed to impassable rapids by the subsidence of the lake below them. Reference was made to various older channels which evidenced former higher levels which the existence of terraces and undoubted water-lines fully confirmed. In the discussion that ensued, several members who had visited the locality and other portions of the Upper Ottawa gave evidence as to the existence of numerous traces of old water-currents at points now much above the present levels.

Mr. H. M. Ami presented a list of the Cambro-silurian fossils of the neighborhood, containing 228 species, and prefaced by a few notes as to its compilation. The report of the geological section on the summer's work was also read, and the president announced that classes in botany and zoölogy would be held weekly.

Franklin institute, Philadelphia.

Jan. 16. — The annual report of Board of managers exhibited the addition of a hundred and thirty-nine new members during 1883, and of over three thousand volumes to the library. Preparations for the Electrical exhibition, to be held during the autumn of 1884, are in an advanced state. A national conference of electricians is in contemplation. The subject of a "Proposed ordinance for the examination of steam-engineers" was warmly debated, *pro* and *con*, but no decisive action was taken. Mr. S. Lloyd Wiegand read a paper defending the use of cast iron in the construction of steam-boilers, it having been alleged by Nystrom and others that steam-boilers with flat cast-iron heads were dangerous. The secretary's report embraced a summary of engineering and industrial progress for the past year.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

The U. S. naval observatory.

Vice-Admiral Stephen C. Rowan was appointed July 1, 1882, to succeed Rear-Admiral John Rodgers as superintendent of the observatory. On May 1, 1883, Vice-Admiral Rowan was relieved by Rear-Admiral R. W. Shufeldt. The report of Admiral Shufeldt to Commodore J. G. Walker, chief of bureau of navigation, under date of Oct. 22, 1883, covers the work of the observatory for the past year.

The *personnel* of the observatory is as follows: —

Rear-Admiral R. W. Shufeldt, superintendent; Commander W. T. Sampson, assistant to superintendent; lieutenants, Pendleton, Moore, Bowman, Gar-

vin, Wilson, Harris, Sewell; ensigns, Brown,[1] Allen, Taylor, Hoogewerff; professors, Hall, Harkness, Eastman, Frisby; assistant astronomers, Skinner, Winlock, Paul; clerk, Thomas Harrison; computer, W. M. Brown, jun.; computers (transit of Venus), Woodward, Flint, Wiessner, A. Hall, jun.; instrument-maker, W. F. Gardner; also three watchmen and nine laborers.

The report, which is not yet published, contains a brief account of the work accomplished with the principal instruments of the observatory, — the 26-inch and 9.6-inch equatorials, the transit circle, prime vertical and meridian transit, — and the progress in the chronometer department, the department of nautical instruments, the library, and also in the reductions of Gilliss's Zones of 1850, 1851, 1852.

The 26-inch equatorial. — This instrument has been in charge of Prof. A. Hall, with Prof. E. Frisby as assistant. Mr. George Anderson is employed as an assistant in the dome. The canvas covering for the opening of the dome is still used, and a change in the raising and lowering of this covering has been made in order to avoid the friction of the wire ropes. Thus far the new arrangement has worked well. This equatorial has been employed, as in preceding years, for the observation of double stars, satellites, and comets. The satellites of Saturn, Uranus, and Neptune have been observed; and we have now collected a large number of observations of these satellites. The ring of Saturn has been observed, but no remarkable changes have been noticed. In fact, many of the strange phenomena frequently described in connection with this unique ring, the observers here fail to see on the best nights. During the greatest opening of the ring, which is near at hand, it is intended to make a set of micrometric measures of the dimensions of the ring. Some observations for stellar parallax have been undertaken; but, as the observer resides at some distance from the observatory, such work is very laborious, and it seems better to defer it until more convenient arrangements are made. At the present time the pressing need on this instrument is, that the observations of satellites already made should be discussed for the purpose of correcting the orbits of these satellites, and of determining the masses of the planets. This discussion has been begun, and the numerical calculations are being made by Ensigns W. H. Allen and J. A. Hoogewerff.

The transit circle. — This instrument, in charge of Prof. J. R. Eastman, was employed in the same class of work as in 1881–82. The observers were Professor Eastman, and Assistant astronomers A. N. Skinner, Miles Rock,[2] and W. C. Winlock. Professor Eastman was absent, in charge of a transit of Venus party at Cedar Keyes, Florida, from Nov. 1, 1882, to Jan. 1, 1883. Assistant astronomer Miles Rock, who was detached in September, 1882, for duty with the transit of Venus party at Santiago, Chile, was away until Feb. 10, 1883. The whole number of observations made with the transit circle from Oct. 18, 1882, to Oct. 18, 1883, is 3,880.

[1] Appointed professor of mathematics, U.S.N., Oct. 13, 1883.
[2] Succeeded, Nov. 1, 1883, by Prof. H. M. Paul.

The meteorological observations have been continued, as in former years, by the watchmen.

The 9.6-inch equatorial. — This instrument has been in charge of Commander W. T. Sampson, assisted part of the time by Lieut. W. E. Sewell, and part of the time by Lieut. John Garvin. It has been used, as in former years, in observations of the phenomena of Jupiter's satellites, occultations by the moon, places of comets, and for obtaining corrections to the ephemeris places of minor planets.

Prime vertical instrument. — This instrument is in charge of Lieut. C. G. Bowman, assisted by Ensign H. Taylor. Observations with it were recommenced Nov. 14, 1882. Continuous observations have been restricted to about forty stars, in no case exceeding 2° zenith distance when on the meridian; and these, with one exception, have been closely confined to the time of the two maxima of aberration. The one exception referred to was in the case of α Lyrae, which has been regularly observed throughout the twenty-four hours, having in view the possibility of a determination of its absolute parallax. Up to this time about five hundred and eighty observations have been secured. In the reductions, Struve's formulae have been used; and the labor has been greatly lessened by the use of his auxiliary tables for the prime vertical transit.

Meridian transit instrument. — This instrument has been in charge of Lieut. U. R. Harris, and Lieut. E. C. Pendleton has assisted. Since July 10, Lieuts. Pendleton and Harris have alternated in determining the correction of the standard mean-time clock. The meridian transit instrument has been used for the observations of stars of the *American ephemeris* for clock and azimuth corrections, and the determinations of the right ascensions of the sun, moon, and major planets. The total number of observations of the character mentioned is fourteen hundred and eight. Observations have been taken as often as practicable, to obtain each day the correction of the standard mean-time clock for setting to correct time the transmitting clock, which is used in sending out the time-signals from the chronometer-room, and in rating the chronometers.

National museum.

Publications. — Volume 5 of the 'Proceedings of the National museum' has just been issued from the Government printing-office. It contains 703 pages, and includes 87 articles by 34 authors, grouped topically as follows: mammals, 4; birds, 21; reptiles, 2; fishes, 48; mollusks, 3; crustaceans, 1; insects, etc., 2; plants, fossil and recent, 4; minerals and rocks, 2; art and industry, 1.

Catlin Indian paintings. — The Catlin collection of Indian paintings recently given to the museum by Mrs. Joseph Harrison of Philadelphia, is now being prepared for exhibition. This collection consists of over six hundred paintings, chiefly portraits and delineations of ceremonies, games, and hunting-scenes, made by the artist during eight years' residence in the western territories, Mexico, and British North America, previous to 1840. It contains authenticated

portraits of three hundred and fifty men and women, and over three thousand figures of Indians of the tribes known as Sacs, Foxes, Konzas, Osages, Comanches, Pawnees, Kiowas, Sioux, Omahas, Missouries, Mandans, Flatheads, Blackfeet, Crows, Gros Ventres, Crees, Assineboins, Chippewas, Iroquois, Ottawas, Winnebagoes, and twenty-seven other tribes. Its value as a record of ethnological characters is inestimable.

There were two collections, — one consisting of the original paintings done in the field, exhibited by Mr. Catlin for many years in Europe; the other, copies made at a later date, which was exhibited in the old Smithsonian building many years ago, and now the property of Mr. Catlin's heirs. The collection given to the museum is the original one, and is regarded by artists and ethnologists as by far the most valuable. The pictures, which have been for fifteen years stored away in a warehouse in Philadelphia, are in a remarkably good state of preservation.

There are also on exhibition five paintings by Stanley, — all that remains of the Stanley collection of Indian paintings destroyed by the fire in the Smithsonian building in 1865.

Naval officers in the museum. — In continuance of the policy adopted two years ago, the secretary of the navy has detailed six more ensigns to duty in the museum. These are graduates of the Naval academy in the classes of 1877–79, who have just finished their first three years' cruise, and will now give two years to scientific work under the direction of the officers of the museum. Mr. C. S. McClain has been assigned to the department of marine invertebrates; Mr. C. H. Harlow, to that of arts and industries; Mr. H. M. Witzul, to metallurgy; Mr. H. S. Knapp and Mr. O. G. Dodge, to mineralogy.

Department of mineralogy. — Prof. F. W. Clarke, chemist of the Geological survey, has been appointed honorary curator of minerals, and is preparing a series of minerals for exhibition. Mr. W. S. Yeates, aid in the museum, who has been in temporary charge of the minerals since the death of Dr. Hawes, the former curator, is acting as assistant in this department.

Mr. Joseph Willcox of Philadelphia has deposited his collection of American minerals in the museum, and one thousand of the choicest specimens have been placed on exhibition.

Foods and textiles. — Mr. Romyn Hitchcock is acting as assistant curator, having in charge the collections of foods and textiles. The collection is very rich in the textile products of the Indians, and has considerable quantities of food-materials acquired from foreign governments at the close of the Philadelphia exhibition.

Explorations in Corea. — Mr. Pierre L. Jouy, of the museum staff, is attached to the American embassy in Corea, and is making zoölogical explorations. Ensign J. C. Bernadou, U.S.N., has sailed for Corea, to spend two years in ethnological and mineralogical explorations. Mr. Bernadou was one of the officers detailed to duty at the museum last year.

Voyage of the Albatross. — The steamer Albatross sailed from Norfolk, Jan. 8, for a four-months' cruise in the Caribbean Sea, in the service of the hydrographic office of the navy. She is under command of Lieut. Z. L. Tanner, and carries a special staff of zoölogical workers, including Mr. J. E. Benedict, naturalist in charge; Mr. Willard Nye, jun.; and Ensigns Miner, Garrett, and Ackerman, U.S.N., of the museum staff.

Mammal department. — Mr. Frederick W. True, curator of mammals, is in England, studying methods of investigation and museum administration with Professor Flower, at the Royal college of surgeons in London.

Foraminifera. — Prof. L. A. Lee of Bowdoin college was in Washington, Jan. 3 to Jan. 8, studying the museum collections of foraminifera with reference to his investigations upon the materials obtained by the Fish commission.

Director's office. — During the reconstruction of the east end of the Smithsonian building, Professor Baird is occupying an office in the north-west pavilion of the museum.

NOTES AND NEWS.

All the parties sent out by the various governments at the suggestion of the International polar commission have returned home safely, and with valuable meteorological and magnetic records, with the exception of three. The Russian station at the mouth of the Lena will continue its work for another year, on account of delay from storms in reaching its destination. The Finnish, at Sodankyla, although it has finished one good year's work, will continue for another, as the government of Finland has supplied the necessary funds. The misfortunes of the Greely party are too well known.

— The first number of the *Auk*, published under the auspices of the newly organized American ornithologists' union, closely resembles the Bulletin of the Nuttall club, of which it is the continuation, and bids fair to be a credit to American ornithologists. An excellent colored plate forms a frontispiece to the number, and the articles are varied and interesting. One would perhaps justly complain of the space given to disputes over words, and lament the entire absence of papers upon either the anatomy or the general structure of birds, but these are perhaps to come in future numbers; and there is a pleasant flavor of careful out-door observation running through some of the papers, such as those of Messrs. Brewster, Barrows, and Bicknell. The effect of the formation of the union four months ago, is already seen in the plan offered by the committee charged with the subject for co-operative work in the study of bird-migration on this continent. We think a brief account of the formation and purpose of the union would have been a fitting introduction to the number.

— Professor F. M. Snow of the University of Kansas, from observations taken at Lawrence, reports that only three Decembers in the past sixteen years have been milder than that just passed, — 1875, 1877,

and 1881. There were very few days during the month in which building operations were not actively pushed. The sky was clearer, the wind was higher, and the rainfall was more than fifty per cent smaller, than the December average. The remarkable prolonged crimson and orange sunset glow, which was observed in the last week of November, continued with a somewhat intermittent brilliancy during the month of December.

— We take the following personal notes from *Nature*: —

Prof. W. H. Macintosh has been elected to the professorship of comparative anatomy in Trinity college, Dublin, *vice* Professor Macalister, F.R.S., who resigned on his appointment to the anatomy chair at Cambridge. —— By the death of the well-known mathematician, the Rev. W. Roberts, M.A., the Rev. Richard Townsend, M.A., F.R.S., becomes a senior fellow of Trinity college, Dublin, thereby vacating the professorship of natural philosophy held by him since 1870. —— The vacancy in the professorship of geology and mineralogy, in the University of Dublin, has been filled by the election of Professor Sollas of University college, Bristol. This appointment will give great satisfaction, and will afford Mr. Sollas large opportunities for paleontological research; the large collections of fossil plants and vertebrates in the museum in Dublin remaining to this day almost unknown. —— M. Houzeau, who was only recently appointed director of the Brussels observatory, has resigned his post; and it is reported that M. de Konkolly of Gzalla observatory, Hungary, will succeed him.

— The Swedish government intends to establish a botanico-physiological station in the north of Sweden for the study of the flora and the diseases of the crops in that part of the country.

— The Finnish government has ordered a steamer to be specially built in Sweden for the scientific researches about to be prosecuted in the Baltic.

— Lord Rayleigh has reprinted for private circulation, in pamphlet form, several of his most valuable optical papers, including those on the manufacture, reproduction by photography, and theory, of diffraction-gratings, and those on color-mixtures. He has also reprinted some of his papers on electricity and on absolute pitch, from *Nature* and from the reports of the British association, in a convenient pamphlet form.

— At its annual meeting, Jan. 11, the Cambridge entomological club elected the following officers: president, Samuel H. Scudder; secretary, George Dimmock; treasurer, B. P. Mann; librarian, C. C. Eaton; executive committee, Roland Hayward and T. W. Harris.

— Prof. H. Carvill Lewis, of the Academy of natural sciences of Philadelphia, has been appointed lecturer on geology and paleontology at Haverford college, Pennsylvania.

— A dissertation on the 'Proper names of Panjabis,' with special reference to the proper names of villagers in the eastern Panjab, by Capt. R. C. Temple, Bengal staff corps, contains a study of the proper names of the peoples of the Panjab. The book contains, also, long lists of names, showing by what classes of the population the various kinds of them are used, and is provided with an index to over four thousand proper names. The book is published at the Education society's press, Bombay, and by Messrs. Thacker Spink & Co. in Calcutta, and Messrs. Trübner & Co., Ludgate Hill, London.

— Sampson, Low, & Co. announce 'Heath's fern portfolio,' — a series of life-size reproductions of ferns, being in form, color, and venation, accurate representations. The work is to be published in monthly parts.

— The *Publishers' weekly* announces that Rev. A. B. Hervey of Taunton, Mass., has translated Dr. Behren's book on methods of conducting microscopical investigations in the botanical laboratory. He has enhanced the value of the translation by adding the methods of work used in this country.

— Cupples, Upham, & Co., Boston, have ready 'The amphitheatres of ancient Rome,' by Clara L. Wells.

— Schuver, during recent explorations in the Galla country, purchased from them a young negro of a race called Gambil, from whom he obtained interesting details in regard to his people. It appears, from his account in the *Revue géographique*, that the Gambils live on the Komonshi River, an affluent from the right bank of the Sobat, — a name which signifies Cow River, because in the dry season their numerous herds find forage only along its banks. Ostriches and elephants abound. They have a tree which bears a fruit two feet long, weighing ten or twelve pounds, which is softened in water, dried, and eaten. The principal village is Komonshok; but some thirty others were named by this negro, among them Kepil, which is a market where iron, copper, and beads are bought by the Gambils from the Gallas. They eat fowls and eggs, which the Gallas abominate, and raise pigs. They break out the two lower incisors, and wear two little horns of the gazelle or goat on the forehead. Some years since, they were attacked by the Denkas, who almost destroyed the tribe; many of whom, for safety, offered themselves as voluntary slaves to the Lega Gallas.

— At the November meeting of the London society of biblical archaeology, Mr. Pinches read a paper on Babylonian art, as illustrated by Mr. Rassam's latest discoveries. Among the discoveries on the site of the ancient Sippar, Mr. Pinches considers the most important to be a "small egg-shaped object of beautifully veined marble, pierced lengthwise with a rather large hole, and engraved with an inscription of seven lines (two double) containing the name of Sargon of Agade (3800 B.C.)."

Another small object, made of a dark-green stone in a bronze socket engraved or cast in the shape of a

ram's head, bears an inscription stating that it was presented to Samas, the sun-god, by a king of Hana. From the character of the writing, Mr. Pinches places the date of the relic at about 850 B.C., and draws from the fact that it was presented by a foreign king the conclusion that the shrine of the sun-god at Sippar must have attained to great renown.

Another most interesting object of about the date 685 B.C. is a lion's head carved in white limestone, perhaps originally forming a part of some piece of furniture. "The mouth, which was opened threateningly, showed the well-formed teeth. Above the upper lip were, on each side, five curved, sunken grooves, which were formerly inlaid with some material, probably to enable the long feelers or whiskers to be inserted. Wavy grooves for inlaying were also to be seen above the nose. The eyes were inlaid, and the holes for the insertion of the long hairs forming the eyebrows still remained. In the middle of the forehead there had originally been inserted the little winged figure emblematic of the god Assur." The accompanying inscription contains the names of the Assyrian kings Sennacherib and Esarhaddon.

Among other objects mentioned were statues of the sun-god and his attendant deities, all clothed in long robes. The reader pointed out that the specimens of art found by M. Sarzec at Tel-lo are finer than those found by Rassam at Sippar; the former coming from the more polished Akkadian, the latter from the more powerful but less refined Semite.

— The domestication of the ostrich in South Africa is of only some fifteen years standing, all previous product of plumes being due to hunting. At first there was much opposition to the proposal; and it was fancied that the plumes of domesticated birds would prove of inferior quality, which has not turned out to be the case. In 1865 there were only eighty, but in 1883 there are more than a hundred thousand tame ostriches. They have even been introduced into California. In 1880 forty millions of capital was engaged in the business, and a hundred and sixty-three thousand pounds of feathers were exported from the Cape, worth nearly $4,200,000. The birds are kept in enclosures, which, in a natural state, must be twenty or thirty acres in extent per pair. When the area is diminished, they must be supplied with food. They begin to breed at the age of four years, but produce plumes after their first year. The plumes are cut or pulled out. In the latter case injuries sometimes result, both to birds and manipulators; so that the former process is preferred, although after six weeks it is necessary to remove the withered remains of the shaft. The feathers are classed according to their character; as, wing feathers (white), female feathers (white), tail feathers, fancy feathers (black and white), black feathers (long, medium, and short), and lastly gray feathers. Formerly the Cape plumes took only the sixth rank after those from Aleppo, Barbary, Senegal, Egypt, and Mogador, valued in the above-mentioned order. Now, however, the Cape plumes are ranked as high as any. The largest exportation is from Port Elizabeth. England is the great market, followed by France. New York is lately taking an important place in the trade. The value of the feathers has diminished one-third under the increase of production, but the cost of the birds has also diminished. A pair of breeders has been sold within two years for twelve hundred dollars; but at present a pair can be had for two hundred to two hundred and fifty dollars. Under good conditions, a bird produces fifty dollars' worth of plumes per annum, to which must be added the value of the eggs and chicks.

— The Catholic missionaries who have recently established themselves among the Massanzé on the west of Lake Tanganyika are meeting with a good deal of success. The men of the district, great travellers, speak mostly a jargon of several languages. Their own tongue is only heard in purity from the women, by whose aid a grammar and vocabulary have been prepared. An excitement was recently caused by one of the whites cobbling a shoe over an iron last. The natives took this for an actual white man's foot which had been cut off; and one of the missionaries was obliged to take off his foot-gear to satisfy them that white men had toes. The Uambembé, reputed cannibals of the adjacent mountains, who have never suffered any whites to enter their territory before, have welcomed the missionaries, and offered them sites for residence in the villages of the three principal chiefs. This mission-station will be re-enforced very shortly.

— The Stirling Castle, constructed at Glasgow especially for the China trade, during the past season has brought from Woosung to London a cargo of tea in thirty-one days. This is four days shorter than the best previous record. The vessel is supplied with engines of eighty-five hundred horse power, and maintained a perfectly regular speed of eighteen knots throughout the journey.

— In view of the constantly increasing number of meteorological stations in Russia, Rikacheff, vice-director of the Central physical observatory, has undertaken a careful verification of the instruments, methods, and conditions at the different stations.

— A. Roberjot, of the French navy, gives, in the *Bulletin* of the French society of geography, the results of a voyage in 1879 among the New Hebrides, and accompanies them by a small chart and several woodcuts in the text. The naval vessel Second sailed from Noumea, New Caledonia, and touched at various islands, beginning at the south-east with Annatom, and ending with Espiritu Santo to the north-west. Numerous interesting facts in regard to the present condition of the natives, some short lists of words and details in regard to the character of the several islands, are given, and form a useful contribution to our knowledge of a people who are rapidly changing under the influences of missionaries, civilization, and the so-called 'labor-trade,' which appears to be a kind of slavery into which the chiefs sell their unresisting people.

SCIENCE.

FRIDAY, FEBRUARY 1, 1884.

COMMENT AND CRITICISM.

As it has now been determined that the Greely relief expedition of 1884 shall be placed in the hands of naval officers, and that suitable vessels shall be purchased for the purpose, it is perhaps advisable to remind those interested of certain essential features of the task before us. It is desirable, that, whatever plans be adopted, it be distinctly remembered that the object of the expedition is to relieve Greely and his men; that it is essential to success that training and brains should lead the expedition, and that a mere naval training is not a sufficient qualification without experience in ice-navigation; that the praiseworthy ambition common to the best naval officers does not fit them for such technical work, any more than it would to write an epic poem; and, lastly, that qualified men may be had, and should be engaged, even if not nominally in command, and their advice should have controlling weight.

We pointed out some time since, that the responsibility for failure would be laid where it belongs, by the public, regardless of official pride or red tape. That brave men should perish because points of precedence cannot otherwise be comfortably settled, is unendurable. It is probably better that only one branch of the service should be concerned in the expedition. That this was not the case in 1883 is generally (whether rightly or not) supposed to have some connection with the *fiasco* which is now a matter of history. Apart from that, there is little doubt that Capt. Pike felt his judgment of the propriety of pushing into the ice overruled by the officer in charge, whether that officer was conscious of his influence or not. In the present expedition not the smallest loophole should be left for any such proceeding, or it is predestined to failure.

It is most unfortunate that at the present time we have probably not a single ranking officer in the navy of experience in the sort of navigation the expedition must necessarily encounter. However, since it is the case, it should be recognized in the organization of the expedition; and, if any doubt exist as to the willingness of the naval authorities to provide for the deficiency by availing themselves of technical knowledge outside of the service, a mandatory clause to this effect might well be inserted in the act of Congress providing for the expedition. It may be thought that we reckon too lightly the effect of the grave responsibility which will fall on the officers who may be selected; but the record of the two previous expeditions for the same purpose is a sufficient warranty for reasonable scepticism.

In order to secure to the fullest extent the unusual advantage arising from the coincidence in the time of holding the proposed International electrical exhibition in Philadelphia, and of the meeting of the American association for the advancement of science in the same city, in connection with the anticipated visit of the members of the British association to that city, the Franklin institute has appointed a special committee to confer with scientific men as to the best method to be adopted for securing, during the month of September, the assembling at Philadelphia of a conference of electricians. To defray the expenses of such a conference, a bill has been prepared, asking for a small appropriation from Congress. Scientific men interested in this measure are earnestly requested to give it all the aid in their power. Communications on the subject are respectfully requested by the committee, consisting of M. B. Snyder, Edwin J. Houston, William H. Wahl, W. P. Tatham.

One cannot fail, while reading books of travel, to note the poverty of geographic terminology.

Even those explorers who attempt to describe closely what they see are hampered by the lack of terms of precise meaning with which to name the elements of a landscape; for, apart from the rarity of teaching in this important branch of physical geography, there is too little recognition of the connection that necessarily and often clearly exists between internal structure and external form, — too great neglect of the evolution of topography, during which the features of youth, maturity, and old age, succeed one another. There should be a terminology as well defined and extensive as that which botanists have invented for the description of leaves; for it is about as indefinite to call a country hilly as to call a plant leafy. There should be a collection of typical forms in models or figures marked with descriptive terms, approved by some authoritative body, to serve as a standard by which travellers might be trained. The question is well worthy the attention of geographic societies and congresses.

It is much to be regretted that it has been found necessary to suspend the operations of the Northern transcontinental survey. It was organized about two years ago, under the direction of Mr. Raphael Pumpelly, to obtain a comprehensive and authoritative knowledge of the resources of the vast region in the northwestern part of our country tributary to the Northern Pacific railroad and the associated companies, at whose cost it was undertaken. Up to that time this extensive territory, embracing, perhaps, one-fifth of the United States, had been very imperfectly explored geographically, and was still less known as regards those resources which will contribute to the business of the railroads that traverse it. A large amount of accurate information has now been gathered, and in small part published. Mr. A. D. Wilson, of broad experience in western exploration, was put in charge of the topographical work, with Messrs. Goode and Nell as chief aids; and we have just received a set of six maps, the fruit of their first season's surveys, a notice of which will be found in the 'Notes and news.'

From a circular just issued by Professor Dohrn, we learn that the cost of publishing the *Zoologischer jahresbericht* for 1879 and 1880 amounted to nearly $7,000, while the income from sales of the publication amounted to only $2,317. The zoölogical station at Naples has thus been obliged to meet a large deficit, amounting to at least two-thirds of the cost of publication. It is plainly not within the means of the station to continue indefinitely this work without assistance. The governments of Italy, Germany, and Russia, as well as one or two zoölogical societies of Holland, have made subventions which cover about one-third of the deficit. The three volumes of this work already completed speak for themselves. Every naturalist will learn with regret that a work of such general usefulness is in danger of being discontinued from the cause above named. We certainly hope that Professor Dohrn's appeal for assistance will meet with a liberal response, both in the way of subscriptions for the *Jahresbericht* and in subventions.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Earthquake waves at San Francisco.

Assistant George Davidson telegraphs the superintendent of the U. S. coast and geodetic survey from San Francisco, that at 7 h. 24 m., last evening, earthquake waves were indicated by the delicate levels of the astronomical instruments of the observatory. The amplitude of each vibration was three seconds of arc, in three seconds of time, and they continued for twenty minutes.

C. O. Boutelle,
Assist. in charge of office, etc.

Coast and geodetic survey office,
Jan. 26, 1884.

Influence of winds on tree-growth.

I notice at p. 471 of the issue of *Science* for Oct. 5 some remarks by Mr. W. S. Kennedy on the influence of winds on tree-growth. It may be of interest to learn that many of the trees on the seashore at Government House, Malabar Point, Bombay, are bent landward from the effect of the prevailing sea-breeze.

H. Rivett-Carnac.

Allahabad, N. W. P., India,
Dec. 8, 1883.

Some curious natural snowballs.

On p. 237, vol. i., of *Science*, under notes and news, is a reference to some curious snowballs noticed in *Scientific American* for March 17. Such an exhibition I lately saw; and it may interest readers of *Science* to know the conditions favoring such a phenomenon.

On Jan. 8 and 9 some thirty inches of snow fell in this region, followed by warmer weather and light rain on the night of the 10th, settling the snow into a

compact mass. On the 11th and 12th came freezing weather, and the fall of a small amount of very light snow. On the 13th the thermometer, toward noon, rose above freezing-point, with a stiff breeze from the south. This wind so acted on the surface-particles of the upper layer of uncompacted snow as to set some of them in motion. Each particle thus set in motion, owing to the soft condition of the surface-snow, formed a nucleus, which, as it proceeded, forced along by the wind, gathered the contiguous portion of the soft layer, and assumed the form of a cylinder, with a conical cavity at each end, and having a length about twice as great as its diameter. The size depended upon the inclination and smoothness of the surface traversed. The largest cylinders I saw were about three feet long, at which limit they acquired sufficient weight to indent the frozen surface of the under or main body of the snow. This, of course, stopped the further rolling of the mass. The only locality where they acquired the above large size was where the surface had a slight inclination to the north; and the snow was deep enough to cover all weeds, leaving a perfectly uniform and smooth surface for their formation. In many cases the balls were rolled up an inclination of as much as one foot in ten, when exposed to the unbroken force of the wind; but those thus formed acquired weight sufficient to resist the pressure of the wind, when about six inches in diameter. When the surface inclined toward or directly away from the wind, the balls traversed a straight path; but, when the surface declined to the north-east or north-west, the path was a curve; at its initial, approximately straight; but, as the ball acquired weight, its direction was a compromise between that required by gravity and that by the direction of the wind, until, in some cases, the ball obeyed gravity alone. The most curious part of the display was the abundance of the balls. While travelling three miles, I saw what I estimated at over a hundred acres dotted more or less thickly with the cylinders. In some cases there were twenty-five balls to the square rod; in others, only two or three; averaging, perhaps, eight or ten. I saw multitudes in the process of formation, which was as sudden as a flash; but they almost immediately assumed a slow rate of motion, about that of a mole taking his leisurely walk. In a few cases the cylinders would stop, and afterward be forced into motion again. The largest examples required for their formation the traversing of from two to three rods. SAM HUSTON.

Richmond, O., Jan. 16, 1884.

The wind performed a very pretty feat in some portions of northern Ohio on the morning of Jan. 13. Loose bits of snow were caught up as a nucleus, and rolled along upon the surface until balls of considerable size and peculiar shape were formed. The whole surface was strewn with the balls; but they were most abundant upon lawns and fields where the wind was not obstructed, every square yard, in some places, bearing a ball of greater or less size. The largest observed here were upon the college ball-grounds, where they reached ten inches in height, and a horizontal length of eighteen inches. Even these were swaying as the gusts passed over them; and their tapering track could be plainly traced back towards the south-west, twenty-five or thirty feet, to the apex where they started. Their shape was cylindrical, deeply hollowed at both ends, so that they looked like 'muffs,' and the spiral formed by the successive layers was finely regular and distinct.

The meteorological conditions which made the phenomenon possible were as follows. Two days before the occurrence a slight crust was formed upon the snow. On the following day an inch of light flaky snow fell upon this crust. Then followed the warm south-west wind on the morning of the 13th, which brought the upper layer of snow into the adhesive state, and rolled the balls before the crust was weakened; the crust sustaining the balls, and keeping them up to the wind, and at the same time furnishing a smooth floor upon which they could be propelled. The nuclei of the balls were obtained from chance foot-tracks, walk-borders, lumps blown from trees, etc., though often it was difficult to account for them. The balls were most abundant and perfect at about nine o'clock A.M. Before noon the crust had been attacked, and all sunk to rounded, insignificant clumps.

Oberlin, O. ALBERT A. WRIGHT.

[Similar snow-rolls were seen at Sharpsville, Mercer county, Penn., on the same day, by J. M. Goodwin.]

Halos round the moon.

On the evening of Jan. 12, at 9.20 (90th meridian time), my attention was called to a peculiar appearance about the moon. The sky was quite clear at the time, and there appeared around the moon several colored circular bands. The first was of a bright silver-gray shade, and about two diameters of the moon in width. The next was yellow, the next faint orange, and the next violet. The three bands were each about one-half a diameter in width. The outermost band was of a green shade, and about two diameters in width. At ten o'clock the innermost light band remained, but all the others had been replaced by a blue band lighter than the surrounding sky.

Lafayette, Ind., Jan. 14, 1884.

Explorations in Guatemala.

Looking over the back numbers of your esteemed journal, I came across a slight error. In the article 'Lorillard City' it is said (ii. 412), "M. Charnay found the ruins of an ancient city, which he named after his generous patron. In his exploration here, he was assisted by a young Englishman, Mr. Alfred Maudslay, with whom he shares the honor of discovery," etc.

Neither Mr. Maudslay, who arrived at these ruins before Mr. Charnay, nor the latter, can claim this honor. In fact, Mr. Maudslay distinctly states (p. 196 of the *Proc. roy. geogr. soc.*, April, 1883) that they have been discovered by Mr. Edwin Rockstroh, tutor on the Lyceo nacional at Guatemala City. This gentleman made, during the first half of 1881, a geographical and archeological exploration in the northern and western parts of the republic, visiting Tikal, and navigating the Rio de la Pasion, Rio de las Salinas, Rio de los Gacandones, and the Usumasinta as far down as the ruins mentioned. He sent a short account of this voyage to Petermann's *Mittheilungen* (1881, p. 396).

In that account Mr. Rockstroh mentioned particularly the building described by Mr. Maudslay on p. 198 of the geographical society's proceedings; and (1882, on p. 435) he clearly states that Charnay's 'Lorillard City' is the same as that discovered by him in 1881. Mr. Rockstroh mentioned in his first letter to the *Mittheilungen* (July 19, 1881), that the Gacandones call these ruins 'Menche,' and promised in his last notice (1882, p. 435) an explanation of this name. I am not aware that he has furnished one.

I find in the 'Historia de la provincia de San Vicente de Chiapa y Guatemala,' by Antonio de

Remesal (Madrid, 1619), libro xi., cap. xviii.–xx., pp. 720–733, a province 'el Manché' mentioned as one of the provinces of Vera Paz, the Indians of which were converted in the years 1603 and 1604. Mr. Maudslay's map contains the Rio del Manché, an eastern tributary of the Rio Sta. Izabel, which latter, in its lower course, is called Rio de la Pasion. The province of Manché must evidently have been situated on the river of the same name, to the north of the village Cahabon, which was the starting-point of the Padres for their trip of conversion, as Remesal states.

Whether the name of this province, 'Manché,' has any connection with the word 'Menche,' as Mr. Rockstroh says the ruins on the Usumacinta (separated by a mountain chain from the central part of the Peten district) have, remains to be seen.

In regard to the notice in the same number and on the same page of *Science*, 'Explorations in Guatemala,' I beg to add, that the ruins of Tikal had been discovered in February, 1848, by Mr. Modesto Mendez, corregidor of the district of Peten, and by the gobernador Ambrosio Tut. Mr. Hesse, minister of Prussia in Central America, published the report of Mr. Mendez, dated March 8, 1848, in vol. i. of the 'Zeitschrift für allgemeine erdkunde' (Berlin, 1853, pp. 162–168), and added some general remarks, and two plates which he had carefully copied from Mr. Mendez's drawings. These plates contain the illustrations of four sculptures (in wood) and five monoliths discovered by Mr. Mendez in Tikal, and those of four monoliths discovered by him in 1852 in Dolores, — another town with ruins, to the south of Tikal, in the same district of Peten. The chairman of the Royal geographical society is therefore mistaken in stating (p. 203 of the Proceedings) that the ruins of Tikal were described for the first time by Mr. Maudslay.

The report of Modesto Mendez is mentioned by Mr. A. F. Bandelier in his Bibliography of Yucatan and Central America, in 'Proceedings of the American antiquarian society,' 1880, p. 92.

Barn-owls in Missouri.

In *Science* for Jan. 11 the occurrence of the barn-owl in southern Ohio in unusual numbers the present winter is recorded. The same fact has been noticed here. Four have been caught in the city in as many different buildings, and a number took up their habitation in an unused chimney in one of the principal residences in the city. Another was killed a few miles out. They are so unusual here that no one knew what kind of owl they were when the first was captured.

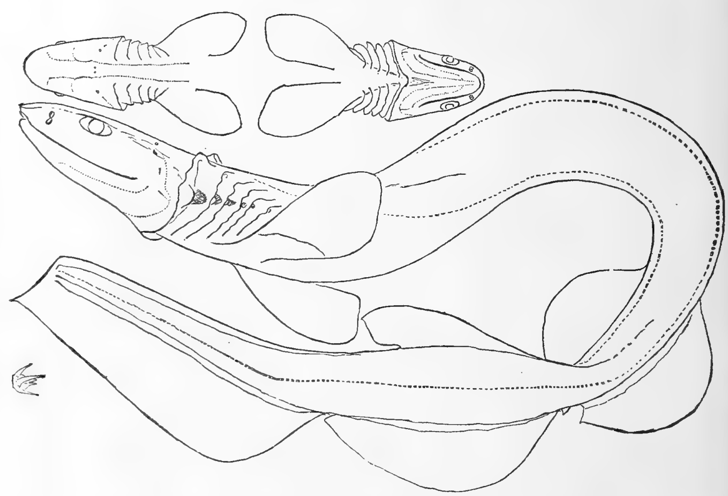
A PECULIAR SELACHIAN.

THE outlines given here are taken from a shark recently discovered in Japanese waters. It is a form of more than ordinary interest on account of the respects in which it differs from the majority of its kindred. 'Is it a sea-serpent?' is asked by all who see it. Those who believe in the existence of the ocean monster may certainly derive some encouragement from the discovery. About the throat the appearance is decidedly fish-like. The body is long and slender, five feet in total length, and less than four inches in greatest diameter; it becomes compressed and thin toward the tail. The head is broad, slightly convex on the crown, and has a look about it that reminds one of some of the venomous snakes. The mouth is anterior and very wide. As in other sharks, the teeth are arranged in rows across



CHLAMYDOSELACHUS ANGUINEUS.

the jaws; they are all alike. Each tooth has three slender, curved, inward-directed cusps, and a broad base, which extends back in a pair of points under the next tooth, thereby securing firmness, and preventing reversion. In the twenty-eight rows of the upper jaws, and twenty-seven of the lower, there are three times as many rows of the fangs or cusps. Of the six gill-openings, the anterior are very wide. Unlike other Selachians, in this the frill, or flap, covering the first opening is free across the isthmus, as in fishes, and hangs down about an inch. On the body the slime-canals — shown by the dotted lines in the sketch — form continuous grooves, as if the skin had been cut with a sharp knife; they extend to the extreme end of the tail. The spiracles are so small as to be useless; but, being present, they point toward an ancestor, a bottom-feeder, in

which they were more developed. In the nearly vertical nostril there is a peculiar arrangement. A fold reaching out from each side divides the opening into two, connected within, the upper of which looks forward, and, when moving ahead, catches the water, and turns it into the nasal cavity to pass over the membranes and escape by the lower aperture, which looks backward. Nictitating membranes are absent. The eyes are placed to look sidewise and downward. Above the anal fin, there is a small dorsal. The pectorals are of moderate size. Ventrals, anal, and caudal are large. From these fins, if it were not for lack of firmness toward the edges, one would conclude the animal was capable of great speed. However, taking into consideration the size of the branchial apertures — which allow the water entering the mouth free escape, whatever the rate of motion — and the position of the large fins, it seems as if the creature had the habit of bending the body and striking forward to to seize prey, as do the snakes. The broad fins, so far back on the body, secure a fulcrum from which to strike. At their margins the fins are very thin, and their extremities are produced in a sort of filament. The structure of the jaws and gill arches is such as to admit of swallowing a large object. At the same time the excessive sharpness of the teeth, and the smallness of the intestine, indicate that the prey is comparatively soft. The vertebrae and other cartilages are flexible, as those of the basking sharks Selache and Somniosus. A certain embryonic appearance in the specimen instigated a search among the fossils for allied species. Most resemblance was found in the teeth of Cladodus of the Devonian; but the cusps were erect instead of reclining, and the enamel was grooved or plicate instead of smooth. One is impressed by a study of this specimen with the idea, that, away back in times when Selachia and fishes were more alike, he would have a better chance to trace the affinities. The Bulletin of the Essex institute, vol. xvi., contains description and figures under the name Chlamydoselachus anguineus. I am inclined to consider this the type of a new order, to which the name Selachophichthyoidi might be given, and which stands nearer the true fishes than do the sharks proper. The shark was secured in Japan by Professor Ward, from whom it was purchased by the Museum of comparative zoölogy.

The sketch on the preceding page gives the entire outline, the upper and lower views of the head, and an upper view of one of the teeth.

S. Garman.

THE RUSSIAN METEOROLOGICAL SERVICE.

Although the idea that Russia is behind the other powers of Europe in civilization is true when we consider the people as a whole, yet, if we look at what has been done by the Russian government for the encouragement and advancement of science, it must be admitted that Russia plays a very important part in the total amount of scientific work accomplished by the world.

The Russians have the best astronomical observatory in the world: they have also the best meteorological observatory. The magnetical studies have been made in connection with the meteorological; and in the observations, as well as the theoretical discussions, we find the same men engaged, and the results are published side by side. In speaking of the meteorological work, one is forced, then, to at least mention the magnetical, on account of this close connection.

The Physical central observatory at St. Petersburg was founded in 1849 through the endeavors of Kupffer. The aim of this observatory was to institute physical observations and research in general, and to advance Russia in the line of physics; and, as part of the latter task, the conducting and publishing of meteorological and magnetical observations was undertaken.

So it will be seen that this observatory was not intended merely as a central office for a meteorological service; but it was to become a physical laboratory, where all sorts of physical investigations could be undertaken, and in such a manner that nothing more could be desired, that is, as far as apparatus and methods employed are concerned.

The first director, Kupffer, separated as much as possible the two departments of the observatory, as his publications show. His researches into the elasticity of metals, published in 1860, which were cut short by his death, show the nature of the purely physical investigations undertaken by him. He published an enormous mass of meteorological material in the *Annales de l'observatoire physique central*, 1847–64; also in the *Correspondance météorologique*, commenced in 1850.

In seven places hourly observations of the meteorological elements were instituted, and in six places of the magnetical elements. These and many of the observations from other stations, made a certain number of times a day, were published.

In speaking of this material, Professor Wild

said, "It is a complete mass of meteorological and magnetical observations published in detail, and therefore easily accessible to every one, and such as no other land possesses: it is of great value to the science; but it would have been much more valuable, yes, invaluable, if it was as satisfactory as comprehensive."

As at first organized, there were few under-officials in the observatory; and most of them were men who received small salaries, and were not especially qualified for their positions, — or, rather, there were no positions for men qualified, — so that the director was obliged to attend personally to all work requiring much thought. A force, then, of a director and five not specially prepared men was to conduct the work of the central office, from which were to be issued the meteorological observations, and their discussion, of a country five times as large as all the rest of Europe, through which about twenty separate meteorological institutes are distributed.

It is not to be wondered at, then, that Russian observations lay for so many years almost unused by their meteorologists. Any one who has attempted to work with magnetic observations knows that little can be done single-handed, especially if the person must also busy himself with the instruments themselves.

Through inability on the part of the director to cope thus single-handed with the great work undertaken, the meteorological service went gradually into decline. The separate stations could not be properly inspected to see that the instruments were correct, nor could the necessary attention be given to the preparation of the observations for publication. Matters finally came to such a pass, that about 1864 a re-organization of the service was agreed upon, and the establishment of forty new meteorological stations. However, the next year, and before any thing could be done, Kupffer died, and Kaemtz was called to succeed him.

This great meteorologist at once elaborated plans for the improvement and enlargement of the service; but a great undertaking of this kind goes forward slowly, and at his death, two years later, not much had been carried practically into effect.

The service, then, was in a disorganized condition when Wild took charge in 1868. Although it is probable that a great improvement would have taken place had Kaemtz lived, yet we can hardly hope that he would have placed the service in that high position which it now holds in reference to others, and which it assumed so shortly after the choosing of Wild as director.

Professor Wild doubled the corps of assistants, and made the positions so desirable and important that university men were glad to accept them, and good men from other continental countries were easily persuaded to accept places. These men were of such ability that they could undertake and successfully carry out, under the supervision of the director, any single investigations, and thus relieve the chief of that care and constant watchfulness which would have been necessary had he had less skilful assistants. The results of these labors can be seen in the papers published in the *Repertorium für meteorologie.*

But it is mainly of the Russian service as it at present exists, and especially of the meteorological observatory, that I wish to speak.

The whole establishment is composed of several observing-stations of the first order (i.e., where either hourly observations are made, or where self-registering barometers, etc., are employed), and about a hundred and thirty stations of the second and third orders, where observations are made at stated times during the day. In order to obtain an idea of the distribution of these stations, the reader must consult the chart accompanying the *Temperatur-verhältnisse des russischen reiches*, published in 1881 by the observatory.

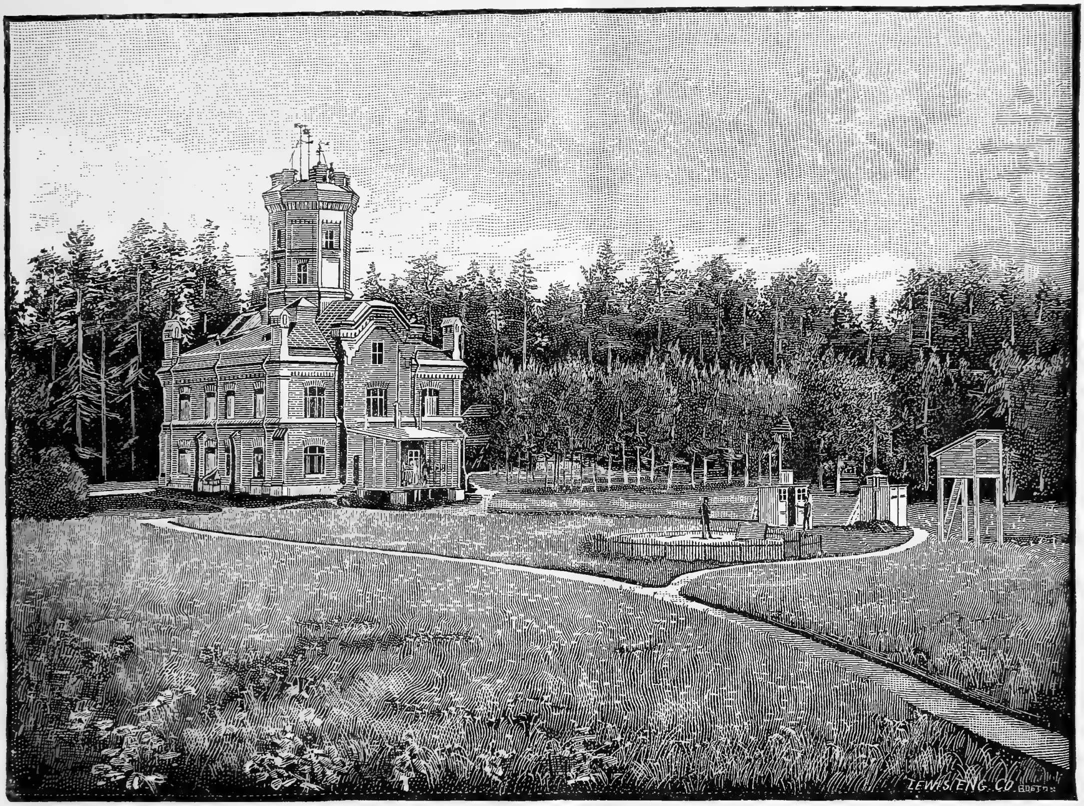
The meteorological observatory at St. Petersburg consists of two parts, — the Central physical observatory, in the city itself; and the observatory at Pawlowsk, in the country, about thirty kilometres distant. The present building occupied by the former was built about 1860, and continued to be the principal observing-station until 1877, when the other was grounded.

The building in St. Petersburg occupies a not prominent position at a little distance from the north bank of the Neva, in the western end of the city; but it has no longer the quiet surroundings that it probably had at the time of its construction, as the city is extending in that direction.

All of the work of standards, instrument-comparing, preparing matter for the printer, correspondence, supplying stations with necessities, and the general management of the whole service, is carried on here, and for eight or nine months of the year it is the dwelling-place of the director.

For the non-meteorologist, however, the only attractive feature of the institution is the large instrument saloon, where there is much fine apparatus, especially standards. The library is a very good one, and the numerous books in foreign languages show the extent to which the

Russians make use of foreign writings. In fact, very few of the books in the library are in the Russian, even when containing their own work. There is, however, a strong reaction in this respect; and before many years we may expect to receive the Russian scientific publications, not in the French and German languages, as at present, but in the Russian. This will be unfortunate for us; because the language is difficult to learn, and much of their science would be buried to us for a long time at least.



METEOROLOGICAL STATION AT PAWLOWSK, RUSSIA.

At Pawlowsk there is much of interest. It requires about an hour's time on the railway to go from St. Petersburg to this place. On the way there, the clump of trees surrounding the great Pulkowa astronomical observatory is visible; and in winter the main building itself can be plainly seen.

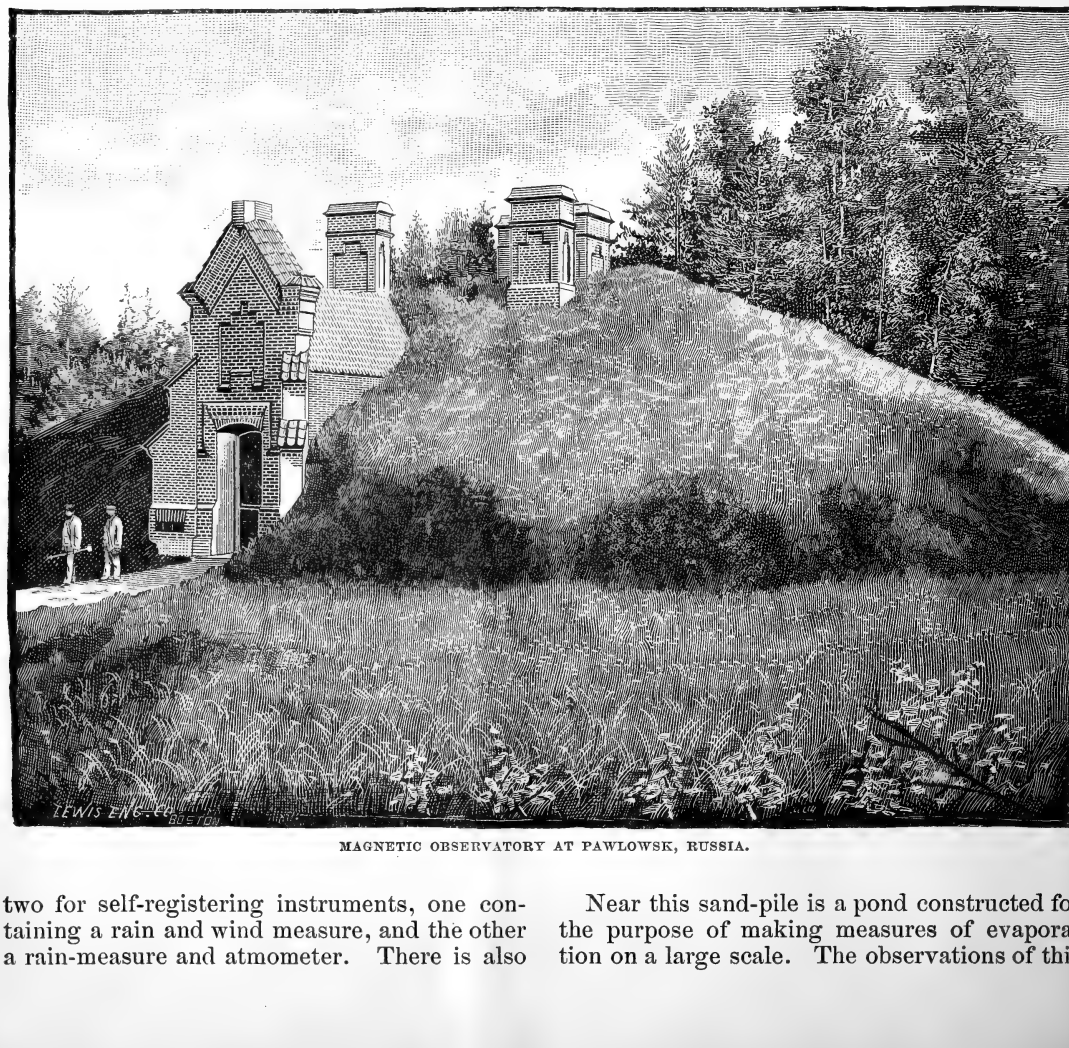
There were several reasons for the founding of this new observatory. Professor Wild had ideas that he wished to carry out, and which he considered essential for the best results: he had found the city observatory in a settled condition, and it would have been impossible to change it into such a form as he wanted. Again, the old observatory was a poor place for magnetic instruments, both on account of the unsteadiness of the instruments, and the close proximity to the iron ships that are constantly passing and repassing on the river, only a few hundred feet away. He also had the idea, which is shared by most meteorologists, that the city itself is no place to make meteorological observations; as the conditions are not the same as in the surrounding country.

This observatory is situated nearly two miles distant from the town of Pawlowsk, which lies thirty kilometres south-east of St. Petersburg. This town, although thinly inhabited in the winter-time, is filled to overflowing in the summer by the people from St. Petersburg, who want to enjoy what little summer country life they can find.

A small portion (several acres) of the park of the uncle of the present czar has been given for the purpose of the observatory, and this piece of ground has been fenced off and the buildings erected upon it. The land lies per-

fectly flat, and is mostly covered with fir trees; although, of course, part has been cleared, so as not to influence the readings of the instruments. The observatory is certainly the meteorological paradise (at least in summer); and the visitor, whether casual, or there for the purpose of study, cannot but be struck by the taste which has been displayed in its organization and construction. The whole establishment was erected at a cost of about seventy-five thousand dollars.

The accompanying illustration shows the main building from the north side. The large thermometer-shelter is seen against the building; a little to the right, through the trees, is seen the stable; and still more to the right the roof of the director's summer residence is visible. Of the smaller buildings, the one to the right is a thermometer-screen; the other another rain-gauge, and the black bulb *in vacuo* near these. Inside of the little enclosure is a sand-heap in which are buried the thermometers for measuring the earth's temperature at different depths. The instruments are placed both in a vertical and horizontal position. In order to get at the horizontal thermometers, a hole has been dug, which contains a box filled with earth, the hole being covered by a trap-door. The box can be slid from its position, and the end of the thermometer-cases exposed to view. These are then drawn out (horizontally) by the observer, and read without taking them from the hole. The vertical thermometers are not in this hole, but are drawn vertically out of the sand when read. The glass tubing surrounding the thermometers is so made that no moisture can reach the thermometer-bulbs.



MAGNETIC OBSERVATORY AT PAWLOWSK, RUSSIA.

two for self-registering instruments, one containing a rain and wind measure, and the other a rain-measure and atmometer. There is also

Near this sand-pile is a pond constructed for the purpose of making measures of evaporation on a large scale. The observations of this

kind are not, however, of a very satisfactory nature; and the pond has apparently returned to its legitimate use, viz., furnishing a home for about a million small fishes.

In no place in the world is so much attention paid to magnetic observations and investigations as here at Pawlowsk. We see in this cut the underground magnetic house, and its size can be seen by comparison with the figures in the foreground. The building consists of two chambers, separated and surrounded by air-chambers which are heated; and the heat is thus conveyed through the walls into the observing-rooms. These rooms remain at a wonderfully constant temperature. The building is quite isolated from the remaining portions of the observatory. It was here that the observations simultaneous with those of the recent international polar expeditions were made.

The whole work of this institution is scientific in the highest degree, and there is little of what we may call popular work done; but this is unnecessary, as those who would be influenced by a more evidently practical result have nothing to say in regard to the conduct of the service.

RED SKIES IN CHINA FIVE YEARS AGO.

The 'red sunsets' which have recently attracted so much attention in so many quarters of the globe, and have called forth considerable discussion in various scientific journals, both in America and Europe, recall very similar phenomena I observed five years ago, under circumstances which seem to me worth recording at this time.

During the early part of the winter of 1878–79, I had occasion to pass several weeks, engaged in geological work, along the base and among the foot-hills of the first mountain range that rises above the plain of northern China, and forms the boundary between the provinces of Chihli and Shansi. Frequently in the month of November my attention had been called to the intense coloring of the sky, and brilliant red afterglows, slowly fading away, and lasting long after the sun had set. On one occasion, Dec. 1, I left the small mountain village of Cheang-Shui, accompanied by my friend Mr. W. N. Pethick of Tientsin, for a long tramp among the hills. We travelled up the long valley, and ascended to the top of the pass commanding an extended view to the westward, over the plateau of Shansi. Although late in the day, we pushed on to the village of Tang-Cheng-Tsun, a mile and a half to two miles beyond, reaching there about sunset.

On our way back to the pass, I was continually looking backward, astonished at the brilliancy of the sky, the orange-red and peculiar brick-red colors of the horizon, and the length of time the vivid coloring remained after the going-down of the sun. How long this intense afterglow continued I am unable to say; as, on reaching the summit, we retraced our steps down what in the Cordillera would be called the cañon, and the western view was completely lost behind an abrupt wall.

All the phenomena connected with the sunset were quite similar to those recently observed in New York, except, as I now recall the scene, the colors seemed to surpass them in brilliancy.

Through the month of December I was frequently impressed with the deep red glare of the skies, and long twilights, although none of them appeared to equal in intensity the one observed from the top of the plateau. This difference I supposed was due to the view being somewhat shut off by the high ridge to the westward.

As early as November the prevailing winds in northern China blow almost continuously from the north-west, across the broad area of country covered with loess-deposits. In consequence, the atmosphere was never wholly free from fine loess-dust; a haziness being at all times noticeable in the mountains, while frequently the air was gray from the large amount of impalpable dust held in suspension. On those days when the dust was most perceptible the colorings of the skies were never remarkable, and were only fine when the lower atmosphere seemed clear and bright.

These brilliant afterglows continued at intervals throughout December and early part of the new year; the last one being noticed about the middle of January, from a small village seventy-five miles east of the mountains, where I had put up for the night on my way to Tientsin. In the following September I again visited the mountains and plateau of Shansi, but do not recall any thing in connection with the sunsets at all comparable to those observed the preceding winter. But, on the other hand, the atmospheric conditions were also wholly changed; the wind was blowing steadily from the east or ocean side; the air was laden with moisture, which was frequently precipitated in heavy rains; and the atmosphere, so far as the eye could detect, was free from dust. I can but think that the great brilliancy and long duration of the afterglow were intimately connected with loess-dust in some such way

as the recent remarkable displays have been attributed to the volcanic dusts of Krakatoa. The peculiar phenomena in the skies, like those described, were not noticed at Tientsin in the spring. This may be accounted for by atmospheric conditions being changed, and the air at this season of the year being overcharged with too much fine material derived from the dust-storms which form, during March and April, so marked a feature of the climate of northern China. I think it quite probable, however, that red skies, similar to those recently observed in various parts of the world, may at times be seen throughout the winter by foreign residents at Peking and Tientsin.

A few more words about loess-dust. During the winter referred to I was much interested in the question of the loess that was annually being removed from the land and carried out to sea, and not only was impressed with the amount transported by streams, but was led to believe that a not inconsiderable quantity was borne eastward by the prevailing winds, and finally precipitated upon the ocean. Inquiries brought out the fact, that, in the China seas, ships many hundred miles from land frequently report showers of fine material falling upon the decks, which in many cases have been wrongly regarded as deposits of volcanic dust. In conversation with the captain of the steamship China, on the passage from Yokohama to Hong Kong in the autumn of 1879, he narrated his experience in a dust-storm, while passing over the same route in the preceding spring. The storm occurred April 25, in latitude 29°, longitude 128°. It lasted twelve hours, with a heavy wind blowing steadily from the north-west. Every thing on board was coated with an excessively fine dust, which, as the captain expressed it, "was so thick that it could be taken up with the fingers like so much snuff." From the rigging, one of the sailors, under orders from the captain, collected with a knife-blade a large amount of the dust, samples of which he forwarded to London for examination. Now, I very well remember that in April the whole plain of northern China was enveloped in several severe dust-storms; two of them, at least, having a duration of three days each, and filling the air at times with dust, so as to completely obscure the sun. There is no question in my mind but that the material which fell upon the steamship came from the loess of China; and I believe that a great deal of the so-called volcanic dusts which are often reported as observed at sea are, at least in Chinese waters, derived from loess-deposits.

Arnold Hague.

THE EVOLUTION OF THE CEPHALOPODA.—I.

Cephalopods, or cuttlefishes, have structural peculiarities which make them the most favorable subjects now known for the special study of the problems and laws of the evolution of forms in time. In two of the orders the animals were shell-covered; and the shell in these is so built that it preserves, even in the fossils, the embryo, the young shell, and all its stages to the full grown. Then, passing on into old age, it shows in the senile period a series of retrograde transformations, often reversing its adult condition and aspect. This record of the entire life is fuller than any one who has not minutely studied this type can imagine from his experience in other branches of the animal kingdom. It is not only in itself a complete cycle of changes, and these of no slight or doubtful character, but the external records of the shell-structure, apertures, and other parts, are supplemented by the hard portions of two internal structures, which are preserved, and also change in accordance with the age of the shell. We have, therefore, in every well-preserved specimen, the unique advantage of being able to study the complete cycle of its individual life in three distinct sets of organic parts. We can therefore compare the changes which we observe in the individual with the modifications which the group has undergone in its progression or retrogression in geologic times with a certain completeness of the evidences, at present unattainable in any other class of animals. In the Belemnites, the third order, the shell and its parts are much less instructive; and finally, in the fourth, the Sepioidea, it is so much reduced, and so frequently absent, as to lose very largely in this respect.

The class has two sub-classes, Tetrabranchiata and Dibranchiata. These were established by Richard Owen as orders,—a purely technical difference, which does not change in any way the value of the structural distinctions as given by this eminent naturalist. The Tetrabranchiata are shell-covered; and they are represented by the modern Nautilus, the only existing genus. The Dibranchiata are descendants of the former, but enclosed the shell, and resorbed it in many forms, so that they appear as naked animals. The cuttlefishes, squid, devil-fishes, etc., are existing types. In studying these types, the author has been led to adopt a new method of characterizing the divisions, and besides the old structural distinctions, which are still available, to apply the

correlations of habit and structure to the elucidation of ordinal differences.

The class Cephalopoda is composed of exclusively aquatic and marine animals, and consequently they breathe with gills. The structures of the two sub-classes coincide with two distinct habitats which they respectively occupy. The Tetrabranchiata, like the Nautilus, were essentially littoral crawlers, though possessing organs suitable for swimming, and doubtless using them more or less for leaping and swimming.

The animal of the Nautilus has a large mantle or fleshy sac enclosing the internal organs, which can be opened around the margin, or closed, at the will of the animal. Admitting the water around the margin, they fill their mantle-cavities with water, and then, closing and compressing the mantle-sac, force it out with violence through a fleshy pipe, which is exclusively used for that purpose, and always situated on the ventral side. The reaction of the stream is sufficiently powerful to drive the body of the animal with varying degrees of swiftness backwards. The fleshy pipe is therefore an ambulatory pipe or hyponome; and we propose, in place of the old and confusing terms, to call it by this name.

The Dibranchiata change the external shell, which they inherit from the Tetrabranchiata, into an internal organ, and taking advantage of the powerful hydraulic apparatus of the Tetrabranchiata, which they also inherit, and increasing its efficiency, become, as is well known, exclusively swimmers.

The ambulatory pipe of the Nautilus causes a corresponding depression or sinus to occur in the aperture of the shell on the outer or ventral side, and its effect is also to be seen in the striae of growth throughout the entire length of the shell on the ventral side; so that we know, from these indications in any fossil, what was the comparative size of the pipe, and whether the animal was more or less powerful as a swimmer. Other indications, such as the openness or contracted form of the various apertures of different genera, exhibit with equal clearness what they could do in the way of crawling. The wide-open apertures indicate powerful arms, capable of carrying and easily balancing the large spire of the shell above: the narrow contracted aperture shows that the arms were small, and that the animal could not so efficiently balance or carry the shell in an upright position, and was therefore, according to the amount and style of the contraction, more or less inefficient as a crawler.

In studying the different types of the Tetrabranchiata, we find that there are two orders as first defined by Professor Louis Agassiz, — the Nautiloidea and the Ammonoidea, — and, further, that these divisions coincide with differences in the outlines of the ambulatory sinuses which indicate distinctions of habit general throughout each order.

The extinct Nautiloidea have large ambulatory sinuses, and were evidently capable, like the modern Nautilus, of rising to the surface, and swimming with a jerky motion; though their open apertures, as a rule, show their normal condition to have been crepitant, or bottom-crawling. The exceptional shells, which depart from the typical form in the sinus and apertures, exhibit their peculiarities in the adults, but not, as a rule, in the young, except in cases where direct inheritance can be proven to have occasioned the exception. The exceptions, then, are, in fact, the most conclusive of our proofs, since they show the power of the habitat to produce permanent changes in the apertures.

The orthoceratitic shells of this order are straight cones, with internal septa dividing them into air-chambers, connected by a tube uniting all the air-chambers, and opening into the body of the animal itself, which occupied a small part only of the whole length of the cone. This is the simplest form: and others are, the bent or arcuate, cyrtoceratitic; the loosely coiled, but with whorls not in contact, gyroceratitic; the closely coiled, with whorls in contact, nautilian; and the still more closely coiled or involute shells, the involute nautilian, in which the outer whorls may simply overlap the inner, or entirely conceal them by their excessive growth, as in Nautilus pompilius.

The Ammonoidea in their earlier forms, the Goniatites, have apertures, with a less strongly marked ambulatory sinus, but still sufficient to show that they must have had considerable powers of rising or leaping in the water, if not of swimming, like the Nautilus. In their later forms, the Ammonitinae, however, the ambulatory sinus is absent; and in its place projecting beaks or rostra are developed, indicating reduction in the size and use of the ambulatory pipe. This and the generally open apertures enable us to see that they were more exclusively bottom-crawlers than the Nautiloidea. The most interesting of the facts in this order lies among the exceptional shells, some of which must have been sedentary, and neither have crawled nor moved about with any ease; but none of these, so far as we know, seems to have exhibited a type of aperture which in-

dicated transition to an exclusively swimming habit. These shells appear in our subsequent remarks among the geratologous and pathological types.

The shells of this order have no such variety of form in the paleozoic formations as we have described in the Nautiloidea. They are close coiled, and even involute, in some of the first forms found in the Cambrian.

The Belemnoidea of the Jura had a solid cylindrical body, called the guard, attached to the cone-like internal shell, and partly enclosing it. Aulacoceras of the trias, as described by Branco, is a transitional form with an imperfect guard, which frequently contains fragments of other shells and foreign matter. This demonstrates an important link in our evidence, that this guard could only have been built by some external flap or enclosing sac, independent of the true mantle. This false mantle must have enclosed both the shell and the guard, and must have been at the same time open, so as to admit the foreign materials which Branco found built into the substance of the guard. One of the straight shells of the Silurian Nautiloidea, Orthoceratites truncatus, regularly breaks off the cone of its shell, and then mends the mutilated apex with a plug. This plug, we are able to say, is the precise homologue, in position and in structure, of the guard of the Belemnite. Barrande showed this plug to have been secreted by external organs, as he supposed, — two arms stretching back from the aperture like those of Argonauta, and reaching beyond the broken apex. The dorsal fold of Nautilus is, however, a secreting-organ stretching back over the shell; and, as the probable homologue of the plug-secreting organ of the Orthoceratites and the guard-building organ of the Belemnoidea, it enables us at once to explain how the Belemnoidea arose from the Orthoceratites, and why Aulacoceras had an imperfect mantle. This fold, which was far larger among the ancient Orthoceratites, would have been necessarily open on the ventral side, then more but not completely closed in Aulacoceras, and finally completely closed in the later Belemnoidea, and able to construct a guard as perfect as that which they carry.

The solid guard of these animals in a compact cylindrical body, such as they were known to possess, could have been only a heavy burden to a swimming animal. The Belemnoidea, therefore, were not purely natatory; but for these and other reasons, which we cannot here discuss, they were evidently ground-swimmers, probably boring into the mud for shelter, or as a means of concealing themselves while lying in wait for their prey.

The old view, that the guard could have been in any sense a 'guard' against collisions with rocks, etc., in their wild leaps backwards, is inadmissible for many reasons. The most obvious are its position as an internal organ, its solid structure, and its weight. We think it more reasonable to suppose that it might have increased the liability to injury from collisions. In tracing the Belemnoidea to the Orthoceratites we have simply continued the labors, and carried out more fully the sagacious inferences, of Quenstedt and Von Ihering.

The modern Sepioidea are known to be almost exclusively swimming types; and the more ancient, normal, flattened forms, and their descendants the existing cuttlefishes, have flattened internal shells, in which the striae of growth are remarkable for their forward inflection on the dorsal aspect, due to the immense comparative length of this side of the aperture. Gonioceras, a well-known Silurian type of the orthoceratitic Nautiloidea, has the same contours in the striae of growth on the dorsum; and if, as we think, it had a corresponding depression in the aperture on the ventral side, in similar proportion to that of other forms, the aperture must have been transitional to the internal shell of Paleoteuthis Dunensis of the Devonian, and to the more modern forms. The septa, also, of Gonioceras, have similar curves to the layers of calcareous matter in the interior of the cuttlefish bone, which we look upon as aborted and retrogade homologues of the septa of other forms. Gonioceras connects directly with a series of less compressed, straight, orthoceratitic shells; and thus the independent derivation of the Sepioidea from the Orthoceratites, among the shell-covered, coniform Tetrabranchiata, is probable. The enclosure and suppression of the shell have already been predicted, with a sagacity which commands our highest admiration, by Lankester, from studies of the embryo of Loligo; and these facts carry out his conclusions, substituting, however, the more ancient Sepioidea for the Belemnoidea, with which Lankester made his comparisons, and the hood for the two mantle-flaps which were imaged by him as the organs which enclosed the shell and formed the shell-sac. Most paleontologists have considered the Sepioidea and Belemnoidea as more closely allied; but they appear to us as two orders, certainly as distinct as, and perhaps even more widely divergent than, the Nautiloidea and Ammonoidea.

Among these two orders we recognize many

exceptional forms, — such as the Spirula among Belemnoidea, and among Sepioidea the octopods; and we think they all prove our position, that the habitat so closely accords with the structural changes of the type that its purely physical agency must be regarded as the efficient and direct cause of the correlated changes of structure which distinguish the different orders and sub-orders, and often of the exceptional genera and species. We will mention but one of these exceptional cases, in some respects the most pertinent, — the existing Argonauta, or paper nautilus. Here a thin shell secreted by the mantle, by the edge of the mantle, and by the two pairs of long dorsal arms, encloses completely the animal of the female alone, the male being naked. As a sexual organ for the protection of the eggs; as an adolescent and adult structure, originating at a late stage in the life of the individual, and not in the shell-gland of the embryo; and in its microscopical structure, — it is not a true shell, or similar to any true shell among Cephalopoda. Still, in form and position, and as built in part by the mantle, it is a homologue of a true shell, and has in part, also, the functions of a true external shell, and ought therefore to support or refute our hypothesis. It belongs to a swimming animal, and should therefore have the sinus and aperture and striae of growth as in Nautiloidea; and these it certainly has. We can appeal to this example as a most convincing exception to prove the rule that the shell is a true index of the most remarkable adaptive structures, and, among the fossils, can give us exact information of important differences in structure and habits.

The *efforts* of the Orthoceratite to adapt itself fully to the requirements of a mixed habitat gave the world the Nautiloidea: the *efforts* of the same type to become completely a littoral crawler developed the Ammonoidea. The successive forms of the Belemnoidea arose in the same way; but here the ground-swimming habitat and complete fitness for that was the object, whereas the Sepioidea represent the highest aims as well as the highest attainments of the Orthoceratites, in their surface-swimming and rapacious forms.

We cannot seriously imagine these changes to have resulted from intelligent effort; but we can fully join Lamarck,[1] Cope, and Ryder, in imagining them as due to efforts induced by the physical requirements of the habitat, and think this position to be better supported by facts than any other hypothesis.[1]

Confining ourselves to the Tetrabranchiata, which we think the most favorable for our purposes, the next problem presenting itself is whether the two orders, Nautiloidea and Ammonoidea, have had a common origin, or whether they bear internal evidence of having had a distinct origin. The embryo of all Ammonoidea, as shown by the author in his 'Embryology of the fossil cephalopods of the Museum of comparative zoölogy,' and since confirmed by the more extensive researches of Dr. Branco, is the little bag-like shell first discovered by Saemann. This is attached to the apex of the secondary shell. The embryonic bag is called the protoconch by Professor Owen; and the secondary or true shell, the conch.

There is no protoconch in Nautiloidea, as first shown by Saemann, then by Barrande, and subsequently by the author and Branco; but where it ought to have been attached on the apex of the conch, or true secondary shell, there is a scar, first demonstrated by Barrande. The view brought forward by the author, that this scar indicated the former existence of a protoconch in the Nautiloidea, has been opposed by Barrande, Branco, and several authors, on the ground that the cicatrix demonstrated the existence of a distinct embryonic form. Therefore, according to Barrande, the Nautiloidea were not similar to the Ammonoidea in their earliest stages of growth, and must have been equally distinct in origin.

Our present contribution to this discussion is simple and straightforward. We have found the protoconch in several forms of Orthoceratites, of some of which we give figures; and, further, it can probably be found on the apex of the so-called perfect shells, which have no scar or cicatrix. These were discovered by DeKoninck, and supposed by him, in his 'Calcaire carbonifère' (*Ann. du mus. roy. de Belgique*), to be fatal to our conclusion. Having no scar, they could not possibly, according to DeKoninck, have had a protoconch. When the so-called perfect apex is broken off, the observer will probably find that this apex was the shrivelled remains of a protoconch which concealed the cicatrix underneath, as in Fig. 2. There is therefore no essential difference between the embryos of the Ammonoidea and those of the Nautiloidea. There are some of

[1] A noted French writer well known to embryologists, Lacaze-Duthier, has lately asked, "Who, at the present time, supports Lamarck?" The author can answer, that some of our leading scientific men consider Lamarck's hypothesis to contain more fundamental truths than Darwin's or any other.

[1] We can also confidently appeal to Dohrn's hypothesis of change of function in support of this view, in which he shows with many convincing examples that organs have latent functions which can be developed by any change of habits, and then become predominant over the older functions, and by their reactions occasion an entire change in the structure of the organs themselves.

minor importance which we cannot discuss here. These, however, do not interfere with the facts of general agreement; and there is great probability that the shell-covered forms of all kinds which have the protoconch — namely, the ancient and modern Gastropoda, Tentaculites, and the ancient Pteropoda, and all the radical forms of Cephalopoda — had a common origin, probably in some chamberless and septaless form similar to the protoconch. Von Ihering has already designated this prototype as probably Tentaculites. No exact correspondent to the protoconch is yet known to us; but certainly Tentaculites is nearer to the protoconch of both Cephalopoda and Gastropoda than any other known ancient form.

The young of the simplest and earliest of Ammonoidea, the Nautilini, have in varieties of two species, as shown by Barrande, a straight apex, like the adult shell of Orthoceras, the radical of the Nautiloidea. We have already claimed that this fact was sufficient to prove the high probability of a common origin from a straight shell like Orthoceras for both of these orders; and we are now able to reiterate this conclusion, and to meet the objections of the great paleontologist Barrande, and his supporters, more effectually than ever before.

FIGS. 6, 7. — Another individual, said to be of the same species, less magnified. *a b*, as before. The author has also, in other species, traced the striae of the outer shell on the protoconch itself, showing the continuity of the shell over this part (*a*), and completing the evidence that it must have been the shell which enclosed the embryo, and could not have been a mere plug, as asserted by Barrande (*Syst. sil.*, pl. 488).

Goniatites compressus, sp. Beyrich (*Sand. verst. Nassau*, pl. 11, fig. 4), is a shell which differs from all other Ammonoidea in an essential and highly important character. The septa have no inner lobe. The v-shaped annular lobe which occurs in all the Ammonoidea except the Nautilini is also absent in this species. What is more to the point, this shell has the sutures of a true nautiloid, since it has the dorsal saddle, in place of the dorsal lobe, of the sutures of its nearest allies, the Nautilini, and all of the remaining Ammonoidea. Goniatites ambigena Barr., of the Silurian, is a close ally of this Devonian species, and the two are the only Ammonoidea which are not truly nautilian in form. The whorls are in contact; but there is no impressed zone, and no sutural lobes on the dorsum, as in true nautilian shells. On the contrary, they are purely gyroceran forms, with rounded dorsum and sutural saddles in place of lobes. All of the Nautilini and G. compressus also have the septa concave, as in the Nautiloidea, in place of the convex character of the septa in later Ammonoidea. As doubts may disturb the mind as to whether G. compressus is an ammonoid at all, we recommend a comparison of this shell with the young of Goniatites fecundus of Barrande, which is a miniature copy made by heredity.

Bactrites is a perfectly straight form, similar to these Goniatites in very important characteristics, especially the siphon and septa.

This same genus includes straight cones like

Orthoceras pleurotomum Barr. (*Syst. sil.*, pl. 296), which are undeniably transitions to true Orthoceras in their striae of growth and position of siphon. There is therefore convincing evidence in the structures of these Cambrian shells that the Ammonoidea, with their distinct embryos, arose from the orthoceran stock, and passed through a series of forms, in times, perhaps, preceding the Cambrian, which were parallel to those characteristic of genetic series among Nautiloidea; viz., straight, arcuate, gyroceran, and nautilian.

The researches of Emmons and Marcou in this country, and the discovery of ten thousand feet or more of stratified rocks under the Cambrian by the U. S. geological survey, and the inferences of Bigsby from the extended study of Silurian and Devonian fossils, are beginning to place the probable existence of a prepaleozoic period beyond question, in spite of the really grand opposition and world-wide researches of Barrande. The study of the tetrabranchs teaches us, that, when we first meet with reliable records of their existence, they are already a highly organized and very varied type with many genera, and that the name 'paleozoic,' as applied to these first records, is a misnomer. There was a protozoic period; and the tetrabranchs, like their successors, certainly must have had ancestors which preceded and generated them in this period, but of which we are at present necessarily ignorant. Whatever the future may have in store for us we cannot now predict; but at present the search for the actual ancestral form, though necessary, is nevertheless not hopeful. We can, however, rely upon the facts of embryology, and predict without fear of failure, that, when our k owledge makes this prototypical form known, it will have a decided resemblance in structure and in aspect to the earlier stages of the shell as observed in the fossil cephalopods.

(*To be continued.*)

SCALES OF COLEOPTERA.

SOME of the more interesting forms of scales of Coleoptera described in the paper by Dr. George Dimmock, noticed in *Science*, i. **455**, are shown in the annexed figures. The scales of the carpet-beetle, Anthrenus scrophulariae, and of the museum pest, A. varius (fig. 1), resemble in general form those of many Lepidoptera, as do also the scales of Valgus squamiger (fig. 3). The scales of V. squamiger are, however, hairy, in fact, almost shaggy. The scales of Hoplia coerulea (fig. 2) vary from round to lanceolate, those of the dorsal surface being transparent yellow when viewed by transmitted light, and blue by reflected light. Those of the ventral surface are purplish, purplish red, red, bluish, and colorless by transmitted light, while by reflected light they are silvery white, with at times a tendency to metallic green. The scales of the dorsum are smooth, filled with fine reticulations (fig. 2, *d*), but those of the ventral portions and of the tip of the

FIG. 3.—Scale of Valgus squamiger. Enlarged 100 diam.

FIG. 4.—Different forms of scales from Chalcolepidius rubripennis. Enlarged 100 diam.

FIG. 5.—Scales of Alaus oculatus: *a*, brown scale; *b* and *c*, portions of white scales to show cross-bands; *d*, transverse section of a brown scale. Enlargement: *a*, 100 diam.; *b* and *c*, 300 diam.; *d*, 500 diam.

FIG. 6.—Scales and hair of Ptinus? rutilus: *a* and *b*, scales from elytron; *c*, hair from elytron. Enlarged 100 diam.

FIG. 7.—Scale of Clytus robiniae. Enlarged 100 diam.

FIG. 8.—Scales of Entimus imperialis: on *a*, *b*, and *c*, vertical lines indicate blue, horizontal lines indicate carmine red, and oblique lines yellow; where two kinds of lines cross, one color is tinged with the other; on *d* ard *e* the fine lines represent the finer striation of the inner layer of the scales. Enlargement: *a*, *b*, and *c*, 100 diam.; *d* and *e*, 300 diam.

abdomen are covered with fine hairs representing the branches of the ordinary hairs of scarabaeidous beetles. The scales of Chalcolepidius rubripennis, an elaterid, are transparent brown when seen by transmitted light, but by reflected light appear bronzed blue, green, or red. Their form is seen in fig. 4. The black and white scales of Alaus oculatus (fig. 5), which give rise to the entire figuration of that curiously marked elaterid, although not of especially pe-

culiar form, are very interesting; because, in the white ones, the striations of the outer lamina, which form the corrugations seen in sections of the scales (fig. 5, *d*), are longitudinal, while the lower lamina, or lamina toward the insect, although smooth, shows transverse bands (fig. 5, *b*, *c*). In the fact of their corrugated surfaces being turned away from the insect, the scales of Alaus and of some other Coleoptera agree with the scales of Lepidoptera and Diptera. The 2–7 pointed scales of Ptinus (fig. 6), which are nestled amongst its hairs, resemble in a general way the plumules of some Lepidoptera. Most of the coloration of the well-known locust-borer, Clytus robiniae, is due to scales (fig. 7), which are of a form not rare in the longicorn Coleoptera.

The Rhynchophora or Curculionidae are the beetles on which scales most generally occur, and where they present their most brilliant coloration. The diamond beetle of South America, Entimus imperialis, often sold by jewellers on account of its brilliancy, has scales (fig. 8) and hairs which present to transmitted light various colors — usually red, blue, and yellow; often all three colors with gradations between them — on a single scale. By reflected light, or upon a black surface like that of the beetle itself, the prevailing colors are green and purple. The colors which are indicated by the direction of the lines on the figure (fig. 8 *a*, *c*) are those seen by transmitted light. When highly magnified, these scales, besides other structural characters, show a very fine striation (fig. 8, *d*, *e*), sometimes in one direction on one part of the scale, and in another direction on another part. This fine striation is probably the cause of the brilliant coloration of these scales.

All the brilliant coloration of scales of Coleoptera appears to be due to interference of light, either by fine striation, or by superposed delicate lamellae; as can be proved by wetting the scales with chloroform, when the color disappears, only to reappear as soon as the chloroform is evaporated. Most of the scales of Coleoptera contain air; and this air, together with the background formed by the coloration of the insect itself, gives rise to the various changeable hues seen in most of the Coleoptera which have scales.

MICROBES.[1]

NONE of the organic substances which form an essential part of our sustenance, and are useful in a thousand ways, can be kept for more than a few days: fermenting and spoiling, they are the despair of the economists. In this decomposition the substance becomes filled with an immense number of very minute organisms. How can a liquid, like milk or soup, free from all foreign germs, become invaded in a few hours by these innumerable legions of microbes? The first hypothesis suggested is, that all these organisms are the result of the decomposition, and that they are produced spontaneously at the expense of the altered substance. This is the theory of spontaneous generation, so vigorously maintained by Pouchet; and it is certainly one of the greatest of Mr. Pasteur's good offices, that he has refuted one by one the arguments of the supporters of this attractive theory, pursued them to their last defence with his invincible logic and his unexceptionable experiments.

The fermentation is produced by the microbes; and these, by a wonderfully rapid propagation, are derived from germs carried by the air, or adhering to the vessels which hold the fermentable liquids. The diligent researches of Mr. Miquel show that the comparatively pure air of the suburbs of Paris holds from a hundred and fifty to a thousand living germs per cubic metre. In a hospital at the centre of the capital, each cubic metre of air contains from five thousand to thirty thousand, according to the season. Although these figures appear prodigious, they are nevertheless very small, compared to the number of spores which cling to all the solid objects surrounding us. A simple cleansing is powerless to remove them: only fire or strong antiseptic solutions can destroy them. A fermentable liquid can be preserved indefinitely if it is protected from all microbes; but it is easily seen, after what we have just said, how difficult it must be to obtain this perfectly insulated state. All these lower vegetable types are found in two forms, — 1°, the vegetative or active form; and, 2°, the passive form, that is, the spores, which play here a part analogous to that of seeds in plants.

In the active state most microbes show little endurance; many species cannot stand a drying of any duration; and in moisture a temperature of 70° to 80° C., continued for two or three hours, destroys them almost without exception. Spores are more hardy: boiling water does not kill them; but, for this purpose, water must be heated to 120°, 130°, and even 150°. When dry, the spores do not succumb to a temperature below 180° to 200°; and, according to Mr. Fricz, cold of 110° has no effect upon them. To disinfect clothing without burning; would, then, be an impossibility, if, fortunately, Mr. Koch had not discovered that the germs cannot resist the action of a continued current of steam at a temperature of 100°.

It is peculiarly difficult to protect a liquid from all germs, or to destroy all those which have penetrated it; however, it is possible, and the liquid is then said to be *barren*. Certain soups are prepared in this way that they may be sown with very small particles of substances containing the microbes to be studied; and thus the desired species obtained, to the exclusion of every other. Laboratories devoted to these studies annually distribute hundreds and thousands of litres of these soups.

The organisms which here claim our attention belong to three families, all allied to fungi, — moulds, yeasts, and microbes proper. Each kind of fermentation is produced by a certain species of these small organisms, and takes place only if the species in question is present in the liquid, from the beginning of the fermentation, in sufficient numbers not to be

[1] By Dr. H. FOL of Geneva. Translated from the *Journal de Genève*.

choked by other species. Thus the mycoderm of wine is found in abundance in the flower of the bitter grape, and is naturally scattered in the must which flows from the press. In Japan the vine grows with wonderful rapidity, and bears magnificent grapes; but the mycoderm is lacking, and the fermentation produced by the other microbes yields only an undrinkable liquid. The bakers and brewers know very well how to introduce into their dough and must the species needed. Without microbes, milk would not curdle, cheese and vinegar would be unknown; the vegetable *débris* would not decompose, and there would be no loam. Some one has calculated that a gram of soil contains a million of these little creatures. We are so accustomed to associate the word 'microbes' with the most dreaded diseases, that we lose sight of the important part they play in nature. We can confidently say that their suppression would completely overthrow the present order of things.

The power of causing fermentations is certainly one of the most curious phenomena which these lower vegetable types present. This power belongs only to certain species. Mr. Pasteur was the first to discover that certain microbes live in the air, and breathe like animals: these do not produce fermentation. Others live only when protected from the air, and cause fermentation in the matter which contains them. To these two classes there has recently been added a third, amphibious microbes, simply vegetating while in the air, and producing fermentations only when the air is withdrawn. Fermentation thus seems to be a kind of respiration. The yeasts decompose liquids in order to obtain products rich in oxygen, which take the place with them of respirable air. These facts are highly important in explaining the mechanism of diseases.

In short, from a practical point of view, we may divide microbes into three classes, — those which are useful, those which seem to have no effect, and those which are positively harmful. We have already mentioned the first class; the second are very numerous; for, to say nothing of the many species which inhabit all the recesses of nature, and concern us only very indirectly, we undoubtedly support quantities of them in the cavities of the surface of our bodies and of our digestive canal. Nothing equals the astonishment and confusion of very solicitous persons, when, by a turn of the hand, the micrograph shows them all the various forms which live at their expense. They are all kinds, from the harmless Spirillum in the saliva to the Leptothrix, which is the most active agent in the decay of teeth. But all this is on the surface: the interior of our bodies is completely free from them; and it may be said that in our organization every means is taken to defend the entrance to the organs from ordinary microbes, and to remove them if they succeed in forcing entry. There is, however, a certain number of species which have the sad privilege of being able to penetrate and support themselves in the body of a subject predisposed to receive them. The microbe of septaecemia enters only through an open wound, while those of tuberculosis and leprosy attack directly the lungs or mucous membranes of the persons afflicted. The surfaces of the lungs and of the alimentary canal seem to be the customary points of attack for the organisms which cause various infectious diseases.

Our organization is like that of a civilized nation, whose citizens are represented by our cells. The skin becomes broken (the wall of China discloses a breach), and immediately there are hordes of savage microbes which enter, at strife with the national soldiers (our cellular tissues). The microbes multiply, and scatter around a poisonous liquid; the cells combine, and try to starve their dreaded enemies and to repair the breach. The battle-field is small; but the victory is warmly contested, and the sight has its exciting aspect. The result of the struggle depends on the number of combatants and on the energy of the competing forces. The antiseptic treatment of wounds, as at present skilfully used by Professors Julliard and Reverdin, and Dr. A. Reverdin, aims to reduce as much as possible the number of microbes which enter, and to retard their development; for no one familiar with the subject would think it possible to entirely exclude them. How interesting it would be to trace the events of the contest between the organism and its invaders in the case of an epidemic disease! Science, we hope, will soon be in condition to give us this history.

The diseases which have been traced with certainty to parasites are as yet few in number: they may be counted on the fingers. To discover the nature of a disease, there must be a uniformity of experiments and evidence, of which the public, and even the majority of specialists, take no account. Nothing is easier than to examine with a microscope small parts of the various organs of a dead body, and attribute the fatal disease to the microbes found under these circumstances. These would-be discoveries, soon disproved, have only the effect of causing the public to mistrust useful investigations, and cast undeserved discredit on serious work performed in the most methodical manner. To know a parasitic disease, it is not enough to have seen the pathogenic microbe: it must have been removed from the other microbes, and cultivated through a long series of generations in sterilized soups; animals must be inoculated at various times with these pure types, and each time all the symptoms of the disease whose cause is sought must be observed. In this way Mr. Koch has revealed the microbes of charbon and tuberculosis; and these discoveries have been granted to science, after being examined by a number of investigators, among them Professor d'Espine. Long and very careful cultivation was necessary to show, after Dr. Haltenhoff's interesting paper on this subject, that the juice of the *jequirity* owes its extremely virulent properties only to the microbes which it contains. We know quite satisfactorily the organisms which produce leprosy, erysipelas, and symptomatic charbon; but for diphtheria, typhus, intermittent fevers, and many other diseases, the agents are still undiscovered.

Intermittent fevers afford a good example of how easily errors arise and spread. They were at first, and

without sufficient evidence, said to be caused by the palms, — comparatively high vegetable types, perfectly innocent of the crime of which they were accused. Late investigations point to a bacterium of elongated form as the cause, but the proofs are still insufficient. To learn to recognize the enemy is certainly the most necessary thing to be done, but it is only half the task: we must then learn to resist it. The more or less effective means of combat which have been employed up to the present time have aimed, 1°, to prevent the dissemination of dangerous microbes; 2°, to make the organism unsuitable for the propagation of the intruders; 3°, to retard, as far as possible, the growth of those which have entered, in order to give the organs opportunity to throw them off. The first of these measures engrosses the attention of the hygienists: hospitals, quarantines, and disinfectants are among the means employed. I will not enter upon a subject which touches so many disputed questions, but will confine myself to noticing certain facts and to rectifying certain very wide-spread errors. Regarding infection, the nose is a poor guide; for the experiments of Mr. Miquel show very distinctly that substances in a state of putrefaction, so long as they are moist, do not emit living germs. The water of the Paris sewers holds eighty million microbes per litre; and yet the air of the sewers contains only eight hundred or nine hundred germs per cubic metre, about one-tenth the number found in a hospital. By inoculating a rabbit, it was shown that these germs are perfectly harmless. The moist earth does not give out living organisms to the atmosphere. On the contrary, the dust of our rooms, which we do not at all mistrust, shows about two millions of these living germs per gram. The bacteria of intermittent fevers, which vegetate in the soil of the Roman Campagna, begin to spread in the air and to become dangerous only when the soil, dried by a scorching sun, is raised by the wind in the form of dust. It would be easy to multiply examples, and to prove, that, in point of hygiene, we must be guided by sense rather than by smell. We have as yet but begun this kind of study; for how does this total number of germs which the air or water holds interest us? We would prefer to know the number of dangerous germs. The proportions would doubtless be very different from those which concise analysis affords.

Until we are better informed, we shall do well to push cleanliness to an extreme, and especially to put little trust in disinfection. The number of subtances which are less injurious to man than to micro-parasites is very small. The best disinfectant is perfectly useless if too weak a dose be used. For each of these substances there is one proportion which will destroy the germs, and another which will arrest their vegetation but not destroy them. This last dose is the one with which we are generally obliged to content ourselves. The experiments of Mr. Koch and Mr. Miquel show that the narcotic effect begins to be effective on microbes only when the substance in which they are vegetating contains, among a thousand parts, 95 parts of alcohol, or 70 of borax, or 10 of salicylate of soda, or 3.2 of phenic acid, or 5 of quinine, or 0.6 of bromine, or 0.07 of bichloride of mercury, or 0.05 of oxygenated water. Certain of the substances indicated are useful in these doses; while others, as bromine, are impracticable. But especially let us not forget that the result is not a radical disinfection: it is merely a momentary weakening. Is it still needful to insist on the uselessness of too mild doses? We are constantly seeing phenic acid used at less than one in a thousand parts with the sole effect of creating a mistaken sense of security. Let me mention another almost unknown antiseptic: essence of terebinthine, according to Mr. Koch, arrests the vegetation of microbes in a dose of $\frac{1}{75000}$, a quantity easily endured by man.

All these hygienic precautions are bristling with difficulties. How convenient it would be to let the microbes live and to protect our bodies from their influence! Unfortunately we know but one way to effect this: it is based on a remark, made long ago, that certain diseases can be retaken only after many years, and that this freedom may be obtained by contracting the disease in a very mild form. This is the principle of vaccination, and also of inoculation, employed by Mr. Pasteur on certain animals. The matter inoculated contains the microbe of the disease from which we wish to protect the subject, but modified by a special cultivation: it is a virus weakened according to the methods of Mr. Toussaint and Mr. Pasteur. We touch here upon a question, at present much contested, in regard to the regularity of specific forms of these very low vegetable types. Mr. Zopf and the school of Munich believe that the most harmless species can, under certain circumstances, be changed into dangerous ones, and *vice versa*. The school of Berlin thinks that artificial modifications are only transient and momentary, and that the species may be considered invariable. However this may be, it is certain, that, if the inoculations of Mr. Pasteur have no great practical importance in their present form, they at least have a considerable theoretical value. We may hope that the time will come when it will be possible to vaccinate for all diseases which can seldom be taken a second time. Who knows if it will not end by discovering the nature of the influence which the parasitic invasion exerts on the tissues of our bodies, and in obtaining the same result in a more direct way without inoculation? When we consider the progress of science in the last half of the present century, we venture no longer to answer, 'Impossible.'

THE WATER-PORES OF THE LAMELLIBRANCH FOOT.

IN 1817 Cuvier showed that in Aplysia there was a closed vascular system, and claimed the same for all Mollusca. His view was followed till 1845, when Valenciennes and others described in many lamellibranchs pores which passed through the foot to introduce water into the lacunar tissue, where the blood circulates. This view found general acceptance, and

was taught by Siebold, Huxley, Gegenbaur, Semper, etc. Recently discussion of the subject has been re-opened by the appearance of numerous papers. Mr. Justus Carrière in several papers maintains that no *pori aquiferi* exist in the lamellibranch foot. Hermann Griesbach, last spring, in a careful paper (*Zeitschr. wiss. zool.*, 38), reviewed the whole subject, studying by sections and injections, and concluded that the molluscan vascular system was not closed, that the blood wandered in the lacunar tissues of the body-cavity, that large lacunar spaces communicated directly with the exterior through aquiferous pores in the foot, and that these pores were for the reception of water to be carried out through the Bojanus organ. He figures sections of Anodonta where the surface-epithelium of the foot bends up into the opening of the pores (there are three in Anodonta), and fades out as the pore opens into the lacunar body-cavity. During last October two quite independent papers appeared simultaneously upon the other side. Dr. Cattie, in *Zool. anzeiger*, vi., No. 151, p. 562, claims to have cut a complete series of about twenty-five hundred consecutive transverse sections through the foot of Anodonta. In no one of these was there any break in the epithelium. He has studied twenty-three species, and in no one finds the least trace of aquiferous pore. Dr. Th. Barrois, in a private imprint from Lille, dated Oct. 30, 1883, arrives at the same results. He discusses the work of Carrière and himself, and finds that they have studied most of the forms where the presence of aquiferous pores has been claimed, and in every case find pores absent, or in such position that it seems they are either connected with the functional byssogenous organ, or, where such is absent, in the aduct, with the remnant of the same. Barrois sums up his views thus: no pores exist for the introduction of water into the circulation; the only pores of the foot are those connected with the byssus organ, which never communicates with the interior of the foot. The blood may have water introduced into it, but this must be effected by osmosis, or in some manner not now to be discussed. H. L. OSBORN.

THE BORDERLAND OF SCIENCE AND FAITH.

Walks in the regions of science and faith: a series of essays. By HARVEY GOODWIN, D.D., Lord Bishop of Carlisle. London, *Murray*, 1883. 310 p. 8°.

Natural law in the spiritual world. By HENRY DRUMMOND, F.R.S.E., F.G.S. New York, *James Pott.* (Apparently sheets of the English edition.) 414 p. 12°.

THE 'science' of these regions is of course physical science; the 'faith' is the theistic and more specifically the Christian faith. These 'walks' are taken along the borders of the two. Normally, the course of this journal of science lies quite away from this borderland, which, indeed, has not always been an agreeable road for a scientific man to travel. Of late, however, a better understanding has made it pleasanter than it was for the peaceably disposed naturalist. And the Bishop of Carlisle, a trained mathematician as well as a divine, whose thoughtful essays are essentially irenical, is an instructive companion in an excursion "through that land which belongs exclusively neither to science nor to faith, but appertains more or less to both." A book "which opens with an essay on the connection between mechanics and geometry, which closes with a funeral sermon preached in Westminster Abbey," and the larger part of which had already appeared in widely read periodicals, — some of the articles being in fact, though not in name, of the nature of critical reviews, — hardly need be, and could not well be, reviewed in our journal; yet we are free to give a brief account of it, enough to indicate its lines of thought.

The first essay, on the connection between mechanics and geometry, is a modified reprint of a paper which was published almost forty years ago. The point made is, that these two sciences are essentially identical, being developments in different subject-matters of the selfsame ideas. The moral is, "that all demonstrations tend to merge in intuition, and that human knowledge, as it becomes more clear and more thorough, converges toward that absolute intuition which is the attribute of the Divine Mind." This idea is further worked out in the second essay (entitled 'The unity of nature, a speculation,' which appeared in the *Nineteenth century* in 1879), in which it is argued, that as the schoolboy begins by painfully proving the simpler theorems in geometry, and ends by perceiving that they are really self-evident, and that as all the propositions of Euclid appeared intuitively true to Sir Isaac Newton, "it is quite conceivable, by merely extending in imagination the powers of which we have actual experience, that all geometrical truth in any department might exhibit itself without intermediate steps of demonstration to a mind of sufficient acuteness, when the appropriate definitions had been given. . . . To a mind like that of Newton, I should imagine that the principles of mechanics would present themselves almost in the same self-evident light as those of geometry." And "that possibly, as the truths of geometry help us to realize those of mechanics, we may use the truths of mechanics to help us to realize some of the truths of the more subtle sciences, say, even that of biology." And the speculation, fortified and illustrated by mathematical analogies, goes on

to the conception, that "there may be a principle or law from which the existing order of physical life, with all its apparent anomalies [and its manifold diversities], flows as a necessary result," the knowledge of which, "if attainable, would exhibit to us the order of living nature as one consistent system, free from exceptions and anomalies."

All this, and indeed all the volume, proceeds on lines quite accordant with those of the purely scientific evolutionist. Moreover, in thus regarding intuition as a kind of acquisition or development, the theologian joins hands with the agnostic evolutionist, although they are moving in opposite directions. But the latter doubts, to use the words of one of them, "whether the law-governed mind of man is not itself the highest form of mind." The former, accepting "the admission which must be made by all parties of the co-existence of fundamental unity with almost unlimited diversity," and of inexplicable anomalies, endeavors to show, through mathematical analogies, that the existence of man may involve "the possibility of snakes, as truly and as really as the existence of elliptic motion involves that of parabolical," and "that a mind higher than human might see in the definition of man the possible existence of useless organs, both in man and in other creatures." At the close of the essay, descending from pure speculation of what may be, to more scientific considerations, his idea may be gathered from the following condensed abstract: —

"Let it be granted that all living beings have been developed according to some law, not necessarily known, or even capable of description in words, but still a real law of development; does this give us all the elements necessary for the solution of the life problem? If we say *yes*, do we not run into the mistake of a beginner who fancies that he can solve a problem of motion round a centre when he has been told what is the law of force? Is it not necessary to know the conditions of projection, the initial circumstances of motion or development? And may not this portion of the data be quite as important as the knowledge of the law of force? It seems to me that they who are most anxious to establish the principle of evolution should be the most ready to perceive the necessity of taking into account the consideration of initial circumstances. . . . A quantity of protoplasm with an assumed power of development will not account for existing forms of life, without the additional hypothesis of some causative power to determine the initial circumstances. Given an original germ, and given some power which shall direct the particular original cause of the development of that germ, and the whole subsequent development is conceivable: but the germ and the law of development left to themselves may be as insufficient as the particle and the law of attraction. . . . We have seen that the parabola, the ellipse, and the hyperbola are all possible curves for a particle moving round a centre of force. Only one of these curves — namely the ellipse, and only the ellipse under the condition of small eccentricity or approximate circularity — can suffice for the orbit of a planet which shall be the home of the highest form of life, namely, that of man. . . . The original conditions of motion, the initial circumstances as a mathematician would call them, must have been delicately adjusted in order to select, out of all possible forms of orbit, that one circular or nearly circular form which is compatible with the existence upon the earth's surface of beings like ourselves. May we not infer from this a similar necessity of original delicate adjustment in the process of the evolution of a highly organized creature from a protoplasmic germ?"

The third essay, entitled 'God and nature,' is mainly the development and application of a point made in a university sermon, which the author thought had been overlooked (but perhaps it really passed unnoticed because it is so obviously true), namely, that "all physical science, properly so called, is compelled by its very nature to take no account of the being of God: as soon as it does this, it trenches upon theology, and ceases to be physical science." And so, coining a discriminating word to express this, he would say that science was *atheous*, and therefore could not be *atheistic*. Intrenched in this position, he sharply criticises, as unscientific, Haeckel's denial of the existence of purpose in nature, and comes down upon Professor Seeley for his rash statement (in 'Natural religion') that 'science opposes to God, nature.'

In the fourth essay, 'The philosophy of crayfishes,' the text is supplied by Mr. Huxley's well-known lecture upon these little crustaceans, which lecture, the bishop insists, "leads the mind of the reader, and, as it would seem, intentionally, beyond the region of natural history into the domain of philosophy, and even of divinity." In that domain the bishop is a match for the naturalist: at least, he is able to verify an old prediction of Huxley's, that the evolutionist need not expect ever to drive the teleologist out of the field. Indeed, it cannot be easy to dislodge a teleologist who is so far-sighted as to "have great doubt whether we can properly speak of final ends at all, unless we embrace in our conception the whole cosmos." To Huxley's favorite line of remark that there is no great good in "demonstrating the proposition that a thing is fitted to do that which it does," and that it is "merely putting the cart before the horse to speak of the mind of a crayfish as a factor in the work done by the organism, when it is merely a dim symbol of a part of such work in the doing," the bishop replies, that the importance of demonstrating a proposition depends upon the point of view

from which the proposition is regarded; that the assumption made, "that the preservation of the individual and the continuance of the species are the final causes of the organization of an animal," is quite on a par with the old-fashioned teleology which is nowadays justly reprobated; that, at any rate, the pleasure which the crayfish apparently takes in watching for and capturing his prey is something quite distinct from 'work done by an organism;' and that, "if pleasure of some kind be denied to the crayfish, contrary to all appearances, I do not know at what point in the scale of animal life pleasure is to be admitted as a factor. If to speak of mind as a factor in work done be an absurdity in the case of a crayfish, is it not an absurdity in the case of a dog, or even in the case of a man?" And he proceeds to vindicate the delight of existence as one of the ends for which animals exist.

This idea, and the vindication of the mind of brutes, have a prominent place in the next following essay, on 'Man's place in nature.'

'Law, physical and moral,' is the topic in the sixth essay, in which a passage from Hooker's 'Ecclesiastical polity' is set over against one from the Duke of Argyll's 'Reign of law.' We need not continue our analysis, which is already longer than was intended: indeed, there is less occasion to continue; for the remaining articles, being popular addresses reproduced, are less thorough, however sensible. Even the last essay, on 'Evolution and evolution,' and the appreciative funeral sermon for Charles Darwin preached in Westminster Abbey on the Sunday following his burial there, need not detain us.

The noteworthy thing, to which this volume adds its testimony, is this: that thoughtful churchmen are following the example of thoughtful men of science. They are accepting the scientific principle of evolution as a working-hypothesis, — trying it, as naturalists and physicists have done, in their several lines of research and thought, and with somewhat similar results. The new science is accepted with complacency, if not with welcome, by the discerning. The questionable philosophy, in which it has too often been dressed, is examined and exposed.

THE second book named above appears to have excited considerable attention in England. Like the volume we have just noticed, it is an excursion into the borderland of science and faith, but with a difference. The divine is the more scientific, the layman and naturalist (for such we take him to be), the more homiletical of the two. The one picks his way along the ground with firm but cautious and carefully chosen steps: the other soars into the air. The one discriminates between science and faith, and in his book guards rather than enters upon the field of morals: the other seeks to identify the two, and in a novel way. He has discovered that natural laws, meaning the principles of physics and biology, extend to the spiritual world, and help us to understand it. He does not mean that there are analogies between the two, which may be profitable for instruction, but identities; that 'in the spiritual world,' to use his own figure, 'the same wheels revolve, but without the iron.' And the laws to which he refers are the principle of continuity, of conformity to type, action of environment as causing variation, the adage *omne vivum ex vivo*, possibly even gravitation, if there be any thing for it to act upon; and, if there is nothing for these laws to act upon, "it is not the law that fails, but opportunity." We cannot look upon this as any great improvement upon Swedenborg's 'law of correspondences;' and, as the helpfulness of the book is entirely upon the religious side, we need not further notice a volume which attracted us by its title, but which we find to be morally edifying rather than scientifically satisfying.

BACTERIA, AND THE GERM-THEORY OF DISEASE.

On the relations of micro-organisms to disease. The Cartwright lectures, 1883. By WILLIAM T. BELFIELD, M.D. Chicago, *Keener*, 1883. 131 p., illustr. 24°.

Bacteria, and the germ-theory of disease. Eight lectures by Dr. H. GRADLE. Chicago, *Keener*, 1883. 4+219 p. 8°.

DR. BELFIELD's little book is cheaply gotten up, and, beyond the possession of a few poor woodcuts, seems to be his original lectures, four in number, delivered before the Alumni association of the College of physicians and surgeons in New York in February, 1883. Even the phraseology of the lecture-room is apparently preserved throughout, and is sometimes decidedly more forcible than polite. Nevertheless, these four lectures, making in all about one hundred and thirty pages, give an admirable summary of the germ-theory of disease as it stood a year ago. Beginners or casual readers, perhaps, will not find the book diffuse enough; but pathologists and biologists will prize it for its lucidity, crispness, and keen discriminations.

After a careful perusal of these lectures, one finds himself impressed with the author's ability to go behind the returns, to draw the line between good and bad work, to catch or to predict the drift of things; and this is the peculiar merit of the book. Indignant at the attitude of some American physicians, Dr. Belfield treats their shallow objections with deserved contempt, sometimes even with harshness; but he preserves throughout the critical insight which might be expected of a follower of Tyndall and of Koch, and holds very fast indeed to that which is good.

To biologists it is of great interest to observe that pathologists are passing beyond the 'germ' theory, and are looking towards the unexplored country of unorganized ferments, ptomaines, etc., for the sources of disease, precisely as they themselves have gone thither to search for the causes of fermentation, of cellular digestion, and for many of the more intricate phenomena of physiology. The future of cellular biology seems to lie in these obscure ferments and ptomaines, affording a golden opportunity for the physiological chemist.

Dr. Belfield states his subject summarily as follows (p. 31): —

"Bacteria then, which, by virtue of their ubiquity, are in constant and frequently recurring contact with the animal body, are, like other minute bodies, organized and unorganized, frequently introduced into the body through solutions of continuity of the integuments, or through intact skin and mucous membranes, particularly by way of the lungs.

"The burning question in pathology to-day is, in what degree are the various species of bacteria, present in human tissues during certain morbid conditions, to be regarded as the cause of the morbid processes with which they are respectively associated?"

If we look for his answer, we find farther on that investigations carried on with rigid exactitude justify us in accepting provisionally the causal relation in some degree, but not so far as to exclude other like causes.

Illness may be caused by the not living products of putrefactions, as well as by the living organisms which abound in and probably produce putrefactions. But in the latter case the disease may be farther extended to fresh, healthy individuals by infection: in the former it cannot be. This points, in the one case, to a self-perpetuating cause; in the other, to one of limited powers. Moreover, good evidence exists that the boiled products of putrefaction which may produce illness owe their septic action to substances of obscure composition (ptomaines?) manufactured by the bacteria of putrefaction. This line of thought leads to the important conclusion (p. 42), —

"Hence we are logically driven, by all this work, to the belief that septicaemia implies the introduction into the animal either of living bacteria, or of a substance which has acquired noxious properties through previous vital activity of these organisms.

"More recent experiments have demonstrated, however, that the etiology of . . . septicaemia is by no means restricted to putrid infection. [For it was noticed by Schmidt that] the introduction or production in the blood of fibrin-ferment in considerable quantity produces effects identical with those of putrid infection — septicaemia."

It has since been asserted that pepsin and trypsin produce similar effects. If so, we may find eventually a cause behind the bacteria, — a fibrin-ferment-liberating cause (p. 44): —

"It would appear, athough not for all cases demonstrated, that the . . . features common to the various forms of septicaemia are attributable to the rapid liberation of fibrin-ferment in the blood; and that any agent — organized or unorganized, putrid or fresh — capable of effecting such liberation may induce the disease."

So with the cause of suppuration. Belfield looks even beyond the germ-theory, beyond the bacteria involved, and with the eye of a biologist perceives that (p. 51)

"Suppuration must be regarded, then, as indicating the presence of an element foreign to the living animal cells; which may be induced directly [as by the introduction of a powerful irritant, e.g., Croton-oil], or indirectly as an incident in the life of various fungi [e.g., bacteria]. . . . Practically, we may regard acute suppuration as proof of the access of external irritant matter, organized or unorganized."

Antiseptic surgery is then easily defined. It is not a hissing spray, nor (p. 60)

"Simply a question as to the relative anti-bacterial properties of this, that, and the other so-called antiseptic agents. It is an attempt to prevent the entrance into, as well as the formation within, a wound of all substances, organized and unorganized, which can interfere with cell-nutrition."

Enough has been said to show the spirit of these lectures. They take a broad but thoughtful and critical view of the various questions involved, treating the scoffers who speak without knowledge as they richly deserve, and taking a rather conservative view of the work done in the direction of protective vaccination; displaying everywhere the thorough training of a German laboratory, and closing with a moral which all scientific men and all believers in rational medicine will do well to read, mark, and inwardly digest (p. 114): —

"And when we consider the problems already half solved, the questions to whose solution the way appears open through the same methods already successfully applied to anthrax and tuberculosis, we may hope for results to which present knowledge shall seem

a mere introduction. But these results can be secured only by earnest, skilful, continuous experimental investigation, which is practically impossible without pecuniary support. In France and Germany such support is liberally supplied by the government; in the United States, where human life is certainly as valuable as there; where live-stock interests are already greater than in these countries combined, and must multiply many fold in the immediate future; where a single infectious disease of cattle has caused the loss of $20,000,000 in one year, and a single disease of hogs the destruction of $30,000,000 in the same time; where infectious diseases are so prevalent among live stock that the fear of infection has closed European markets against American meat and cattle — the government of this great commonwealth, which advances enormous sums for local river and harbor improvements; which sends expensive commissions over the world to observe the transit of Venus or of the moon, or to find an open polar sea; and engages in other undertakings of purely scientific interest, has not yet made one judicious, systematic, liberally supported inquiry into the possibility of acquiring protection against pleuro-pneumonia, hog-cholera, and other devourers of the national wealth. A glance at the imperial German health bureau and its work during the last four years, and a mental comparison of the pecuniary resources of Germany with those of the United States, inspire the hope that we shall not always lag so far behind in matters which appeal to the tenderest spot of the American anatomy — the pocket."

Dr. Gradle's book is made up of eight lectures delivered in Chicago, and is published on a more ambitious scale than are those of Dr. Belfield. For the beginner, or for one who is neither a pathologist, biologist, nor physiologist, this book is the more suitable. Its style is diffuse — not always, however, with a gain in perspicuity; and its index, its references to authorities, and its evident intention to give to all sides a fair showing, are features to be specially commended.

In these lectures we have, in fact, rather the report of the evidence than the judge's charge to the jury. We miss that critical and even judicial flavor which is so pleasant a feature of Dr. Belfield's book; and on that account we must consider the latter more suitable for the connoisseur; the former (Dr. Gradle's), for the beginner or the casual reader.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Yellowstone national park. — During the season of 1883 Mr. Arnold Hague began work in the Yellowstone national park, preliminary to a series of careful and systematic observations which are to be prosecuted in this field through a number of years. The geysers are to be made the subject of minute study; and the volcanic rocks, so abundant at numerous points in the park, will be examined in detail, not only as regards their geologic relations, but also in regard to their structure and composition. The field investigations in the park during the past season were confined mainly to the preliminary examinations necessary to determine what geologic and physical problems have to be solved, and to ascertain what thermal changes had taken place since the observations of 1878 recorded by Dr. Peale. Mr. Hague's party was constituted as follows: Mr. Arnold Hague, geologist in charge; Messrs. Joseph P. Iddings, W. H. Weed, George M. Wright, and C. D. Davis, assistant geologists; Dr. William Hallock, physicist; Mr. W. H. Jackson, photographer, with an assistant; Mr. Roland Holt, volunteer assistant; and cook, packers, etc.

Geologic work. — Mr. Hague took the field the latter part of July, outfitting at Bozeman, Montana. Work was begun in the park at Mammoth hot-springs early in August. From this point, slow marches were made to the upper geyser basin of Fire Hole River, to allow of a geologic reconnaissance of the route followed. At the latter locality a permanent camp was established until the last of August. In the mean time a hurried trip was taken to the Shoshone geyser basin and the Heart-lake basin, for the purpose of comparing them with the geyser basins of the Fire Hole River, and to note what changes have occurred during the past five years. While on this trip, Mount Sheridan was ascended. Mr. Hague thinks that this mountain, from which a fine view of the surrounding country was obtained, is a volcanic crater, which has been so greatly modified by glacial action that its true origin has been obscured.

Camp was moved from the geyser basin to the Great Falls of the Yellowstone, Sept. 1, and kept there until the 19th. While at this point, the structure of the Mount Washburn was examined, and a trip made to the head waters of the Gardiner and Gibbon Rivers. The region of the Grand Cañon was also investigated, and the bottom reached at four different places. The Grand Cañon is an admirable place to study the decomposition of rhyolitic flows, the weathering of which has produced the brilliant coloring for which the cañon is so justly celebrated. A trip was also made from this camp to Steamboat Point, on Yellowstone Lake, from which point the ascent of Mount Chittenden was made. Mr. Hague considers this mountain one of the best points of observation within the limits of the park, and, after a trail has been built to it, thinks it will become one of the objective points of tourists who visit the lake. It surpasses Mount Washburn; as it gives a closer and more detailed view of the lake, and presents a magnificent panorama of the high mountain range on the east side of the park. The prospect is perhaps not so ex-

tensive as that seen from the summit of Mount Sheridan, but it is superior to it from the fact that the objects one wishes to see are nearer at hand. On the eastern slopes of the mountain is a remarkably fine glacial cañon.

From the Yellowstone Falls, camp was moved once more to the geyser basins, whence a trip was made to the western limits of the park, *viâ* the Madison plateau, returning through the Madison cañon, which exposes a fine section of the rhyolitic rocks that form the plateau.

The latter part of September camp was again established at the Mammoth hot-springs. The weather throughout the month had, with the exception of a few days in the latter part, been exceptionally fine for field-work; but October was ushered in with a severe snow-storm. Notwithstanding the inclemency of the weather, Messrs. Iddings and Wright undertook a reconnaissance of the region north of Mount Holmes, on the west side of the park, with a view to obtaining more accurate information as to the granitic area that lies just east of the rhyolitic flows that form the plateau of the park. The results, however, were meagre, on account of the severity of the storms and the depth of the snow.

At the same time Mr. Hague, accompanied by Mr. Weed, crossed the park in the opposite direction, to the head waters of Soda Butte Creek, with two objects in view, — 1°, to make a rapid geological reconnaissance across the northern part of the park to obtain definite personal knowledge of the Yellowstone Range; and, 2°, to visit the Clarke's Fork mines in order to learn their position in relation to the park boundaries, and to ascertain the extent to which mining operations have been pushed, and also to form an opinion as to the future prospects of the district as a mining-centre. The trip was a valuable one for general geologic purposes, and as suggesting plans for future operations, but for detailed work was not perfectly satisfactory, as the country was covered with snow, and snow-storms were of daily occurrence.

Although work was continued for some time longer in the vicinity of the Mammoth hot-springs, the weather remained so stormy that it was decided to pack the collections and leave the field; which was done the latter part of October, when the members of the party returned to the east.

Physical researches. — The geysers of the park suggest a number of physical questions which can be solved only after a complete and careful investigation, opportunities for which are nowhere presented with greater facilities than within the limits of the Yellowstone national park. The study of these questions was assigned to Dr. William Hallock, who steadily carried forward his observations in the Fire Hole geyser basins during August and September, and, since his return from the field, has been conducting a series of experiments in the laboratory at New Haven. When the results of these studies and experiments shall be made public, it will be seen that they are of the utmost scientific value.

Photographic work. — Mr. William H. Jackson, so well known from his photographic work in the park, while connected with Dr. Hayden's survey of the territories, accompanied Mr. Hague's party, and had a most successful season. His series of instantaneous views of the geysers in action will prove of great interest.

He obtained a large view (sixteen by twenty-two inches) of the lower falls of the Yellowstone, from a point at the bottom of the Grand Cañon just below where the water reaches the cañon, after its descent of more than three hundred feet. He also secured a fine large panoramic view from the summit of Mount Washburn.

A number of views of Yellowstone Lake were taken, that are particularly good.

Topographic work. — In order that the detailed geologic structure of the park may be correctly delineated, it was decided to begin topographic work for a detailed map, especially as the survey of the western and north-western portions of the park had never been completed. This work was intrusted to Mr. J. H. Renshawe, who undertook plane-table work on a scale of two inches to the mile. He outfitted his party at Bozeman, Montana, and began work in August in the West Gallatin Range, — a beautiful and interesting group of mountains, seldom or never visited by tourists, lying in the north-west corner of the park, between Gardiner's River and the West Gallatin River. The outlying spurs are cut and worn into most peculiar forms by glacial action. The survey of this area, comprising about four hundred square miles, occupied nearly a month, on account of the rugged character of the country and the detail with which the work was carried on. In the more level portions of the park it progressed more rapidly. Three hundred square miles of the plateau region lying more to the southward were surveyed during the latter part of the month. In September the work was extended still farther to the southward, until the heavy snows early in October compelled the postponement of further work to another season. The entire area surveyed in detail during the season is outlined as follows: on the north and west the limits are the boundaries of the park in those directions; on the east it is bounded approximately by the Norris wagon-road and Gardiner's River; and on the south by the lower geyser basin and the Fire Hole River. Besides the detailed work thus defined, meanders were run, and preliminary work extended, over all the usually travelled routes.

Upon the return of the party to Bozeman in October, a remeasurement, with compensated bars, was made of the base-line at that place, laid out in 1877 by the 'Geographical surveys west of the 100th meridian.' In this work Mr. Renshawe was rendered efficient service by Messrs. Chase and Garrett of the U. S. navy. The former is now at work on the computation and adjustment of these measurements.

Potsdam fauna at Saratoga, N.Y. — Mr. C. D. Walcott is closing up his work on the paleontology of the Eureka district, and preparing to take up the Potsdam fauna of the United States. From the past season's field-work, it was discovered that a massive

limestone, containing a typical Potsdam fauna, overlies the Potsdam sandstone of the New-York geologists in Saratoga county, N.Y. This limestone rests above the sandstone of Keesville, Whitehall, and Corrinth, and is shown to be the true representative of the Potsdam sandstone of Wisconsin, as it contains Lingula accuminata, Platyceras minutissima, Metoptoma cornutiforme, Crepicephalus sp.?, Lonchocephalus calciferous, Dicellocephalus Harti, and Ptychaspis speciosus, — species all closely allied to those from Wisconsin. This limestone was referred to the calciferous formation originally; the great Stromatopora-like bodies of Hoyt's quarry, four miles west of Saratoga, occurring in it.

The contained fauna was partially described by Mr. Walcott in the thirty-second annual report of the New-York state museum of natural history, and referred to the calciferous formation.

The U. S. naval observatory.

Chronometers. — This department of the observatory is in charge of Lieut. E. K. Moore, assisted by Lieuts. E. C. Pendleton and U. R. Harris. There are at present in the chronometer-room 233 chronometers, of which 22 are ready for issue; 21 are on trial; 71 require repairs, and will be repaired as wanted for issue; and 119 are condemned to be used only as 'hacks.' A temperature-room has been constructed for the more perfect testing of chronometers, and the observatory is now prepared to test them at any temperature to which they will be subjected in their practical uses. A proposition was made to the chronometer-makers, each to place four chronometers at the observatory for a competitive trial, beginning Jan. 1, 1884, the bureau of navigation to purchase the four passing the best trials. This has been accepted by William Bond & Son, Boston, T. S. & J. D. Negus, John Bliss & Co., and D. Eggert's Sons, of New York. By this method of purchasing, the best American made chronometers will be obtained.

Transmission of time-signals. — This work is in charge of the officers having the care of the chronometers. The time continues to be sent over the wires of the Western union telegraph company, and time-balls to be dropped at New York and Washington, as stated in last report. This work is all done automatically by direct connection with the observatory clock. The fire-alarm bells continue to be struck, and the time to be given to the horological establishments of the city at six A.M., twelve M., and six P.M.

Nautical instruments. — This work is in charge of Lieut. W. E. Sewell. 121 sextants and octants have been received at the observatory for examination. 46 of this number have been found in good order. There are remaining on hand at the observatory 77 instruments, 10 of which may be made serviceable by repairs: the remainder have serious defects, which will render most of them worthless. The principal of these defects are bent arcs or bent pivots. Another very common defect is want of parallelism in the glasses. Few of the makers seem to have exercised much care in this respect. The sextants and octants made by Stackpole & Brother of New York are superior to all others. The shades of 5 artificial horizons have been tested for parallelism of the glasses; and 3 were found defective, changing the direction of the rays from 1′ to 2′.5. Two standard thermometers, made for the observatory by J. & H. J. Green of New York, have been tested for their freezing and boiling points, and their tubes calibrated. At no point was the error found to be greater than a fifteenth of a degree. Tables of corrections for 45 clinical thermometers have been made for the marine hospital service.

The library. — The library now contains nearly twelve thousand volumes. The accessions for the year aggregate sixteen hundred and two volumes, besides a large number of pamphlets. The annual volume of astronomical and meteorological observations for 1879 has been recently received from the public printer, and the copies are now being sent out. The demand for the volumes is very great, there being six hundred addresses on the regular list. The manuscript, consisting of eight hundred and seventy-five pages, for a complete catalogue of the books and pamphlets in the library, July 1, 1883, alphabetically arranged by authors and subjects, is now ready for printing.

Publications. — The printing of the volume for 1880 is nearly finished, while the manuscript for the volume for 1881 is nearly ready for the printer. The printing of the annual volume is falling behind from year to year; and, with the apparently necessary expenditure of the printing-fund at the disposal of the navy department, this seems inevitable. The department fund is ususally exhausted by the last of April, and then two months' time is lost. If there were a fund at the sole disposal of the observatory, this difficulty could be overcome. The superintendent therefore urges that Congress be asked to appropriate seven thousand dollars annually for printing the observatory volumes, until the back work can be brought up as near as practicable to date.

U. S. astronomical expedition to Chile. — Professor William Harkness, assisted by Mr. Emil Wiessner, has made progress in reducing the zone observations made in Chile during the years 1850, 1851, 1852, by the expedition under the late Capt. J. M. Gilliss, U.S.N. The total number of stars is about seventeen thousand. On June 30, 1883, the appropriation from which Mr. Wiessner was paid became exhausted, and the work ceased. About a thousand dollars are needed to finish the preparation of the star catalogue from these zones, and it is hoped that Congress will grant that sum at the next session.

Increased estimates have been submitted for the coming year. The reasons for such increase are explained in each case in the letter accompanying the estimates. Experience suggests that the efficiency of the observatory should be increased by the appointment of a board of visitors, to consist of a limited number of distinguished astronomers, whose duty it would be annually to examine into the working of the observatory, and report to the secretary of the navy. They should have power to advise with the superintendent as to the character of the work to be done at the observatory.

NOTES AND NEWS.

THE death of Professor Ercolani on Nov. 16, 1883, at Bologna, inflicts a severe loss upon Italy; for he was distinguished both as a *savant* and a patriot. Count Giovanne Battista Ercolani was born in Bologna in 1819, and descended from an ancient patrician family. He was a favorite pupil of Antonio Alessandri, and early devoted himself to comparative anatomy and pathology. During the revolutionary movement, which swept over Europe in 1849, he was an ardent defender of Italian liberty, with the result of becoming an exile. He sought refuge in the near city of Turin, and there was appointed professor, afterwards director, of the veterinary school connected with the university. He remained in Turin until 1863, when he returned to Bologna to accept a similar position in the old university of that city. By his energy and influence, new buildings were erected, the school reorganized and greatly enlarged, and a valuable pathological museum established. For several years he held the position of rector of the university, and for a considerable period was permanent secretary of the Academy of science of the Institute of Bologna. Like Virchow, he was also a patriot. His reputation was not alone that of a teacher and *savant;* but his early career as a defender of popular rights made him a favorite with the citizens, and he was three times elected and served in the national parliament at Rome.

His numerous publications have contained the results of investigations made for the most part with the microscope, and have secured a wide reputation to his name. Most of his contributions first appeared in the memoirs of the Accademia di Bologna. His works show ability both as an observer and a draughtsman, and a tendency to touch upon general problems; but his arguments are not always clear, nor his observations sufficiently complete to establish his general theorems. He was an enthusiastic, careful, and industrious investigator, of whom Italy was justly proud.

His most extensive series of researches was upon the histology of the placenta, which led him to the conclusion that the lining membrane of the uterus degenerates, the placental membrane being a new formation, the lining being reformed afterwards from the uterine glands. This is not in accord with the views generally held at present. His single law of embryonic nutrition in vertebrates can hardly be considered novel, and is vague rather than profound. But the details recorded in these researches are of great value and interest. These memoirs, together with some additions supplied by the author, were translated into English, and published at Boston in 1880, under the direction of an enthusiastic admirer, Dr. H. O. Marcy.

His studies covered a wide range, — zoölogy, histology, and pathology were all included; but his most valuable work lay in the field of microscopical anatomy. His career has been justly admired, and his memory will long be cherished by his countrymen.

— The Government printing-office has just issued the third volume of the report of the tenth census. This relates to agriculture, and contains, besides the extended statistical tables concerning that industry, and discussion of them by the late superintendent, Gen. Walker, monographs upon cereal production, by William H. Brewer; flour-milling, by Knight Neftel; tobacco-culture, by J. B. Killebrew; manufacture and movement of tobacco, by J. R. Dodge; and meat-production, by Clarence Gordon.

Of the 1,182 pages embraced in this volume, 328 are devoted to the general statistical tables. These are exhaustive, and are very judiciously arranged for reference and use. A general summary, by states, of the principal statistics in 1880, 1870, 1860, and 1850, forms the first table. It treats of the number of farms; the area in farms, classifying the land as 'tilled,' 'permanent meadows, pastures,' etc., 'woodland,' and 'other unimproved' land; the value of farms, farming implements, and machinery; of live-stock, fences, fertilizers, and of all farm products; the number of the different classes of live-stock; the dairy products; cereal and fibre crops; sugar and molasses; hay, poultry, and eggs; apiarian products; rice, tobacco, Irish and sweet potatoes; orchard, market-garden, and forest products; wool, hops, broom corn, and pulse. Following this is a tabular discussion of the number and area of farms, and their form of tenure, by states and by counties. After this are placed county tables relating to the principal agricultural products. These tables are preceded by Gen. Walker's discussion (comprising 33 pages), in which are pointed out the limitations and qualifications of the statistics, and our progress in the different branches of the industry. It treats, in the author's well-known terse, incisive manner, upon the number and size of farms, their area and tenure, their value and that of farm products in total, and the principal agricultural productions severally.

The monograph by Professor Brewer upon the cereal crops is, like all work by this well-known authority, complete and exhaustive. He discusses the cereal product of this country as compared with that of other countries, especially with that of Europe; showing, that, with a surplus production in the United States of 650,000,000 bushels during the census year, there was a deficit in Europe of 380,000,000. The deficit in Great Britain was 280,000,000; in France, 170,000,000; and in Germany, 115,000,000 bushels. Following this discussion, the author naturally treats of the exports of cereals, noting their rapid increase in recent years. Their geographic and climatic distribution is next discussed, and is followed by a brief sketch of the principal classes of soils with relation to their applicability to cereal culture. Taking up the cereals severally, Professor Brewer discusses the product of each, its geographical and climatic distribution, its history, varieties, methods of culture, chemical composition, diseases, injurious weeds, and insects. The report closes with a brief history of American agriculture, and a discussion of the relations of this to other industries, and

of cereal culture to other branches of agriculture. The report is illustrated with sixteen double-paged colored charts of the United States; showing the proportional extent of cereal culture, and the relative yield of cereal crops per acre, and per head of population.

The report upon flour-milling processes is one of a series upon power and machinery, which subject was under the general direction of Prof. W. P. Trowbridge of Columbia college, New York. It treats somewhat at length of the various milling processes and machinery, and is freely illustrated with outline plates.

Professor Killebrew's report upon the culture of tobacco occupies not less than 286 pages. Besides the tables of production, and a few pages descriptive of the principal types of tobacco, the report consists of descriptions of soils, climate, methods of culture, curing, and marketing of tobacco. Each state is treated separately and very fully, which necessarily produces a great deal of repetition, and thereby unnecessarily extends the report. The concluding chapter consists of a treatise upon the chemistry of American tobaccos, by Gideon E. Moore, Ph.D.

The manufacture of tobacco is treated by Mr. J. R. Dodge, now and formerly the statistician of the department of agriculture. Commencing with a history of tobacco-production in this country, he traces it up to the present time, sketching the origin and the present habitat of the different varieties. Proceeding then to the subject proper of the report, the author submits the statistics, and discusses them exhaustively. He next takes up the subjects of taxation and the revenue from this product, exports and imports, the commercial movement and prices, with which the report closes.

The report upon cattle, sheep, and swine, by Mr. Clarence Gordon, is supplementary to the statistics upon live-stock. This report relates to live-stock upon ranches as distinguished from that upon farms. The distinction is not an easy one to draw in all cases, the line between ranch and farm being by no means a plain one; and one cannot help questioning the utility of attempting to separate them. The report opens with a short chapter upon pasture and forage plants by Professor Brewer. The report proper follows, each state and territory being treated separately. The matter relating to each consists of an historical sketch, a description of the pasturage areas, and the management of the ranch business, both in cattle and sheep raising and in cattle-driving. The estimates of pasture-land are in most cases undoubtedly very much too great; as, for instance, that four-fifths (50,000,000 acres) of the area of Wyoming is available as pasture-land. The report closes with a summary of the exports of meat and live-stock, and tables of the numbers of live-stock on farms and ranches.

In its outward appearance, this volume, as well as those which have preceded it, is not by any means above criticism. The only part of the mechanical execution of these volumes which deserves commendation is the colored plates, which were presumably printed by the lithographers. It is greatly to be regretted that so important and valuable a series of volumes should not be dressed in a garb in better keeping with their intrinsic merits.

— Dr. R. W. Shufeldt has asked authority of the surgeon-general of the army to compile an illustrated catalogue of the collection of comparative anatomy in the army medical museum, of which he has lately been placed in charge. Such a work as is intended, would be contained in a volume conformable in size with other illustrated catalogues of this institution that refer to the sections of surgery and medicine.

There are contained in the section in question upwards of three thousand specimens. These are chiefly osteological in character; and the classes of mammals, birds, reptiles, and fish, are pretty well represented. The general plan of this catalogue is to make it a complete work of reference to the collection. Each of the genera of all the vertebrate classes are to be awarded an illustration, and the text will present a concise account of the anatomy of the form treated. In every instance where it will be possible, the subject, be it an osteological one or a wet preparation of the soft parts, is to be chosen from the museum collection; so that any person using this catalogue will have the actual type before him, and the one that was selected to illustrate the text. Special attention is to be paid to the anatomy of such vertebrates as elucidate the principal questions in human physiology and anatomy, and good figures and illustrations of such forms will invariably be presented. Again: the vertebrates of our own country will be the subjects chosen in each case, as far as possible. By this means the student and anatomist may pursue his studies away from the museum after he has investigated all that is to be found there in his special line of research, and that, too, upon similar subjects. In short, it is evident that such a work will constitute a more or less exhaustive contribution to the literature of vertebrate anatomy, and be of special value to all scientific and professional men. The army medical museum contains within itself unusual facilities for the prosecution of such a work at comparatively little expense; since it has its own corps of workers, including photographer, artist, and others.

— Mr. Joseph Wharton of Philadelphia writes to the *Public ledger* of that city (Jan. 22) that he has found volcanic glassy dust in fresh, clean snow of recent fall. The snow, melted under cover in the porcelain vessel it was gathered in, showed at first no sediment; but after a time, and aided by a gentle rotatory movement which brought all to the deepest point, a slight deposit appeared. By pouring off most of the water, and evaporating the remainder, a little dry dust was obtained, which, even to the naked eye, showed, in the sunlight, tiny vitreous reflections. The dust weighed by estimate a hundredth of a grain, and showed under the microscope the characteristics of volcanic glass. It was partly irregular, flat, and blobby fragments, and partly filaments more or less contorted, which were sometimes attached in little wisps, and were mostly sprinkled with minute glass particles. Under a knife-edge, the filaments broke easily and cleanly. The irregular

fragments were of various sizes and shapes, mostly transparent, but, even when examined by strong transmitted light, showed no trace of crystalline structure. Their diameter was about that of single filaments of silk. No crystalline particle of pyroxine, or black crumb of augite, such as observers have found elsewhere in similar dust, was present; nor did a strong magnet stir any particles of magnetic oxide of iron, though they also have been found in other volcanic dust. It may fairly be assumed that those heavier minerals, if at first mingled with the volcanic glass, had been already deposited during the long voyage through more than ten thousand miles of space and more than four months of time, while the tenuity of the intrinsically lighter glass threads (the Pele's hair of Mauna Loa) enabled them to float farther from the point of eruption.

— The maps recently published by the Northern transcontinental survey, the discontinuance of which we regret, include the Crazy Mountains and Judith Basin in Montana, and the Yakima and Colville regions in Washington Territory, — a total area of about twenty thousand square miles, on a scale of two miles to an inch, with contours every two hundred feet. One has only to look at the best previous compilations of these districts to see the need and superiority of the new work. With this excellent basis, Prof. E. W. Hilgard of the University of California, in charge of studies of soils, has prepared three maps, four miles to an inch, printed in colors, of the Yakima and Colville districts, showing the characteristics and possibilities of the surface in much detail. Mr. T. S. Brandegee, working under the direction of Prof. C. S. Sargent of Harvard university, in charge of forestry, has also completed a map of the Yakima district, showing the distribution of the valuable trees in much detail: a regretably large area is marked as burnt.

These maps form but a small share of the material now collected: the greater part is not yet prepared for publication. In Mr. Pumpelly's first annual report, mention is made of the discovery, by Mr. George H. Eldridge, of valuable coal close to the line of the Northern Pacific railroad, near Bozeman, Montana; and of explorations of the coal-fields west of the Cascade Range by Mr. Bailey Willis. Studies of climate and rivers were undertaken by Prof. E. S. Holden of the Washburn observatory, — studies of the utmost importance in the interior region, where cultivation, unless on the lowest bottom-lands, is impossible without irrigation in the drier summer months. Much material has been brought together by Mr. W. M. Canby concerning the distribution and relative abundance of the various forage-plants on which the stock-raising interests depend. It is sincerely to be hoped that the results of these practical studies may be brought to light, together with the scientific information gathered during the two seasons during which the survey has been in operation.

— *Nature* reports that the French Société des électriciens has completed its organization, and has been divided into six sections, — Theoretical electricity, M. Marie Davy, president; Dynamo-electrical machinery, transmission of force to a distance, distribution of energy, M. Tresca, president; Electric lighting, M. du Moncel, president; Telegraphy and telephony, M. Blavier, president; Electro-chemistry and electrotherapy, M. Jamin, president.

— At the last general meeting of the Société de géographie, M. de Lesseps announced his conclusions on the subject of the Suez Canal. A project had been submitted to the English government; and, if a favorable response be not received, the canal company will proceed to carry out its own plans. He claimed that no one else had a right to make a canal by the side of the present one, and that this occupies the only feasable route. To the west the topography presents obstacles. To the east, a new canal would destroy the system of irrigation upon which the wealth of the country depends. All that is needed is to enlarge the present canal. When this was projected, the most eminent engineers of all countries decided on a canal with forty-four metres width at its maximum depth; but, owing to great expense and opposition encountered, the company contented themselves with a width in this part of twenty-two metres, which completely satisfied the needs of the commercial world of that day. Twenty-five years ago the increase of steam-navigation was not dreamed of. In 1830, of five hundred vessels composing the expedition to Algeria in the port of Toulon, there was not one steamer. In 1882 seven millions of steam tonnage passed through the canal, and only one sailing-vessel of seventy-five tons. The principal question to be determined at present, is, whether the enlarged canal shall consist of two waterways with an embankment between them, or whether the breadth of the present waterway should be extended to forty-four metres at the bottom and a hundred and twenty at the surface of the water. This would be decided by the engineers consulted, though the speaker was in favor of the latter plan, as swift vessels could then pass slow ones. The embankments of the canal are a relic of the days when vessels were towed. He saw no reason why the enlarged canal should have any embankments purposely constructed. The dredgings, which will be much less considerable than in the original work, can be dumped by the side of the canal, and thence spread out without maintaining a bank of any kind. This, at least, was M. de Lesseps's opinion.

— Prof. F. H. Snow, of the University of Kansas, reports that the chief characteristics of the weather of 1883, from observations taken at Lawrence, were the low mean temperature of all its months except April, November, and December; the unusually long period of immunity from severe frost; the large and well distributed rainfall; the slight preponderance of northerly over southerly winds; the high average wind velocity; the very high mean barometer, surpassing that of any previous year of our sixteen years' record; and the remarkably brilliant and long-continued orange and crimson sunrise and sunset glow of the last five weeks of the year.

SCIENCE.

FRIDAY, FEBRUARY 8, 1884.

COMMENT AND CRITICISM.

THE modern revolution in biology has made it plainer than ever before, that a certain elasticity of scope, a power of adaptation, should belong to scientific foundations. These are usually the outgrowth of enthusiasm, which, at a white heat, is not always so tempered with wisdom as to foresee that the special end then to be met may not forever be of paramount importance. It must be some such explanation as this, which is to be given of the state of affairs recently described by Dr. Harrison Allen of the University of Pennsylvania, as existing in Philadelphia. In the *American* of Jan. 26, Dr. Allen asserts that the existing foundations of Philadelphia are unequal to the present emergencies of biological science, and urges with much force that "an institution for the advancement of biological research, which will be open to both sexes, is imperatively demanded" in that city.

With the widening of the field of biological science, it has come to pass that what we need most at the present time is a new order of things. Academies and museums we must always have; and fortunately, in these respects, we already equal our transatlantic brethren. But that these alone do not cover all of the ground, is evident from the following remarks of Dr. Allen, concerning the Academy of natural sciences in Philadelphia: "The institution is committed to the task of accumulating a reference-library and a museum, of publishing proceedings and occasional memoirs, and affording a reading-room to any and all who are in the remotest degree interested in natural history, and, to this end, to give rudimental instruction at stated intervals to miscellaneous gatherings." All this is well, except that it 'is committed' to this line of work; and even this would be highly satisfactory, if it were not 'committed' to this alone, as appears to be the case: for the author continues, "The representative members of the academy have acknowledged that the higher education is not within the scope of its work, and have uniformly opposed any attempts at so changing the policy of the society as to admit of any responsibility being unreservedly assumed by its scientific men." That this view should be entertained by the members of organizations instituted long ago, and now endowed with a host of venerable traditions, is, of course, natural; but it is perfectly plain that these alone are no longer sufficient.

Dr. Allen would supply the deficiency which he laments by another foundation, — a biological institute, free from restrictions, liberally endowed, and headed by some one of high repute, qualified especially to inspire and to direct research. We see no reason why a plan like that proposed should not be an immediate and pronounced success, especially in Philadelphia, where science has long been at home, and which is so fortunate as to possess in Professor Leidy an enthusiastic leader and investigator eminently qualified to be the head and front of the new enterprise. We should rejoice to see some such enterprise begun in Philadelphia, particularly if it might enable advanced workers to take immediate advantage of that rich field for zoölogical research in our country which is the admiration and envy of European zoölogists. To this end the endowment should be ample, — we believe, considerably larger than the one hundred thousand dollars suggested by Dr. Allen. It should be, at the least, sufficient to enable advanced workers to proceed to points of timely and special interest; as, for instance, to the Great Lakes, or to the shores of the Gulf, — not to establish laboratories, but to pursue certain lines of research which imperatively require the presence

of the investigator in the field. It is certain that such an enterprise would arouse enthusiasm at home, and command respect abroad.

Mr. B. J. Lossing has recently published a paper on the proposed celebration, eight years hence, of the four hundredth anniversary of the discovery of America. We refer to it now, not to discuss this project, but to call attention to an historical question of such interest that it is worth a thorough investigation. Among mistakes which might almost be classed as popular superstitions must be placed the wide-spread notion that the rotundity of the earth was nearly unknown until comparatively recent times. Mr. Lossing goes so far as to say that the scholars in the time of Columbus ridiculed the idea of the earth being globular, and in this he only echoes the popular belief on the subject. Now, the fact is, that the form of the earth has been as well known as it is now from the earliest historic times, and has never been denied by a scientific writer on scientific grounds. Through twenty centuries of discussion among rival systems and theories, this one has stood undisputed as the fundamental fact of astronomy. Nor has it ever been the subject of religious controversy, as the Copernican theory was. Under these circumstances, it is a question of interest, whether a state of things of which the astronomers never heard existed in Spain four centuries ago; whether, in fact, there are books or documents of any kind showing that men who then ranked as scholars believed the earth's surface to be flat. We suggest the subject to historical investigators.

It must, of course, be understood that we are now speaking of professed scholars, in a position to be consulted by the authorities, and not of the ignorant masses. It is quite likely that Queen Isabella's chambermaid may have ridiculed the idea of the earth being round, and that her spiritual confessor may have looked upon astronomical theories generally as the work of men very dangerous to orthodox religion. But if the knowledge of an epoch is that of the majority, where shall we stop? It might be found, that, at the present day, the majority of the human race believes the earth to be flat. We leave our readers to picture in their minds an encyclopedia of the thirtieth century, in which it will be stated, that although the astronomers of the nineteenth century knew of the motion of the earth, yet their more numerous and influential contemporaries, the theologians, as represented by one of their leaders named Brother Jasper, believed it to be at rest.

The acquittal of General Cesnola of the charge of libel, in the case so long before the courts, is probably satisfactory to the trustees of the Metropolitan museum of art, but is far from satisfactory from a scientific stand-point. So far as the trial related to libel, it made no difference to science which side won; but it does make a difference when it appears, that, by legal twists and turns, the vital spot was not touched. As the result stands before the scientific world to-day, the curator, while acquitted of the charge of libel in his hot reply to a former business agent, is still, directly or indirectly, responsible for the manipulations of ancient sculptures in the museum under his charge. One good result may follow from the Cesnola trial. In future, fragmentary objects in museums will probably either be left as found, or else so joined, that, while holding their relative positions, they will still show that they are fragments. The so-called restorations are too often the conceptions of the officers in charge; and, while Cesnola has followed a plan often sanctioned by supposed requirements of art, it is one which will never be permitted by science.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Tropical cyclones.

In Mr. Davis's paper on whirlwinds, cyclones, etc., in *Science*, vol. ii. pp. 758–761, I notice the use of the term 'equatorial cyclone,' which should be discontinued, as I have already had occasion to state before.[1] There being no deflection of the winds from the normal to the isobars on the equator, there can be no cyclone there; and it is, I think, generally ad-

[1] *Nature*, vol. xix. p. 517.

mitted by meteorologists, that in the latitudes 0°–6° the deflection is also too small to admit of cyclones; and really I know of none. And even outside India, and the seas around it, there are scarcely cyclones in latitudes lower than 10°.

Thus, what Mr. Davis calls 'equatorial' should be called 'tropical' cyclones. If anybody wishes to mention 'equatorial cyclones,' let him first prove their existence. So long as this is not done, meteorologists having a mind for exact scientific terms will hold to my opinion. A. WOEIKOF.

St. Petersburg, Jan. 7, 1884.

I shall be well pleased if so distinguished a meteorologist as Dr. Woeikof finds no other points needing correction in my papers on storms than this one. That I fully agree, as to the facts, with him and with Dr. Taylor, who first, so far as I know, states this matter in connection with its cause,[1] is shown in my seventh paper (this volume, p. 40); but, while my use of the objectionable term was accidental rather than deliberate, there is, perhaps, little to choose between 'equatorial' and 'tropical,' both of which occur in this connection in my papers: for, if the first apply in strictness only to points in latitude 0°, the second is equally limited in its exact meaning to points in latitude 23½°; and if 'tropical' has come to mean 'within or between the tropics,' so 'equatorial' may mean 'near the equator.' *Tropenzone* of the Germans is not to be translated 'tropical zone,' but 'torrid zone;' and in English, 'tropical' should not be applied in an exact nomenclature to the equatorial low pressures of the doldrums, as in Buchan's writings, but rather to the high pressures of the horse-latitudes, as Ferrel uses it; and 'tropics,' when properly rendered into German, would be *wendekreisen*, or it might be paraphrased into *die polargrenzen der passate*. Inasmuch, then, as the truly tropical belts of the ocean are best characterized by regions of high pressure, free from cyclonic conditions, except where storms from lower latitudes cross them near their western shores; and as the *inter*-tropical rains of the doldrums are not called 'tropical,' but 'equatorial,' even when off of the equator, and by Dr. Woeikof himself, — it can hardly be considered a serious error to speak of the cyclones, which begin in the doldrums, as equatorial also.

Cambridge, Jan. 30, 1884. W. M. DAVIS.

Osteology of the cormorant.

Mr. Jeffries' answer in *Science* (iii. 59), to my letter in a former number of this paper (ii. 822), caused me genuine surprise. His suggestion that the occipital style of the cormorant 'is the ossified tendon of some of the extensor muscles of the neck,' made in a former communication (ii. 739), is here, apparently, announced as his conviction, and Selenka is introduced to sustain the statement. Now, I am informed by Mr. Jeffries, that, "in view of such eminent authority, it would seem that something more than simple denial is required to upset a statement accepted by anatomists for many years;" and a few lines farther on, I am said to acknowledge my mistake, because I ignored the point. Permit me to say, that nothing of the kind has been accepted by anatomists for many years. I met this statement by a simple denial, in order to save space in the columns of *Science;* but, if Mr. Jeffries must be informed as to what the occipital style of the cormorant is, I would inform him that this bone is not an ossification in any tendon of the extensors of the neck, because it is situated, as we know, in the median plane of the skeleton, at a mid-point on the occipital ridge. The tendons of the extensors in a bird's neck, which are inserted at the occiput, are in pairs, their insertion being bilateral; and their tendons are *never* inserted in the median plane: consequently this style cannot be an ossification of any of them. On the contrary, *it is* an ossification of the fascia between the extensors of the neck and what may be compared to the ligamentum nuchae.

As Mr. Jeffries seems to be anxious about the position in which I drew this occipital style, I would call his attention to the fact that it is shown as occupying its *proper site*, only tipped up somewhat, as it was on my dried skull. Such license is perfectly permissible in anatomical delineation, and is seen in the illustrations throughout the literature of anatomy. It often shows the parts to better advantage; and, in structures as well known as this style is, no explanation is necessary. Acquainted, as I am, with the *anatomy* of this 'nuchal style' and its anatomical relations, I must again acknowledge that I am still ignorant of the *physiology*, or really the function, of this style, or why it should occur in a cormorant and not in other birds nearly related.

As to Mr. Jeffries' concern at my not being, to his mind, thoroughly informed upon the homologies of the patella in birds, I would invite his attention to a paper of mine written some time before my 'Osteology of the cormorant' appeared. To show that I have always agreed with the eminent authorities he alludes to for my benefit, in the co-existence of a patella and an elongated cnemial process of the tibia in most divers, I refer to my article entitled 'The number of bones at present known in the pectoral and pelvic limbs of birds,' in which I say, "I know of but two free bones that occur about the knee-joint. The first of these is the patella; and this may co-exist with the cnemial ridge of tibia, as in Colymbus (Owen). The other is a free sesamoid found in some birds in a notch at the head of the fibula (Speotyto)" (*Amer. nat.*, November, 1882, 894). I repeat, that 'I find myself misquoted' by Mr. Jeffries, in his remarks upon my paper, 'more than once;' that is to say, he has failed to include statements falsely attributed to my article in the customary quotation-marks. I do not say, (1) that I figure this style '*in situ*,' nor (2) positively affirm that it has never been figured before (ii. 739), but do say, "I do not believe we have a figure showing the site of this bonelet" (ii. 640). Selenka's and Eyton's figures had slipped my mind for the moment, as their works had not been available for a year or more. Furthermore (3), I do not refer to Professor Owen to have him authorize any thing in regard to Podiceps, but only to the patella of the loon, as any one accustomed to anatomical reading can see by referring to my article on the 'Osteology of the cormorant' (ii. 640).

R. W. SHUFELDT.

Upperglow of the skies in relation to halos and coronas.

These striking and beautiful atmospheric phenomena, which have manifested themselves over the entire globe, have attracted much attention, and been minutely described by correspondents in various countries. But there is one feature, which, although incidentally noticed by some writers, has attracted but little attention. I allude to the fact, that, wherever

[1] On tropical hurricanes (Brit. assoc. report, 1852, pt. 2, 31). Herschel used this in his Meteorology, but failed to do justice to Taylor's explanation of how a deflective force arises from the earth's rotation, and omits mention of the effect of the conservation of areas, which Taylor recognizes as of essential importance.

the phenomena have been sufficiently pronounced, the sun is during the day encircled by a more or less distinct *colored halo or corona.* At this place the assumed supra-cirrus volcanic dust seems not to have been sufficiently dense to have developed the colored rings; and there was observed nothing more than a *whitish glare* extending over the sky from 20° to 25° from the centre of the sun. But the Rev. S. E. Bishop writes me from Honolulu, that this chromatic circle around the sun has been constantly observed in all of the Hawaiian Islands for several months. It has likewise been observed in England as a frequent accompaniment of a conspicuous manifestation of the upperglows of sunset and sunrise.

It is an interesting question, whether this more or less distinct colored zone encircling the sun is a true *ice-crystal halo*, or a *diffraction corona.* Its want of sharp definition, and the absence of the regular succession of prismatic tints due to refractive dispersion, would seem to point to diffraction as the true cause of the chromatic phenomena. On the other hand, the large size of the colored circle, having a radius of from 20° to 30°, would seem to connect it with the well-known ice-crystal halo of about 22° radius.

While I am disposed to regard this chromatic feature of the phenomena as mainly due to the diffractive action on light of the impalpable dust-particles suspended in the lofty supra-cirri regions of the atmosphere, yet it is by no means improbable that ice may be associated with the phenomena: for it appears from the experiments of M. Coulier, and more particularly from those of Mr. John Aitken, communicated to the Royal society of Edinburgh, Dec. 20, 1880 (*Nature*, vol. xxiii. pp. 195–197; also vol. xxiii. p. 384), that the presence of dust-particles in the air is essential to the formation of fogs and clouds; that, when aqueous vapor condenses in the atmosphere, it always does so on some solid nucleus; and that the dust-particles in the air form these nuclei. Now, it is evident that the presence of these attenuated dust-particles in the supra-cirri regions of the atmosphere would produce condensation of the rarefied aqueous vapor at these lofty altitudes. But inasmuch as this region must, even within the tropics, be far above the plane of perpetual congelation, the condensed vapor must necessarily assume the form of aggregations of ice around these nuclei: hence the diffractive coronas may be associated with imperfectly developed ice-crystal halos. JOHN LECONTE.

Berkeley, Cal., Jan. 25, 1884.

Inheritance of physical injuries.

Well-authenticated instances of the inheritance of a physical injury are so rare, that I wish to put upon record one which has recently fallen under my observation. A gentleman, when a boy about seven years of age, had the second toe of the right foot deformed by wearing a tight boot. The first and third toes were crowded together, forcing the second one under and backwards, and causing a curvature of the second joint, which, in time, became permanent. The joint, being somewhat elevated above those of the other toes, received the pressure of the shoe, and always after was more or less troublesome in consequence. The gentleman was twice married. By his first wife he had six children, the second of which was a daughter; the rest, sons. The daughter inherited the crooked toe; but the feet of all the sons were normal. The deformity appeared, however, in the son of one of these, — the brother next younger than the sister, — affecting the same foot and toe as on the grandfather. By his second wife the gentleman had only one child, a son, who also inherited the peculiarity; but in this instance it was the second toe of the *left* foot, instead of the right, that was affected.

Knowing that much doubt still exists whether the results of a slight physical injury, like the one I have described, are ever transmitted, I have taken pains to examine carefully all the evidence under my observation; and I feel assured of its correctness. All four having the deformed toes are now living, and all agree upon the facts. The gentleman is positive that his feet were normal until he was about seven years old, and says he remembers very distinctly wearing the boots which caused the deformity. An examination of the foot does not show any congenital peculiarity which might have been transmitted. The toe, when restored to its correct position, appeared normal in every way. No peculiarity of this kind has ever appeared in any other of the gentleman's relatives. I can see no way, then, of avoiding the conclusion that the injury, or rather its results, have been transmitted to two generations.

The case presents some features which render it especially interesting. The peculiarity's appearance in the children of both wives seems to eliminate altogether the element of the mother's influence in producing it. The recurrence of the variation in the grandchild, the father being normal, indicates how powerful was the tendency to perpetuate this slight deviation from nature's standard. In the other cases which I have studied personally, if a variation did not appear in a child, that child's children were free from it also. I should be glad to know if any one of your readers has observed this tendency toward reverting to the ancestral type under similar circumstances. IRVING P. BISHOP.

Perry, N.Y., Jan. 28, 1884.

Pumice from Krakatoa.

Capt. A. W. Newell, of the bark Amy Turner of Boston, has brought in some pumice which was washed aboard his vessel, Sept. 17, 1883, in latitude 7° 25′ south, longitude 103° 21′ east, about a hundred and sixty-five miles south-west from Krakatoa, Sunda Straits. It covered the sea in windrows, and was observed as fine ashes as far distant as thirteen hundred and fifty miles from its source.

A piece about seven inches by five, which came to my notice, is of a reddish-gray color, and very much inflated: it carries porphyritic crystals of plagioclase felspar, in many cases surrounded by dark-brown glass, forming small black spots in the gray mass, which might at first sight be mistaken for augite or hypersthene. There is, besides, dark-green augite and brown hypersthene, which is strongly pleochroic, and resembles closely that found in the lavas from the volcanoes of northern California and the Cascade Range (Notes on the volcanoes of northern California, Oregon, and Washington Territory, *Amer. journ. sc.*, September, 1883).

The percentage of silica for this pumice was found to be 62.53, and is almost identical with that of the hypersthene-bearing pumice from Mount Shasta, which is 62. It is undoubtedly the pumice of a hypersthene andesite, and is especially interesting because of its similarity to rocks found on the western coast of North America. The observations of Rénard on the ashes that fell in Batavia soon after the eruption of Krakatoa (*Nature*, Dec. 6, 1883) show the same component minerals, and have doubtless been made on similar material.

U.S. geological survey, New York,
Jan. 30, 1884.

THE EVOLUTION OF THE CEPHALOPODA.[1] — II.

THE individual coiled shell of every existing Nautilus may be said to pass through the stages of the protoconch, when it is always nearly or quite straight; then through the first of the conch, when it becomes slightly curved; then through a more completely curved period, in which the first whorl of the spiral is completed. After this it continues the spiral, the whorls on the outside touching the exterior of the inner ones, and spreading so rapidly by growth as to begin to envelop them, and, in extreme cases, to completely cover them up.

The natural inference from these facts would be, that there was a similar succession of forms in past times, — the straight in the most remote, the arcuate and the gyroceran in succeeding periods, and the nautilian only in comparatively modern times. This would be a perfectly clear and legitimate mental conception. The structural relations of the adult shells appeared also to demand the same solution, as shown by the researches of Quenstedt, Bronn, and Barrande, and later of Gaudry. Barrande's researches also demonstrated that this idea could not be maintained, and that there were no such serial relations in time, but that the whole series of forms were present in the earliest period, and occurred side by side in each paleozoic formation. This great author's conclusions have had a curious effect upon paleontologists. It has been hastily assumed by some, that the mental conception was more perfect than could be realized in nature; by others, that the imperfection of the recorded succession was an obvious refutation of the doctrine of evolution, and all pursuit of a solution unworthy of serious attention.

Statistically, the logical picture coincides with the observed succession in time. The straight cones predominate in the Silurian and earlier periods; while the loosely coiled are much less numerous, and the close coiled and involute, though present, are extremely rare. The loosely coiled and close coiled gain in numbers in the carboniferous, and the involute are more numerous than in the Silurian; while, in the later times of the Jura, all disappear except the close coiled and the involute, there being a decided predominance of involute shells. Thus we are able, by reversing the record and travelling back to the Silurian, again to see, that antecedent to that period, in the protozoic, there must have been a time when the straight cones or their immediate ancestors predominated, to the exclusion of the coiled and perhaps even of the arcuate types or varieties.

The involute shells of the earliest geological times were therefore probably evolved from the straight cones in regular succession; and we may perhaps hope to eventually get the evidence of this succession in the formations. The exact counterpart of our logical picture, as Barrande[1] has truly stated, does not, however, exist in the known geological records of later periods. Judged by the common classification, by the prevalent ideas about the affinities of adult structures, and by the modes of occurrence of fossils in the geological formations, the forms seem to be without law or order in their succession.

But let us imagine, during the paleozoic, a different condition of affairs from what is now the general rule. Let us suppose such a thing possible as the quick evolution of forms and structure, and that in these ancient periods, near their points of origin, animals found the earth comparatively unoccupied, and were not only able, but in fact forced, to migrate in every direction into different habitats, and to make perpetual efforts to readjust their inherited structures to the new requirements demanded by these comparatively unoccupied fields. Food and opportunity would have acted, in such localities, as stimulants to new efforts for the attainment of more perfect adaptation and for changes of structure useful to that end. We can neither imagine the effort to change of habitat and habits, without its cause, the primary physical stimulant, nor the change of structure, except as a result of the direct effort to meet the physical requirements with corresponding or suitable structures.

Let us also compare the changes taking place during the whole of paleozoic time with those known to have occurred in certain isolated cases in more recent times; such, for example, as that of Steinheim, where a single species, finding itself in an unoccupied field, proceeded with unexampled rapidity to fill its requirements by the evolution of new series and many species, all differing from each other, but all referable, by intermediate varieties, to the original form, — in this example, really a single species, the well-known Planorbis aequiumbilicatus.

[1] Concluded from No. 52.

[1] We regret that space does not permit some account of th author's wonderful book, the Système silurien de la Bohême. While opposed to almost every theoretical conclusion and the general arrangement of the facts made by him, we have the strongest feelings of respect and admiration for his powers of observation, the technique of his work and publications, and the surpassing unselfishness of his life, spent in the pursuit of what he deems to be vital truths (see *Science*, Nos. 43, 44)

If we admit such possibilities, and then find similar phenomena in the paleozoic epoch, we shall no longer need our first picture, but can construct a far more natural one.

The Nautiloidea will not then present themselves as a simple chain of being, but as they really were, — several distinct stocks, or grand series, and each of these grand series divisible into many smaller lines of genetically connected forms. In the Cambrian, or perhaps earlier, some of these do not have close-coiled forms at all; some of them have: but all, except the most primitive series, which are composed wholly of straight or arcuate forms, have some close-coiled species. These we can often trace directly with the greatest exactness, both by their development and by the gradations of the adult forms, to corresponding species among the straight Orthoceratites.

The series we have described above, from Orthoceras to Goniatites, compares closely with any single genetic series of the Nautiloidea, and shows that this ordinal type arose very suddenly in the protozoic, and evolved true nautilian shells in the Cambrian or earlier.

The Ammonoidea evolved from the nautilian forms of the Cambrian into series, which are structurally much more distinct from each other in the paleozoic than any groups of the same value (i.e., genera) in the succeeding formations, and thus, in different but equally plain characters, teach us that they also had a quicker evolution within that period itself than in the later formations. Either this was the case, or else the Ammonoidea must have been created in full possession of an organization only attained by similar parallel series of congeneric, close-coiled nautiloids, after passing through all the intermediate transformations above described. Here is a curious fact: though taxonomically equal, we cannot compare the order of the Ammonoidea with the whole of the Nautiloidea, but only with a more or less perfect single series of that order. This phenomenon fully accords with the true picture of the genetic relations. The remarkably sudden appearance and fully developed structures of these earlier ammonoids finely illustrates the fan-like character of the evolution of forms from chronological centres of distribution, and the quickness with which they must have spread and filled up the unoccupied habitats.

After the paleozoic, no absolutely new structural modifications are produced; though the complication of the structures is carried so much farther that we are at first apt to imagine that there are several new types of structure in the trias and Jura. We can carry out this assertion, even into some minute structural characters. Thus the mesozoic ammonoids have, in all forms, a curious little short collar, which arises from the septa, and surrounds the siphon. It seems to be useful simply to close the joint, and perhaps make the connections of this tube more perfect, and exists in no nautiloid at present known. It was supposed from its development, etc., to be confined to the Ammonoidea of periods later than the paleozoic, but has recently been noted by Beyrich in a Goniatites of the carboniferous. We have found in a similar way every distinctive structural peculiarity of the mesozoic Ammonites appearing in some form among the Goniatites of the carboniferous.

The contemplation of the wonderful phenomena presented by these series has finally led the author, not without reluctance, to the conclusion that the phenomena of evolution in the paleozoic were distinct from those of later periods, having taken place with a rapidity paralleled only in later times in unoccupied fields, like Steinheim.[1]

The hypothesis of Wagner, that an unoccupied field is essential for the evolution of new forms, gains immensely in importance, if, as we suppose, it is practical to apply it to the explanation of the phenomena we have observed. Every naturalist must see at once, by his own special studies, that this is the only reasonable explanation of the frequent rapid development of types in new formations, as well as the sudden appearance of so many of the different types of invertebrates in the paleozoic. Newberry's theory of cycles of sedimentation shows that the sudden appearance of types is inexplicable, except upon the supposition that they retired with the sea between each period of deposit, and again returned after long intervals of absence, or perhaps made their appearance for the first time in a given fauna.

With this explanation and that of Wagner the facts we have observed fully coincide, and, we think, amply explain the phenomena, both of sudden appearance in the first deposits of formations, and subsequent quick development in the necessarily unoccupied habitats. The researches of Barrande, Alexander Agassiz, Bigsby, Gaudry, and many others, show us that this must have been especially true of the paleozoic or of the protozoic, if this supposed period is admitted, as compared with subsequent periods.

We find, then, that, in order to make our

[1] Another statement of these facts in the form of a law of evolution is given in the author's 'Genera of fossil cephalopods' (*Proc. Bost. soc. nat. hist.*, xxii. 1884).

logical and generalized picture of exact correspondence between all the changes in the life of a nautilian close-coiled shell and the life of its own group accord with the facts, we must be careful to limit it to groups quickly evolved, and these exclusively paleozoic.

In 1843 Auguste Quenstedt began researches which ought long ago to have led to this solution. He demonstrated by repeated examples, that among diseased types the most extensive changes of form and structure might take place in a single species, and within the narrowest limits of time and surface-distribution. Quenstedt was thus the first to show that in diseased forms the shell had the inherent habit of reversing the process of growth and evolution, and of becoming more and more uncoiled by successive retrograde steps. Von Buch and Quenstedt, master and disciple, and the author independently of either of these predecessors, in three successive researches, have arrived at the identical conclusion, that these uncoiled shells are truly distorted, or, as we may more accurately express it, pathological forms. They are not, however, rare or exceptional, as one might at first suppose, but occur in numbers and in every grade, — from those that differ but little from the normal forms, to those that differ greatly; from those that are exceedingly confined in distribution, to those which lived through greater lengths of time. But in all cases they exhibit degradation, and are expiring types. The author has repeatedly traced series of them, and studied their young, partly in Quenstedt's own collection. In all cases they show us that great changes of form and structure may take place suddenly; and this lesson could have been learned from Quenstedt's work and example as well forty years since as now: and in all species the young are close-coiled, even in some which are arcuate in the later larval, adolescent, and adult stages. Baculites, the extreme form, is straight, and the young still unknown.

When we attempt to resolve these pathological uncoiled series and forms, which show by their close-coiled young that they were descended from close-coiled shells, we find ourselves without comparisons or standards in the early life of the individual. The laws of geratology — that the old age of the individual shows degradation in the same direction as, and with similar changes to, those which take place in successive species or groups of any affiliated pathological series of uncoiled and degraded forms — here come into use, and serve to explain the phenomena. This correspondence is shown in the uncoiling of the whorls, loss of size, the succession in which the ornaments and parts are resorbed or lost, the approximations of the septa, and position of the siphon. It is quite true, as first stated by Quenstedt and also by D'Orbigny, that every shell, when outgrown, shows its approaching death in the close approximation of the last sutures, the smoothness of the shell, the decrease in size, etc.; but, in order to realize that these transformations mean the same thing as those which take place in any series of truly pathological forms, we have to return to the types in which unfavorable surroundings have produced distortions or effects akin to what physicians would term pathological. This frequently happens in small series of Nautiloidea; and, if we confine ourselves to these, we can make very accurate comparisons: or, on the other hand, in the case of the Ammonoidea, we may trace the death of an entire order, and show that it takes place in accordance with the laws of geratology. Such series, among the Nautiloidea, are abundant in the earlier formations; but they have not the general significance of the similar forms among the Ammonoidea, and can be neglected in this article. There are no known cases of degraded series of uncoiled forms among the ammonoids of the earlier or paleozoic periods: they may have occurred, but they must have been excessively rare. In the trias and early Jura, pathological uncoiled forms are rare among ammonoids, but in the middle and upper Jura they increase largely; and finally, in the upper cretaceous they outnumber the normal involute shells, and the whole order ceases to exist. Neumayer has shown, that a similar degradation occurs in all of the normal ammonoids of the cretaceous, and that their sutures are less complicated than those of their immediate ancestors in the Jura. This proves conclusively, that the degradation was general, and affected all forms of Ammonoidea at this time; since the uncoiled forms are not confined to special localities, as in the Jura, but are found in all faunas so far as known. The facts show that some general physical cause acted simultaneously, or nearly so, over the whole of the known area of the world during the cretaceous period, and produced precisely similar effects upon the whole type as had here and there been noticeable only within limited localities and upon single species or small numbers of species during the previous periods. This general cause, whatever it may have been, acted on the type so as to cause the successive generations of the larger part of the shells to become distorted

smaller and more cylindrical in their whorls, smoother, and to lose their complicated foliated sutures. In extreme cases they became again perfectly straight cones, like the orthoceratitic radicals. So much alike are they, that it is quite common for those who are not students of this group to mistake the degraded Baculites for the radical Orthoceras. This decrease in size, increasing smoothness, and uncoiling, is precisely parallel with the similar transformations taking place during old age in the normal involute shells of the Jura, which, when old enough, also depart from the spiral, or tend to straighten out, and always lose their ornaments, decrease in size, and so on.[1]

The universal action of the surroundings, as we now know them, is certainly not exclusively favorable to the continuance of life, and may be wholly more or less unfavorable. It certainly perpetually excites the animal to new and more powerful exertions, and, like perpetual friction, wears out its structures by the efforts which it obliges it to make for the support of the structures in doing work. At first this leads to development, the supply being greater than the demand; but sooner or later, and with unvarying certainty, the demand exceeds the powers of supply, and old age sets in, either prematurely, or at the termination of the usual developmental periods. The remarkable and at present unique example of the Ammonoidea places us in a position where we can see the same process taking place in the whole of a large group, with attendant phenomena similar in every respect to those which we have observed in individual shells of the same order.

In numbers of species and genera, and in the complication of the internal structures and the production of the external ornaments on the shells, the order reaches what appears to be the highest stage of development in the Jura; then retrogression begins, and, steadily gaining, finally affects all forms of the type, and it becomes extinct. Smaller series of the Ammonoidea and Nautiloidea go through the same process in their respective time-limits, and in the same way, but can be compared with the individual much more accurately and closely. It is evident, then, that the comparison of the life of an individual with that of its immediate series or group reaches a high degree of exactitude, and that the observed phenomena of the life of an individual should enable us to explain, in some measure, the equivalent phenomena of the life of the group; and we are unavoidably led to entertain the expectation that it does explain it. This expectation was actually formulated as a probable law for the whole animal kingdom by Haeckel in the same year (1866) as the author first published on the Tetrabranchiata. We are therefore able to quote this leader in science in support of our weaker knowledge; and also a pupil of his, Wurtemburger, who has announced the same results attained by researches on the Ammonites of the Jura, but, naturally perhaps, omitted to recognize any one but his honored master.

The evidence is very strong, that there is a limit to the progressive complications which may take place in any type, beyond which it can only proceed by reversing the process, and retrograding. At the same time, however, the evidence is equally strong, that there are such things as types which remain comparatively simple, or do not progress to the same degree as others of their own group. Among Nautiloidea and Ammonoidea these are the radical or generator types. We have no case yet of a highly complicated, specialized type, with a long line of descendants traceable to it as the radical, except the retrogressive: but all our examples of radicals are taken from lower, simpler forms; and these radical types are longer-lived, more persistent, and less changeable in time, than their descendants.

We find the radicals of the Nautiloidea living throughout the paleozoic, and perpetually evolving new types in all directions; then this process ceases, and the primary radicals themselves die out. But they leave shells, which are in that stage of progression which I have called the nautilian. These, the more direct descendants of the radicals, become secondary radicals, and generate series having more involute shells. These, in turn, as secondary radicals, exhibit very decidedly a greater chronological distribution than their descendant involute forms, persisting, even to the present day, in Nautilus umbilicatus. The same story may be told of the Ammonoidea, but substituting at once the close-coiled shell (the secondary radicals) for the primary radicals of the Nautiloidea, even as far back as the Cambrian. These secondary radicals, greatly modified but still carrying in their simpler organizations and mode of coiling the possibilities of a number of new series, existed by the side of the expiring degraded forms of the cretaceous.

This is the essential element of difference between the life of the whole order and that of

[1] We are aware of the existence of evidence that Ammonites of the normal form, the types of which we have seen, have been described from the lower tertiaries: but there are still doubts about the reputed age of the formations; and, in any case, they only tend to confirm the general trend of the facts.

the individual. We can accurately compare the rise and fall of the individual and its whole cycle of transformations with that of any of the single series or branches of the same stock which become highly specialized and then degenerated; but, when we attempt to go farther, we meet with similar difficulties to those encountered in tracing the progress of types and orders. The radical and persistent types are still present, and teach us, that, as long as they exist sufficiently unchanged, new types are a possibility. We have traced many of these in the two orders, and have found that they change and become more complicated, and that probably a purely persistent or entirely unprogressive type does not exist among the fossil Cephalopoda. The most celebrated example of unchanging persistency has been, and is now supposed to be, the modern Nautilus. We think, however, that when our observations are fully published, it will become evident that the similarities of this shell to some of the Cambrian coiled forms — which have caused Barrande and others to suppose that it might be transferred to the Cambrian fauna without creating confusion — belong to the category known to the naturalist as representation; that is, similarities of form, and even of structure, in the adults, but with young having entirely distinct earlier stages of development, and belonging to distinct genetic series. Still, comparative unprogression or persistency is common in all radicals; and they force us to recognize the fact, that the orders could have produced new series, perhaps even in the cretaceous, if it had not been for the direct unfavorable action of the physical changes which then took place, so far as we now know, over the whole earth.

Thus, in making our comparisons between the life of the individual and the life of the group, we cannot say that the causes which produced old age and those which in time produced retrogressive types were identical: we can only say, that they produced similar effects in changing the structures of the individual and of the progressive types, and were therefore unfavorable to the farther development and complication of these types. In their effects they were certainly similar; but in themselves they might have been, and probably were, quite different, agreeing only in belonging to that class of causes which we distinguish as pathological, or those whose nature can be generally summed up as essentially unfavorable to the progress, and even to the existence, of the organization.

In order to understand the meaning of these evidently degraded structures, we must turn back to our first remarks upon the order. The apertures and forms of the retrogressive shells all show that they were exceptional, that they had neither well-developed arms for crawling nor powerful pipes for swimming; that, in other words, they could not have carried their spires in any of the ordinary ways. Their habitats, therefore, must have been more or less sedentary; and like the sedentary Gastropoda, as compared with the locomotive forms, they presented degeneration of the form and structure of their higher and more complicated ancestors. Their habitats did not require the progressive grades of structure, and they dispensed with or lost them; and in many cases this took place very rapidly. This retrogression was in itself unfavorable to a prolonged existence; and the geratologous nature of the changes tells the same story, so that we can attribute their extinction to the unfavorable nature of their new habitats, and also call them pathological types without fear of misrepresenting their true relations to other forms.

We have necessarily avoided even allusions to some of the most important confirmatory facts; but we hope our effort will at least show that the theory advanced is a reasonable one, and that the fossil Cephalopoda are worthy of the attention of even the most enthusiastic of the young disciples of the modern school of embryology. The theories of this school will have to stand tests of which they have now not even a faint idea, and it is to be hoped they will not long neglect the precaution of knowing also the past history of the types they often so incautiously and confidently handle.

ALPHEUS HYATT.

THE MOTION OF WAVES OF COLD IN THE UNITED STATES.

THE chief signal-officer of the army desiring to learn the progress of waves of cold across the United States, an investigation has been undertaken in order to determine the appearance of such waves, their approximate velocity, and general line of advance. It would seem, at first sight, as though the problem might be solved by drawing isotherms (i.e., lines through points at the same temperature) on consecutive days, from simultaneous observations over the whole country. If, then, there were a progressive motion, the study of these lines would show it. It has been found, however, that a cold wave does not travel in a well-defined closed curve; and, more than that, the gradual increase of temperature, as the curves approach

the south, masks and often obliterates the motion we seek to find. Again: such waves are frequently divided, then united, thus by the loss of their identity making it impossible to trace them for a long period. One of the simplest methods of procedure in an investigation of this nature would be the projection of the observations of temperature in curves, one for each station, and then studying the fluctuations from station to station. This was done by Professor Elias Loomis, in his ninth paper, in which he investigated the motion of waves of high and low pressure.

An investigation of this kind, a short time since, gave 19.8 days for the mean interval of time of sixteen waves, moving from St. Michael's, Alaska, to Turuchansk, Siberia, along the sixty-fifth parallel, or an approximate mean velocity of 15.8 miles per hour. Such a determination, however, cannot be regarded as entirely satisfactory, because it simply takes into account a series of stations lying in an east and west direction.

In order to extend the investigation to a large number of stations, we may take daily 'departures' from the monthly mean, and, projecting these upon charts, determine the character of the fluctuations over a large area. In practice, however, this method fails, for the reason that the fluctuations diminish toward southerly latitudes, thus masking the progressive motion.

The following method has been adopted for obviating the latter difficulty. We may consider, that if a cold wave advance in any direction, without disturbance from dense clouds or mountain ridges, it will carry minimum temperatures to successive stations in its path; the intervals of time between the passage of such a minimum over any one station taken as a starting-point, and others in the line of progress, gradually increasing. By determining, then, the time of passage of a minimum across each station in a country, and charting these times, we can ascertain both the line of advance and the velocity of the wave.

In order to obtain the time of passage of a minimum temperature over a station, where a series of observations has been made each day, it is essential first to eliminate the effect of diurnal range. This may be done by obtaining the residuals for each observation of a month, taken at any hour; then, determining the approximate time of passage, we can, by examining the successive residuals near that time, obtain the time sought. An effort has been made to apply the above principles to the observations of the U. S. signal-service, taken five times each day during November, 1881, at forty-two selected stations. In this month there were four prominent cold waves; and the following table gives the interval of time which elapsed between the passage of each of these over Fort Dunvegan, North-west territory, and each of the forty-two stations. These figures are inserted exactly as determined from the observations. It was found, however, that many of the apparent discrepancies in a progressive law of motion were due to the appearance of clouds at the time of an observation, thus throwing the minimum forward or back four and even eight hours. Blanks indicate that the minimum could not be determined satisfactorily.

This shows that in November, 1881, the cold waves were about two days in travelling from Fort Assinaboine to Washington. It would be an interesting comparison if a like investigation were undertaken for waves of heat, also, during other months of the year. A similar method may be applied to the advance of waves of high and low pressure, with the great advantage that clouds would not interfere with the determination of the time of passage.

This subject has attracted much attention from time to time, and recently it has been taken up by Mr. A. N. Pearson of India (*Nature*, Aug. 9, 1883).

The chief signal-officer has kindly permitted this publication in advance of a more extended investigation. H. A. Hazen.

TISSANDIER'S ELECTRIC BALLOON.[1]— I.

In describing recently the new hydrogen-gas apparatus which we had constructed in our workrooms at Paris-Auteuil, we mentioned that the governable electric balloon, which has been in preparation since the electrical exposition, was ready for trial. This took place the 8th of last October.

The arrangement of the controllable electric balloon consists of three distinct pieces of apparatus, — the air-balloon, properly so called; the gas apparatus to inflate it; and the electric motor to supply freedom of motion by means of a screw.

The construction of an elongated aerial ship presented serious difficulties. We were aided by two experiments, — that of Mr. Henri Giffard in 1852, and that of Mr. Dupuy de Lôme in 1872. In the model which we tried at the time of the electrical exposition, we arranged for the suspension of the little boat a low rod, running longitudina similar to that of the air steamship of Mr. Giffard. We afterward concluded that it would be better to place the screw behind a large parallelopiped-shaped boat, high enough to protect the propeller against the danger of a shock on descent. The boat, in this case, is connected to the balloon by suspension-cords running obliquely; and the deformations of the arrangement are escaped by means of a flexible shaft fixed at either side of the balloon. The balloon was constructed by my brother, in the rooms of Mr. H. Lachambre, to whom was intrusted the making of the new air-ship. A model 15 cubic metres in capacity was first made; and, after studying the action of this in a captive state, the construction of the large balloon (fig. 1) was begun. Its shape was like that of Mr. Giffard's and Mr. De Lôme's balloons: it was 28 metres long, and 9.2 metres in diameter through the middle. On its lower surface, there is a cone with an automatic valve: it is made of a thin cloth, rendered impermeable by a new varnish prepared by Mr. Arnoul of Saint-Ouen-l'Anmône. The capacity of the balloon is 1,060 cubic metres.

The netting over the balloon is formed of ribbons woven with longitudinal spindles, which keep them in their proper geometric positions. The ribbons thus easily adapt themselves to the inflated material, and do not form projections, as do the meshes of a net. The netting is connected on the sides of the balloon with two flexible shafts, which perfectly conform to its shape, passing along the centre of each side. The shafts are made of thin walnut laths fitted with bamboo: they are connected by silk belts. At the lower end of the netting are intersecting rods, at the ends of which are twenty suspension-ropes connected in groups of five to the four upper corners of the car. This latter is in the form of a cage made of bundles of bamboo rods, strengthened by cords and threads of copper covered with gutta-percha. The lower part is made of walnut cross-pieces, which support the willow basket. The suspension-ropes entirely cover the boat: they are woven into the basket, being previously sheathed in caoutchouc, which, in case of accident, protects them from the acid liquid contained in the boat to feed the batteries. The suspension-ropes are connected horizontally by rigging about two metres above the boat. The guide and anchor ropes are attached to this rigging, which also serves to equally distribute the traction during the descent. The rudder, a broad surface of unvarnished silk supported by bamboo, is also arranged behind. The weights of the different parts are as follows: —

[1] Translated from *La Nature*.

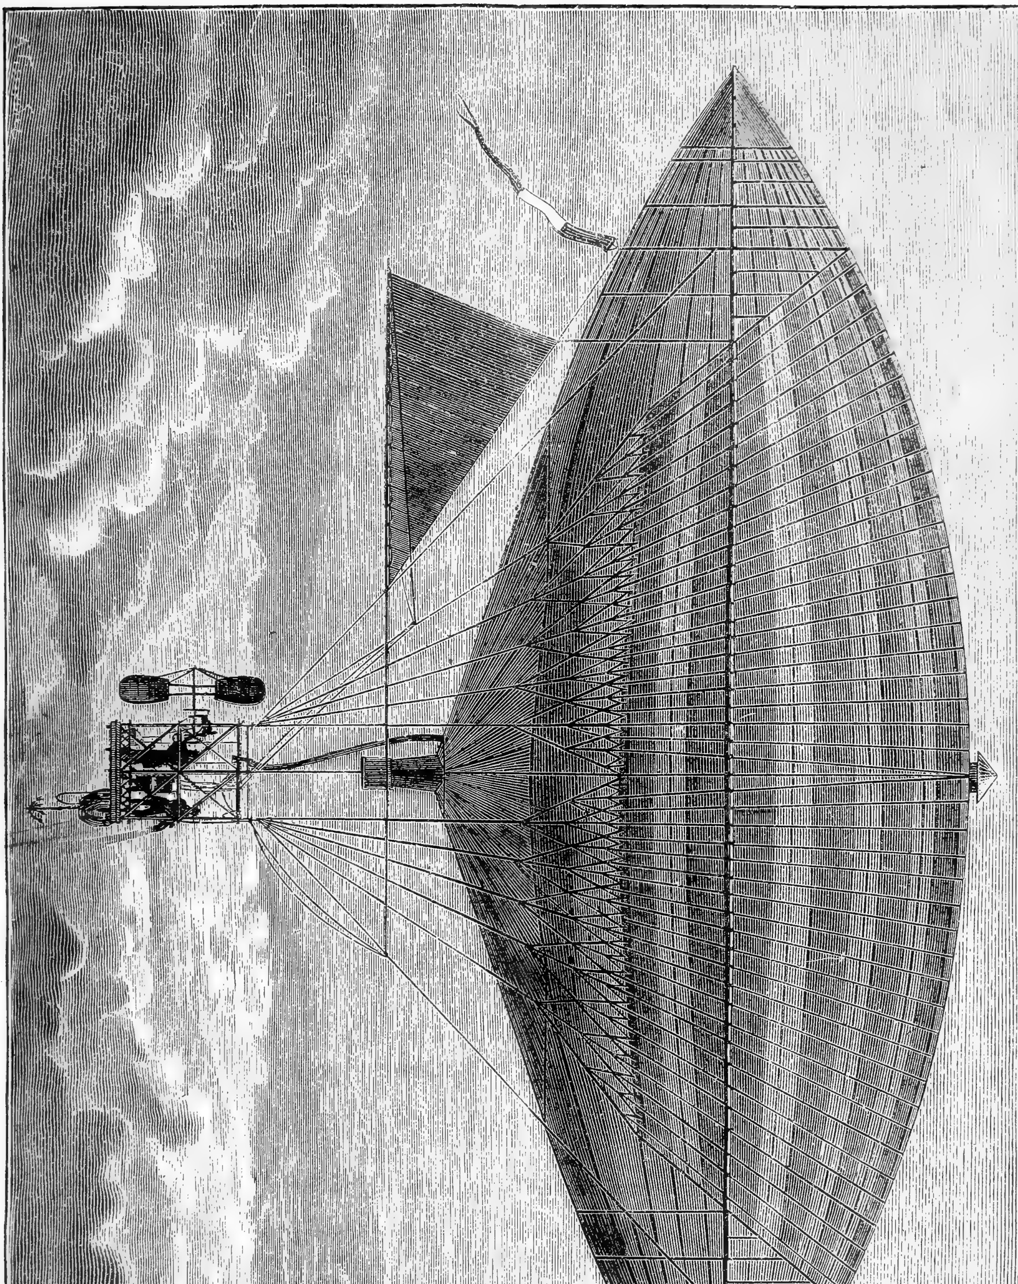

FIG. 1.—TISSANDIER'S FLYING BALLOON AS USED, OCT. 8, 1883.

	Kilograms.	
Balloon, with the valves	170	
Cover, with rudder and suspension-ropes	70	
Flexible side-shafts	34	
Car	100	
Motor, screw, and batteries, with liquid for 2 h. 30 m.	280	
Stopping-machinery (anchor and guide rope),	50	
Weight of material		704
Two passengers, with instruments		150
Ballast		386
Total weight		1,240

Allowing 10 kilograms, the lifting-force was 1,250 kilograms. The capacity of the balloon being 1,060 metres, the gas had a lifting-force of 1,180 grams per cubic metre, — a result not hitherto obtained in the production of large quantities of hydrogen.

By the end of September the gas apparatus was ready for trial; the balloon was stretched out on the ground under a long tent, in order that it might be immediately inflated; the boat and the motor were stowed under a cart-house; and my brother and I were only awaiting good weather to make the trial. On the 6th of October there was a rise of barometer; on the 7th the weather was fine, with light wind; and we decided to make the experiment the following day, Oct. 8, 1883.

The inflation of the balloon began at eight o'clock in the morning, and continued, without pause, till half-past two in the afternoon. This operation was expedited by means of the equatorial ropes hanging at the right and left of the balloon, and to which were attached the ballast-bags. (The ropes are shown in fig. 2, which also presents the spindle-shaped balloon as seen from one end.) The inflation completed, we proceeded to arrange the boat and the ebonite tanks, each of which contains thirty litres of the acid solution of bichromate of potassium. At twenty minutes past three, having heaped in the ballast and obtained equilibrium, we were slowly raised into the air, a light east-south-east wind blowing. On the ground there was almost no wind; but, as frequently happens, it increased with the altitude; and we found, when the balloon had risen five hundred metres, that it attained a velocity of three metres a second.

My brother was especially engaged in regulating the ballast, in order to keep a constant low altitude. The balloon was kept very regularly at a height of four or five hundred metres. It remained perfectly inflated; and the superfluous gas escaped by opening, under its pressure, the automatic valve, the action of which was very uniform.

Several minutes after the departure, I tried the bichromate of potassium batteries, composed of four troughs with six compartments, making twenty-four elements in circuit. A mercury commutator enabled us to use at pleasure six, twelve, eighteen, or twenty-four elements, and thus to obtain four different speeds of the screw, varying from sixty to a hundred and eighty revolutions per minute. With twelve elements, we found that the speed of the balloon was insufficient; but above the Bois de Boulogne, when our motor was working with great speed, with twenty-four elements a very different effect was produced. The movement of the balloon became suddenly appreciable, and we felt a fresh breeze produced by our horizontal motion. With the balloon head to the wind, pointing toward the belfry of the church of the Auteuil, near our starting-point, we remained

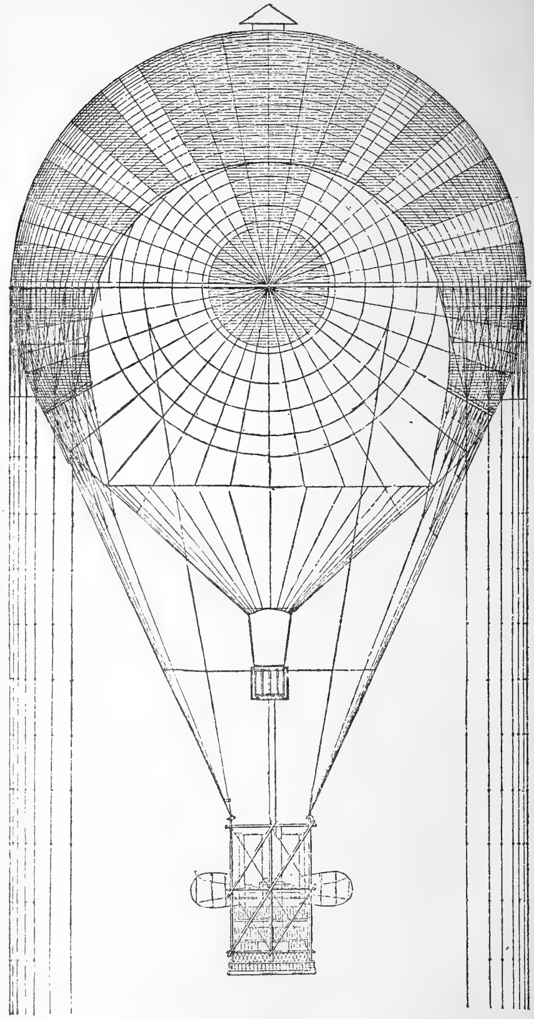

FIG. 2.

motionless, as we proved by noting conspicuous points beneath our car. Unfortunately it did not long maintain this position; but, after acting well for several instants, it suddenly began gyratory motions which the rudder was powerless to completely control. In spite of the rotations which in later trials we were able to prevent, we tried the same experiment for more than twenty minutes, during which we could perceive that we were over the Bois de Boulogne. When we tried to change our position by cutting the wind perpendicularly to its direction, the rudder became inflated like a sail, and the rotations were produced with much greater violence. From this we

assume that the position which an air-ship ought to occupy should be such that its major axis may make with the line of the wind an angle of several degrees.

After the experiments we have just described, we stopped the motor, and the balloon passed over Mont-Valérien. Once, when it had taken the direction of the wind, we began again to turn the screw, proceeding this time with the current. The speed of the balloon was increased, and by means of the rudder we were now easily able to turn to the right or left from the line of the wind. We proved this by taking, as before, some point on the surface; and several spectators also verified it.

At thirty-five minutes past four we made the descent in a large plain near Croissy-sur-Seine. The operation of landing was conducted by my brother with great success. We left the balloon inflated over night, and the next day it had not lost the least gas. Painters and photographers were enabled to obtain views of our air-ship, which was surrounded by a numerous and sympathetic assembly which the novel sight had attracted from all sides.

We had intended to make a new ascent on this day: but, on account of the cold of the night, the bichromate of potassium in our ebonite tanks had crystallized; and the battery, which was by no means exhausted, was on this account, however, incapable of action. We drew the balloon to the shore of the Seine, near the bridge of Croissy; and there, to our great regret, we were obliged to discharge the gas, and to lose in a few instants what had required so much care in its preparation.

Without describing in greater detail our return, we have concluded from this first trial that, 1°, electricity furnishes a balloon with the most convenient power, the management of which in the car is remarkably easy; 2°, in our own case, when our screw, 2.8 metres in diameter, made a hundred and eighty revolutions per minute, we were able to keep head to a wind moving three metres per second, and, when proceeding with the current, to deviate from the line of the wind with great ease; 3°, the mode of suspension of a car from an elongated balloon by means of bands running obliquely, and supported by flexible side-shafts, insures perfect stability to the whole.

We ought to say that our ascent of Oct. 8 should be considered only as a preliminary trial, which will be repeated with the alterations which our experience commends. In addition, we would mention that there was in the car a considerable excess of ballast, and that eventually it will be possible for us to use a much more powerful motor. Aerial navigation will not be made practicable through a single attempt: it will require many trials and efforts and great perseverance under every ordeal.

(*To be continued.*)

THE DISCOVERY OF THE GERM OF SWINE-PLAGUE.

IN a communication read before the Paris academy of sciences, Nov. 26, 1883, by M. Pasteur, the following paragraph occurs: —

"As soon as I received his [Thuillier's] first letters from the commune of Peux, in the department of Vienne, it was certain that he had perceived in the blood and humors of the dead hogs a new microbion which it seemed should be the author of the disease. This microbion had escaped the observation of Dr. Klein of London, in the course of a long and remarkable account of autopsies and experiments published three years before in the report of the English sanitary office. Dr. Klein stated that a microbion was the cause of the affection; but he committed an error, for the microbion that he described has no connection with the cause of *rouget*. Thuillier by his observation had overcome the principal difficulty to a knowledge of this disease of the hog. Historic truth, however, obliges me to declare, that in 1882, and also in the month of March, the microbion of *rouget* was signalled at Chicago, in America, by Professor Detmers, in a paper which does great honor to its author. Thuillier could not have been acquainted with this paper, and I myself only learned of its existence very recently. The observation of the microbion of *rouget* of the hog by Thuillier dates from the 15th of March, 1882."[1]

It is so very seldom that investigations on this side of the water receive any notice whatever abroad, and particularly in France, that it seems a pity even to call attention to the very great injustice done to American work in the above statement, since any recognition at all is so much better than being quietly ignored. There is, however, so much of general interest in regard to the gradual development of our knowledge of the germ of this disease, so much of interest in the success and failures of those who have worked upon it, that, aside from our desire to see history correctly written, there is sufficient incentive for tracing the progress of this study, which commenced when the first real light was breaking upon the germ-theory of disease.

Dr. Klein deserves more credit for his share in the discovery of the micrococcus of swine-plague than M. Pasteur seems inclined to grant. In 1876 he published one of the first, if not the very first, reliable microscopic studies of this disease. The care and skill shown in this investigation are more apparent to-day than when the details were first published; and, although he subsequently made the unfortunate mistake of attributing the cause of the disease to a bacillus, this fact should not be allowed to weigh against his former and really valuable researches.[2]

In his account of the microscopic appearances of the intestine, the following sentence occurs: —

"From and even before the first signs of necrosis of the mucosa, viz., when the epithelium begins to break down and be shed from the surface, there are found masses of micrococci, which in some ulcers occupy a great portion of the *débris*."[3]

A little farther on he says, —

"There is one more point which I believe deserves careful attention. In the ulceration of the tongue just mentioned, and at a time when the superficial scab has not become removed, I have seen masses of micrococci situate chiefly in the tissue of the papillae, but at some places reaching as far deep as the inflam-

[2] Report on the so-called enteric or typhoid-fever of the pig, by DR. KLEIN. In Reports of the medical officer of the privy council and local government board. New series, No. VIII. Report to the Lords of the council on scientific investigations, etc., 1876, pp. 91-101.

[3] Loc. cit., p. 98.

mation extends. That they are micrococci was proved by their forming lumps of uniform granules; these lumps stain deep purple-blue in haematoxylin, and are thus very conspicuous, and besides resist the action of caustic potash, with which all the rest of the tissue disappears. These heaps of micrococci in locality correspond to the papillae, and are on the surface of the scab, but underneath the covering epithelium, some parts of this having changed into a dry, hard, discolored mass, others containing larger or smaller vesicles filled with fluid."[1]

In the examination of the respiratory organs we are given even stronger evidence for connecting these organisms with the cause of the disease. In the mucous membrane of the anterior surface of the epiglottis, which was only slightly inflamed in its submucous tissue, he found —

"Lymphatic vessels filled with micrococci. . . . In the infiltrated, firm, more or less disintegrating parts [of the lung] I find great masses of micrococci filling up capillaries and veins, and also contained in lymphatics around arteries.[2] . . . The pleura is much swollen, and contains great numbers, continuous layers, of lumps of micrococci. The free surface of the membrane is in many parts covered with them. The exudation fluid is also charged with them as has been mentioned above."[3]

We have here the record of the unbiassed *savant* seeking after the truth, and describing what he sees without any attempt to draw conclusions or build up theories. It was before Koch's brilliant investigations, identifying the Bacillus anthracis as the active principle in charbon virus, had seen the light. There was still the greatest doubt as to whether the contagia were essentially animal cells, vegetable organisms, or chemical poisons. It would have been premature to have presented the micrococci at that time as the cause of the disease, though it is evident from these observations that they existed in the tissues of the body before the death of the animal. We have consequently two questions to consider in an inquiry of this kind; viz., (1) Who is entitled to priority for discovering and demonstrating the presence of micrococci in the tissues and liquids of diseased animals? and (2) Who was first in proving the connection between the micrococci and the essential constituent of the virus?

It seems very evident that Dr. Klein discovered the micrococci as early as 1876, but it is equally evident that his investigations were not sufficient to show that this parasite was the cause of the disease. The fact that from later observations, of an entirely different nature, he attributed the cause to another organism, surely can at this day detract nothing from the merits of the paper from which I have just quoted; and it must consequently be acknowledged as a matter of historical truth, the data of which are fully recorded, that Klein discovered the micrococci of swine-plague long before they were seen by Pasteur and Thuillier.

We can now pass to a brief consideration of the investigations which were intended to connect certain organisms found in the tissues or liquids of diseased and dead animals with the cause of the disease.

In 1878 a second and very elaborate report was made by Dr. Klein,[4] in which he gives experiments that are supposed to demonstrate the pathogenic nature of a specific bacillus found in certain liquids of diseased hogs, and cultivated for several generations in the aqueous humor from rabbits' eyes. Coming so soon after the publication of Koch's remarkable studies of the life-history of the anthrax bacillus, and agreeing so closely with them in all important respects, it is scarcely to be doubted that the earlier conclusions had more or less influence in shaping the later ones. While it might be interesting to the specialist to enter into details in regard to the defective methods of cultivation used, the unsatisfactory results of the microscopic examination of the tissues and fresh liquids for the bacilli, and the still more unsatisfactory results of the inoculation experiments with the cultivated organisms, our space will not permit this at present. In behalf of a most indefatigable worker, however, I would call attention to the fact that this mistake of Klein's was not so extraordinary as it may appear to many to-day, because the methods of cultivating and studying disease-germs have to a large extent been perfected since that time.

In the same year a number of persons were appointed by the U. S. commissioner of agriculture to investigate the disease known in this country as hog-cholera. The greater part of these served but two months; but Dr. Detmers, having reported the discovery of the disease-germ, was allowed to continue his investigations. In his first report, Dr. Detmers stated that the disease was caused by a bacillus, which he named Bacillus suis, because the same, so far as he was able to learn, was peculiar to and characteristic of swine-plague.[1] He saw micrococci, but regarded them as bacillus germs: indeed, he states that he constantly observed one of these under the microscope while it "budded, and grew to double its length, in exactly two hours."[2]

This report of Dr. Detmers, coming so soon after Klein's, and attributing the virulence to a bacillus of substantially the same characters as that described by Klein, while the latter's micrococci were made to do duty as bacillus germs, — a relation which had been previously ascribed to them by the medical officer in his 'preliminary note,' though it was not suggested by the English investigator himself, — did much to confirm the bacillus theory, and to convince scientific men that the parasite of another contagious fever had actually been isolated, and its connection with the disease demonstrated.

In January, 1880, M. Mégnin published the results of a microscopic examination of the blood in this disease, in which he described and figured a micrococcus.[3] This organism existed in single granules, and also in clusters and chains, and agreed so closely with one subsequently studied by me that I reproduced the drawings of it in connection with my report written the following December.[4]

[1] Loc. cit., p. 99. [2] *Ibid.*, p. 100. [3] *Ibid.*, p. 101.

[4] Report on infectious pneumo-enteritis of the pig (so-called pig-typhoid), by Dr. E. Klein, F.R.S. Report of the medical officer of the local government board. London, 1877 and 1878, pp. 169-290.

[1] Department of agriculture. Special report, No. 12, 1879, p. 42.

[2] Loc. cit., p. 53.

[3] Recueil de médecine vétérinaire, 1880, pp. 36, 37.

[4] Department of agriculture. Special report, No. 34, pp. 80, 81, plate IX.

In his second report,[1] Dr. Detmers does not seem to have materially modified the views referred to above, though he had been studying the disease during the whole of another year. In discussing accepted classifications in his supplemental report, he says, —

"All, however, seem to agree, that those Schizomycetes classed by them under the name of 'Bacillus' do not form clusters or colonies (rasen, zoogloea-masses, gliacoccus, orcocoglia), and do not undergo metamorphoses from globular to rod-shaped Schizomycetes, two things decidedly characteristic of the microscopic parasites of the Schizomycetes family as found in swine-plague; consequently the name adopted, Bacillus, was not well chosen and is not suitable."[2]

As I have shown elsewhere,[3] the two points referred to would not exclude an organism from the genus Bacillus. The best-known bacilli certainly develop from resting spores of an oval form, as seen under the microscope: some of these spores approach very closely to the globular; and, if they should be perfect spheres, the classification would not be affected in the least. The other point — that an organism, multiplying as a micrococcus, after a time develops into a rod-shaped body — is an idea, that, although it is persistently pressed in some quarters, has never been accepted by the best authorities, and is no more true of the organism in question than of other forms of micrococci, as I have assured myself by long series of cultivations. The fact of greatest importance to the present inquiry is, that up to this time Dr. Detmers considered the organism of swine-plague to be rod-shaped in its developed form. This supplemental report, in which the first doubts are expressed in regard to the organism being a real bacillus, was dated six weeks after the appearance of Mégnin's paper, and was not distributed for seven or eight months subsequent to this. It is to be remembered, also, that in none of the above investigations were any sufficient precautions taken to exclude atmospheric germs from the liquids examined, and no pure cultivations were made. It was therefore a matter of considerable doubt whether the organisms described were really in the blood as it circulated in the living animal, or whether they were introduced *post mortem.*

The third report of Dr. Detmers bears the date of Dec. 4, 1880.[4] In this it was stated that the "swine-plague Schizophytae present themselves in different shape and form." The simplest form is that of a micrococcus. The second form is bispherical: the spherical cell has grown and become contracted, or indented in the middle, forming two united granules.

"These bispherical Schizophytae are always more or less numerous, are either at rest or moving, and usually provided at one end with a flagellum or post-flagellum, which, however, is so exceedingly fine that I have never seen it except with the $\frac{1}{15}$ homogeneous immersion objective of Tolles, and an amplification of over 1,500 diameters, and then only while the Schizophytae was moving."[5]

[1] Department of agriculture. Special report, No. 22, pp. 13–67.
[2] Loc. cit , p. 60. [3] Special report, No. 34, p. 68.
[4] Special report, No. 34, pp. 153–195. [5] Loc. cit., p. 187.

He then goes on to describe the formation of a chain of bispherical elements, and mentions the existence of zoogloea masses as well. He had not yet given up the rod or bacillus form: for he states that in the blood and pleural exudation, when a day or two old, and sometimes while yet fresh, rod-shaped bacteria can be observed; and it appears probable that the same constitute another form of the swine-plague Schizophytae.[1]

The same volume contained a report of mine in which are detailed certain experiments and observations on the schizophytes peculiar to this disease. In this report was given a description of the first successful attempts, as I believe, to demonstrate what micro-organisms, if any, existed in the blood and other liquids of living hogs sick with swine-plague. To keep the liquids to be examined free from all suspicion of contamination, vacuum tubes were prepared by drawing to a point the two ends of a small piece of glass tubing about a fifth of an inch in diameter. A drop or two of water was then aspirated into this tube, boiled to secure a vacuum, and the ends immediately sealed. The tube was now heated to redness to destroy any bacteria spores that might still be in it, and it was ready for filling with the virulent liquid. In use, a very sick hog was killed, a vein laid bare, sometimes before the animal was quite dead, the vacuum tube was passed through the flame of an alcohol lamp, the finely drawn-out end forced into the vein and broken across its walls, when it would immediately fill, and was sealed in the lamp as soon as withdrawn.[2] It is plain that such tubes could be preserved indefinitely for examination without any suspicion of atmospheric contamination. The only change that could occur would be due to a continued multiplication, — a kind of cultivation of the organisms which had existed in the blood of the living animal.

Three separate outbreaks of swine-plague at widely separated points were investigated; and in every one, I found, by the method of study just referred to, that the virulent liquids contained micrococci, single, and in chains and clusters, but never rod forms, except in those cases where the tubes did not fill well, or where they were imperfectly sealed. And blood from the most perfect of these tubes, which contained no visible organisms but micrococci, produced unmistakable and severe cases of swine-plague in inoculated animals.[3] These were the first experiments in which the virulent material, preserved free from suspicion of atmospheric contamination, was shown to contain but a single species of schizophytes; and they were consequently the first which indicated any connection between the micrococci and the essential cause of this disease.

In his fourth report, Dr. Detmers states positively that some of the swine-plague organisms develop a lasting spore, and are changed into a helobacterium.[4] But there is no account of any measures adopted to decide which of the forms observed in the impure liquids examined had existed in the body of the

[1] Loc. cit., p. 188. [2] *Ibid.*, p. 22. [3] *Ibid.*, pp. 23, 24.
[4] Department of agriculture. Annual report, 1881 and 1882.

living animal; nor was there any substantial reason given for considering the helobacterium as belonging to the same species as the micrococci, or, if they happened to be different, which, if either, was able to cause the disease.

The same volume contains my report bearing the date of Jan. 27, 1882. In this are details of successful inoculation experiments with the sixth pure cultivation of micrococci which had been obtained and cultivated with every precaution known to science at the present day.[1] It was the first real evidence of the pathogenic action of these organisms. It was equally satisfactory with the experiments of MM. Pasteur and Thuillier; and the inoculations were made Jan. 17, 1881, or fourteen months before the discovery of this same organism by these gentlemen.

The communication of Dr. Detmers, referred to by M. Pasteur, appeared in the *American naturalist* for March and April, 1882, and was a *résumé* of his studies for the department of agriculture. In this article he still thinks there is just cause to suppose that the organism of swine-plague has a helobacterium, or rod form, and a resting spore. There are, however, no new observations or experiments referred to, there is no additional proof that the micrococci seen by him were not the result of atmospheric contamination, — nothing to show that a pure cultivation of these would produce the disease. On the other hand, the organism which he describes possesses a flagellum, and a moving stage or period, neither of which have I been able to observe with the true germ of this disease, nor with the closely allied micrococcus which causes fowl-cholera.

It is a matter of record, therefore, that the organism which constitutes the cause of swine-plague was first discovered by Klein in 1876, but that he failed to connect it in any way with the virus of the disease, and afterwards concluded that it depended upon a very different schizophyte. It is also a matter of record that I was the first to demonstrate by satisfactory methods that this micrococcus exists in the blood during the life of the animal, that it can be cultivated in flasks, and that the sixth successive cultivation, made in considerable quantities of liquid, and which contained no other form than micrococcus, still produced the disease. Neither Pasteur and Thuillier, nor any other investigators that I am aware of, have added one particle of evidence, except by way of confirmation, to that previously advanced by me. M. Pasteur is usually very particular in giving credit, but he does not seem to be keeping up with the progress of American science. D. E. SALMON.

MIGRATION OF BIRDS IN ENGLAND.[2]

THE general report of the committee of the British association, of which this is in fact an abstract, comprises the observations taken at lighthouses and lightvessels, and a few special land-stations, on the east and west coasts of England and Scotland, the coasts of Ireland, Isle of Man, Channel Islands, Orkney, and Shetland Isles, the Hebrides, Faroes, Iceland, and Heligoland, and one Baltic station (Stevns Fyr, on Stevns Klint, Zealand), for which the committee is indebted to Professor Lütken of Copenhagen. Altogether, a hundred and ninety-six stations have been supplied with schedules and printed instructions for registering observations, and returns have been received from about a hundred and twenty-three, — a result which is very satisfactory, showing, as it does, the general interest taken in the work, and the ready co-operation given by the light-keepers in assisting the committee.

As in preceding years, the line of autumn migration has been a broad stream from east to west, or from points south of east to north of west, and covering the whole of the east coast. In 1880, to judge from the returned schedules, a large proportion of the immigrants came in at the more southern stations; in 1881 they covered the whole of the east coast in tolerably equal proportions; but in 1882 the stations north of the Humber showed a marked preponderance of arrivals. Altogether, a vast migration took place this year upon our east coast; the heaviest waves breaking upon the mouth of the Humber, Flamborough Head, the Farne Islands, Isle of May at the entrance to the Firth of Forth, and again, after missing a long extent of the Scotch coast, at the Pentland Skerries. The Bell Rock also came in for a share, although apparently a much smaller one than the Isle of May. The easterly winds prevailed all along our east coasts, generally strong to gales; and the succession of south-easterly and easterly gales in October, between the 8th and 23d, occurring as they did at the usual time of the principal migration, brought vast numbers of land-birds to our shores. From the Faroes in the north, to the extreme south of England, this is found to have been the case.

Although migration — that is, direct migration — on our east coast is shown to have extended over a long period, commencing in July, and continuing, with but slight intermissions, throughout the autumn and into the next year to the end of January, yet the main body of migrants appears to have reached the east coast in October, and of these a large proportion during the first fortnight in the month. From the 6th to the 8th inclusive, and again from the 12th to the 15th, there was, night and day, an enormous rush, under circumstances of wind and weather, which, observations have shown, are most unfavorable to a good passage. During these periods, birds arrived in an exhausted condition; and we have reasons for concluding, from the many reported as alighting on fishing-smacks and vessels in the North Sea, that the loss of life must have been very considerable. Large flights, also, are recorded as having appeared round the lanterns of lighthouses and lightvessels during the night migration. From the 6th to the 9th inclusive, strong east winds blew over the North Sea, with fog and drizzling rain; and from the night of the 12th to 17th very similar weather prevailed. Mr. W. Littlewood, of the Galloper lightship, forty miles south-east

[1] Loc. cit., pp. 267-269.

[2] Report of the committee of the British association for the advancement of science, appointed for the purpose of obtaining observations on the migration of birds at lighthouses and lightships, and of reporting on the same. (From *Nature*.)

of Orfordness, reports, that, on the night of Oct. 6, larks, starlings, tree-sparrows, titmice, common wrens, red-breasts, chaffinches, and plovers were picked up on the deck, and that it is calculated that from five hundred to six hundred struck the rigging and fell overboard: a large proportion of these were larks. Thousands of birds were flying round the lantern from 11.30 P.M. to 4.45 A.M., their white breasts, as they dashed to and fro in the circle of light, having the appearance of a heavy snow-storm. This was repeated on the 8th and 12th; and on the night of the 13th a hundred and sixty were picked up on deck, including larks, starlings, thrushes, and two red-breasts. It was thought that a thousand struck, and went overboard into the sea. It is only on dark, rainy nights, with snow or fog, that such casualties occur: when the nights are light, or any stars visible, the birds give the lanterns a wide berth.

Undoubtedly the principal feature of the autumn migration has been the extraordinary abundance of the gold-crested wren. The flights appear to have covered not only the east coast of England, but to have extended southward to the Channel Islands, and northward to the Faroes (see report, East coast of Scotland). On the east coast of England they are recorded at no less than twenty-one stations from the Farne Islands to the Hanois lighthouse, Guernsey, and on the east coast of Scotland at the chief stations from the Isle of May to Sunburgh Head; at which latter station they have rarely been seen in previous years. Mr. Garrioch, writing from Lerwick, says, "In the evening of Oct. 9 my attention was called to a large flock of birds crossing the harbor from the Island of Bressay; and, on coming to a spot on the shore where a number had taken refuge from the storm, I found the flock to consist of gold-crests and a few fire-crests amongst them. The gold-crests spread over the entire island, and were observed in considerable numbers till the middle of November." The earliest notice on the east coast is Aug. 6; the latest, Nov. 5, or ninety-two days. They arrived somewhat sparingly in August and September, and in enormous numbers in October, more especially on the nights of Oct. 7 and 12, at the latter date with the woodcock. This flight appears to have extended across England to the Irish coast; for on the night of the 12th a dozen struck the lantern of the Tuscar Rock lighthouse, and on the night of the 13th they were continually striking all night. During the autumn, enormous numbers crossed Heligoland, more especially in October. On the night from the 28th to the 29th, Mr. Gätke remarks, "We have had a perfect storm of gold-crests, perching on the ledges of the window-panes of the lighthouse, preening their feathers in the glare of the lamps. On the 29th all the island swarmed with them, filling the gardens and over all the cliff, — hundreds of thousands. By 9 A.M. most of them had passed on again." Not less remarkable was the great three-days' flight of the common jay, past and across Heligoland, on Oct. 6, 7, and 8. Thousands on thousands, without interruption, passed on overhead, north and south of the island too, — multitudes like a continual stream, all going east to west in a strong south-easterly gale. It would have been interesting if we had been able to correlate this migration of jays with any visible arrival on our English coast, but in none of the returns is any mention made of jays. Subsequently we have received numerous notices of extraordinary numbers seen during the winter in our English woodlands. This seems especially to have been the case south of a line drawn from Flamborough Head to Portland Bill in Dorset. Additions and unusual numbers were also observed at Arden on Loch Lomond side.

The returns show very clearly that the spring lines of migration followed by birds are the same as those in the autumn, but of course in the reverse direction, — from west and north-west to east and south-east. Another point worth noting is the occurrence of many species in spring at the same stations frequented by the species in autumn: thus double records occur at the Mull of Galloway, Bell Rock, Isle of May, as well as at some English [illegible]

As this is the fourth report issued by the committee, we may, perhaps, with the mass of facts at our disposal, be expected to draw deductions which, if they do not explain, may serve at least to throw some light on the causes influencing the migration of birds. We might reasonably reply that the work undertaken by us was not to theorize, or attempt explanations, but simply to collect facts, and tabulate them. This we have endeavored to do in the shortest and simplest manner consistent with accuracy of detail. There is, however, one circumstance which can scarcely fail to present itself to those who have gone carefully into the reports issued by the committee; namely, the marvellous persistency with which, year by year, birds follow the same lines, or great highways of migration, when approaching or leaving our shores. The constancy of these periodical phenomena is suggestive of some settled law or principle governing the movement. It is clearly evident, from the facts already at our disposal, that there are two distinct migrations going forward at the same time, — one the ordinary flow in the spring, and ebb in the autumn, across the whole of Europe. A great migratory wave moves to and from the nesting-quarters of the birds, in the coldest part of their range, — north-east in the spring, and south-west in the autumn. Quite independent of this, there is a continual stream of immigrants, week by week and month by month, to the eastern shores of these islands, coming directly across Europe from east to west, or more commonly four points south of east to north of west, and the reverse in the spring. These immigrants are mainly composed of those common and well-known species which annually make these islands their winter quarters, and, as a rule, take the place of our summer birds. They come in one broad stream, but denser on some special lines or highways than others. Cutting the line of ordinary migration at nearly right angles, one flank brushes the Orkney and Shetland Isles, pouring through the Pentland Firth, even touching the distant Faroes. The southern wing crosses the Channel Islands, shaping its course in a north-westerly direction to the English coast.

SPANG'S LIGHTNING PROTECTION.

A practical treatise on lightning-protection. By HENRY W. SPANG. New York, *Van Nostrand,* 1883. 63 p. 8°.

THIS is a new and enlarged edition of the author's treatise on lightning-protection, published in 1877. The book contains altogether too many good things to be bad, and too many bad things to be entirely good. There is a wholesale condemnation of all systems and methods other than those described, which is a little perplexing, until one discovers, and in fact the author confesses, that it is issued with a view of effecting a general introduction of a *patented* system of lightning-conductors. The business air which pervades the whole is thus clearly explained.

The author frequently pronounces against the 'lightning-rod men and scientists,' attributing the blunders of the former to the mistakes of the latter. A brief examination of his book will suffice to fully acquit him of the charge of belonging to the latter class; and it must be confessed, that the many excellent rules which he has emphasized oblige us to rank him considerably above the general average of the former. The general principles of lightning-protection, as presented, are in the main correct; and, as general principles, they deserve a wide dissemination. The particular system urged as the only efficient one is more complicated, and, even if it were not patented, more expensive than is necessary. Some novel statements are made, concerning what lightning 'will do' under certain circumstances, in the same paragraph in which the author bemoans the ignorance shown by scientific men on the subject of lightning-protection.

The author does not seem to be aware of the existence of what is doubtless the most complete and authoritative treatise on the subject yet published, — the elaborate 'Report of the lightning-rod conference,' edited by G. J. Symons, F.R.S. This conference was made up of delegates from the London meteorological society, the Royal institute of British architects, the London society of telegraph engineers and electricians, the London physical society, and two co-opted members, Profs. W. E. Ayrton and D. E. Hughes.

The examination of the various problems presented was exhaustive, and the code of rules for the erection of lightning-conductors published in the report is simple and easily understood. The proper construction of an efficient lightning-conductor is, after all, a matter of no great difficulty, and of comparatively little expense. The inauguration of a proper system of testing conductors would certainly reveal some astonishing facts in regard to the efficiency of rods as generally erected, elaborate and expensive as they often are. The wide circulation of the rules adopted by this conference would undoubtedly be the means of bringing about a much-needed reform in this direction.

COHN'S 'DIE PFLANZE.'

Die pflanze: Vorträge aus dem gebiete der botanik. Von Dr. FERDINAND COHN, professor an der Universität zu Breslau. Breslau, *Kern,* 1882. 8 + 512 p. 4°.

THIS elaborately gotten up book of over five hundred pages comes to us as a contribution to general literature, and does not address itself to the scientific botanist, except as he is interested in a popular presentation of botanical facts and problems with which he is supposed to be more or less familiar. Dr. Cohn believes it to be the duty of those versed in any branch of science to produce a literature which shall invite a large circle of readers to an interested acquaintance with their chosen science. "Nor are they to recoil from this task," says he, "because of the difficulties which present themselves for satisfactory solution, or because popular writings on natural science have been undervalued by many." Actuated by his conviction, Dr. Cohn has collected the addresses which he delivered at various places in Germany between the years 1852 and 1881, and, while retaining their original form, has remodelled them sufficiently to bring them up to date and compact them into a shapely whole.

In the preface the author sets forth a difficulty which besets the popular lecturer on scientific topics, — one which doubtless every one who has tried this style of address has fully realized,—namely, the meagre knowledge and hazy comprehension with which the majority of hearers listen to his words, necessitating so long a dwelling on the elementary facts of the topic that little time is left for the consideration of the more recondite and interesting points.

If we may be allowed to judge, Dr. Cohn has overcome this difficulty to a large degree in a very happy manner. He devotes the first lecture, entitled 'Botanical problems,' to a brief history of the development of botany, and an explanation of some of the elementary principles of the science, thus paving the way for subsequent discussion of more special matters. Some idea of the variety of the topics treated may be gained from the titles of the sixteen lectures, which are as follows: 'Botanical problems,' 'Goethe as a botanist,' 'The cell state,'

'Light and life,' 'The plant calendar,' 'From pole to equator,' 'From sea-level to eternal snow,' 'What the forest tells of itself,' 'Grapes and wine,' 'The rose,' 'Insectivorous plants,' 'Botanical studies on the seashore,' 'The world in a water-drop,' 'Bacteria,' 'Invisible enemies in the air,' 'Gardens in ancient and modern times.'

The lectures are written in an entertaining style, and vary in interest as little as the inequality of the subjects will allow. The two on 'Light and life' and 'The cell state' are especially happy, particularly the latter in an apt comparison of a plant to a state.

The design of the book is laudable, and its execution admirable. We commend both as models to our American biologists and physicists, who owe it to the American public to provide better opportunities for a general acquaintance with scientific problems and methods.

REPORT ON SORGHUM-SUGAR.

Investigation of the scientific and economic relations of the sorghum-sugar industry; being a report made in response to a request from the Hon. George B. Loring, U. S. commissioner of agriculture, by a committee of the National academy of sciences, November, 1882. Washington, *Government*, 1883. 152 p. 8°.

A PROBLEM, which, if not the most important, is certainly the most prominent, agricultural problem of the day, is that of the profitable production of sugar from sorghum. The experiments made during the last few years at the U. S. department of agriculture and elsewhere have attracted general attention, both on account of the interesting scientific questions involved, and still more because they promise to create a new branch of agricultural industry, and to greatly enlarge our domestic supply of sugar.

The report of the committee of the National academy on this subject must prove very valuable to all interested in the promotion of this infant industry, because it contains a very full summary, prepared by thoroughly competent and impartial persons, of all that has been accomplished in this direction up to the date of the report, and thus collects in one publication information previously scattered through numerous state and other reports. That the work has been well done is sufficiently guaranteed by the names of the committee. They were Prof. William H. Brewer, Ph. D., of the Sheffield scientific school; Prof. Charles F. Chandler, Ph.D., of Columbia college; Prof. S. W. Johnson, M. A., of the Sheffield scientific school; Prof. B. Silliman, M.A., M.D., of Yale college; Prof. J. Lawrence Smith, M.D., late of the University of Louisville; and also, not of the academy, Gideon E. Moore, Ph.D., of New York. Prof. C. A. Goessmann, of the Massachusetts agricultural college, was also a member of, and acted with, the committee until Sept. 15, 1882, when he resigned.

The committee begins its report with several pages of citations from earlier (chiefly American) investigations upon sorghum as a sugar producing plant, showing the conflicting opinions upon almost every essential point of the subject entertained by the authorities quoted. On such points as the kind of sugar present in the juice, the best varieties of sorghum, the proper time for harvesting and working, etc., diametrically opposite opinions, each by reputable authorities, are quoted.

This was the state of the question, when, in 1878, the U. S. department of agriculture, by its chemist, Dr. Peter Collier, began its well-known investigations, which went far to decide many of the points just spoken of. This work the committee does not review in detail, but contents itself with a favorable criticism of the analytical methods employed, and with pointing out the material value of the results and the need of further investigation.

At the time when this report was prepared, the successful work of the department of agriculture consisted chiefly of chemical examinations of sorghum-juice, attempts to produce sugar from it on a manufacturing scale having proved partial failures: the committee therefore closes its report with brief accounts of the results of practical attempts to make sugar from sorghum. Among these are noted two failures, and seventeen cases of more or less pronounced success, several on a manufacturing scale.

In an appendix are collected divers interesting papers bearing upon the subject of the report. Some of them present fuller details of experiments referred to in the report, and some contain accounts of later successes in sugar-production. This portion of the report concludes with a 'Bibliography of sorghum,' which cannot fail to be of great value to investigators in this field.

It is evident from the facts collected in this report, and from the experience since gained, that, with skill in working, sugar can be successfully made from sorghum. It is also equally evident, that, without that skill and the proper appliances, failure is more probable than success. Sirup can easily be made from sorghum on a domestic scale, but not sugar.

Finally this report makes very evident the need for further investigation in regard to such important points as the best varieties of cane, and the possibility of their improvement by selection and crossing, the most suitable soil for sorghum, the effect of fertilizers on its growth and content of sugar, the methods of extracting the sugar from the cane, and the prevention of losses in the further treatment of the juice. In a word, while sugar can be made from sorghum, it yet remains to be seen how economically it can be manufactured, and how completely the great waste involved in the present crude processes can be avoided; and the committee closes its report by urging upon the U. S. department of agriculture especially, the duty of continuing the investigations which have already yielded such important results.

HANN'S CLIMATOLOGY.

Handbuch der klimatologie. Von Dr. JULIUS HANN. Stuttgart, *J. Engelhorn*, 1883. (Bibliothek geographischer handbücher.) 10 + 764 p. 8°.

THERE are many treatises upon the subject of climate. The larger number of these are devoted to the consideration of the special characteristics of the climate of some particular country, and contain numerous statistics derived from meteorological observations, together with a description of the prevailing weather conditions. A few discuss the subject from a broader stand-point, and take account of the general conditions which prevail over a large area, with their causes and modifications. The treatise before us, however, differs from its predecessors in its aim as well as in its execution. It is designed to give a view of climatology as the result of certain forces which are at work in nature, and to investigate the result of the operations of these forces as they are exhibited in the climate of the world. Its author is the acknowledged head of meteorological science in Austria, — one who has done much to place meteorology on a scientific basis, and who is especially qualified to speak with authority upon the subjects which he treats, on account of his well-known familiarity with the current work of other investigators, and his ability as a critic. It is to be expected that a work written by such an author will be comprehensive, thorough, and masterly, that it will indicate the present condition of the subject from a scientific stand-point, and be as accurate as the best data at hand can make it. All these conditions are fulfilled and abundantly satisfied in the work before us.

The aim of the treatise is to present a comprehensive view of climatology. First the word is defined, its object specified, and the various climatic factors mentioned, briefly discussed, and illustrated. After this introduction, which is, in fact, a concise treatise upon the subject of climatic statistics rather than a simple introduction, the author proceeds to treat the subject in two divisions, — general and special climatology. Under the former head are considered, 1°, 'solar climate,' or that which would result directly from solar radiation; then, 2°, the modifications introduced by atmospheric and terrestrial conditions, resulting in climate as actually existent. Under the latter head are considered the special climatic characteristics of different portions of the globe, with copious illustrations. In carrying out this plan, the author treats the various topics with conciseness but with singular clearness, and advances in logical progression without dwelling too much on the minor details, or retarding the course of thought by discussing the many collateral subjects which are naturally suggested. In a few instances, where a controverted subject is discussed in the text, an elaborate footnote is devoted to a defence of the author's position, or a statement of the dissenting opinions of others; and several appendices contain fuller explanations of the special topics touched upon in the main portion of the treatise. In this way the author preserves the unity of the work, and at the same time calls attention to important considerations to which he cannot give much space in the body of the treatise. The work is not exhaustive: indeed, that would be impossible in so comprehensive a subject. In many cases it does not enter into the details of an investigation, but gives the results obtained without discussing the methods of investigation employed.

At the outset the author carefully defines the word 'climatology,' and shows the relation between climatology and meteorology. By climate is to be understood the average weather conditions of different places on the earth's surface, together with the extent of the deviations from the average conditions. The climatologist, in treating the causes of climate, necessarily makes use of the laws which the meteorologist in his broader study of atmospheric phenomena has deduced, and, in turn, furnishes the latter with facts which he must account for by the meteorological principles he has established. The two sciences are therefore intimately connected; and we may, if we wish, regard climatology as a part of the

science of meteorology, which takes into account the phenomena included in the latter only in so far as they affect the well-being of living creatures on the earth. It is well to establish a definite position for climatology; and the author is wise in restricting it to average weather conditions, and deviations from the average, for these are the controlling influences which determine the relations of any place to animal life. The important climatic factors are temperature, moisture, cloudiness, wind, atmospheric pressure, evaporation and the chemical composition of the air, mentioned nearly in the order of relative importance; temperature, rainfall, and wind being usually given as the three essential factors. These factors are not independent, and are so mutually connected (as, e.g., cloudiness and temperature) that they cannot be discussed separately. Atmospheric electricity is recognized as important, but needing further study before it can be classed as a factor. It would seem as if a similar reason would have prevented the insertion of the composition of the air in the list of factors; for the relation of the chemical constituents in their varying proportions to animal life is confessedly obscure. In the discussion of these factors, those special features with regard to each are mentioned which would be useful in representing statistically the climate of a place. Especial prominence is given to temperature statistics; and eight different subjects are named which deserve representation in tables, such as the monthly and annual means, magnitude of daily ranges, etc. An important omission in the tables usually given is pointed out; viz., some expression for the rapidity of temperature changes. The author suggests two ways in which this can be done, — 1°, by the difference between consecutive daily means, and, 2°, by the rapidity of changes in some adopted period of time. These and other suggestions can be profitably considered by those who have charge of the preparation of weather statistics: they should be presented in such a shape as to enable any one to readily obtain the facts as to the climate of any place for which he consults them. The statistics of Vienna are presented in illustration of the subject.

The section devoted to general climatology is of special value. Quite properly, it begins with a discussion of climate as dependent upon the distribution of solar heat, and thus includes the results of investigations in solar radiation. Disregarding for the time the effect of the atmosphere, the distribution of solar heat is treated as dependent upon the sun's altitude, the length of the day, and the distance between the earth and the sun. The combined effect of these elements is seen in different latitudes and in the two hemispheres, and is the basis of actual climate. The effect of the atmosphere in modifying these results is next considered, and the subjects of atmospheric absorption, diffusion, and reflection treated. For the sake of comparison, the relative effects on light, heat, and chemical power, are considered, though that relating to heat alone properly comes into consideration. The little knowledge which we possess on these subjects is the cause of the somewhat meagre presentation which the author gives. Coming finally to the further modifications in the distribution of solar heat due to the earth itself, the characteristics of insular, continental, and mountain climate are pointed out, and the effect of marine and aerial currents noted. In this way the author arrives at the actual climate which prevails over the earth, having started with its prime source, the sun. The discussion throughout is general, but is very suggestive of further study by the reader, in the different topics treated. The author quotes extensively from the works of others, and gives copious illustrations. It would be a great help to the student, however, if, as has been elsewhere suggested, references to the works themselves were given, in addition to the names of the authors, which are always carefully mentioned. This section could be expanded into a larger treatise, and may serve with advantage as the basis of extended research, or as a help to class instruction.

The section devoted to special climatology occupies two-thirds of the whole work. After an introduction upon the division of the earth into climatic zones, the author considers the observed climate in each zone, quoting extensively from the publications which describe the prevailing conditions in each country, giving numerous tables, and summing up under each zone its general characteristics. In this section we have, therefore, a compendium of accessible statistics covering the whole world, given in as much detail as the generous limits of the work will allow, and combined with carefully prepared summaries. In order to judge of the excellence of this section, it is only necessary to note how thoroughly the different countries are treated, whether the selections made for illustration are typical or not, and whether the author has made use of the most reliable publications. In all these respects it will be found that the work before us excels. Thus, in describing the climate of North America, the author first gives a statement of

the topography of the country, and the important distinctions in climate which result therefrom; then, passing to the climatic factors, he describes in detail the temperature, rainfall, humidity, cloudiness, pressure, and winds as they exist in the different sections, and illustrates principally from the publications of Schott, Woeikoff, Blodgett, Loomis, Coffin, Dall, Gannett, Whitney, and the signal-service. Not content with general characteristics, he further specifies peculiarities, such as the suddenness of temperature changes in certain localities, tornadoes, northers, and Indian summer, with appropriate quotations from various writers; and he also appends special descriptions of the climate of Illinois, Lake Superior, the Mississippi valley, Canada, Manitoba, Hudson's Bay, Alaska, the plateau region, Colorado, California, Arizona, and the Bermudas. The climate conditions of other countries are treated with similar thoroughness, making the whole valuable for reference, while its chief merit lies in the running descriptions and summaries. A defect in the work is the lack of charts illustrating the various data. A few only are given; the main reliance for illustration being in the statistical tables, which are almost unnecessarily abundant. Graphic representations are always specially valuable to the reader, and their addition to the work would be a real improvement. It would also have been well to mention the analytical method of representing data, as well as the statistical and graphical; for, while its use is limited, it will surely grow in favor with the advance of the science.

The work of Dr. Hann represents the latest investigations, and is brought down almost to the very date of publication. It will therefore not be soon superseded; and, while additional data will accumulate in coming years, the general discussions will require but little alteration. The work is recommended for the general reader, not to be read in course, but by proper selection. The general chapters and the summaries contain a large amount of information, for which the details and illustrations can be obtained from the accompanying pages. The student will find the work useful in calling attention to the authorities in each subject. Especially in the section on general climatology, where such topics as solar radiation and atmospheric absorption are, from the design of the work, treated in a general way only, will be found quotations from the publications of the latest investigators. It would be well, too, if the treatment of the subject of climatic factors should call attention to the need of publishing statistics in such a way as to be useful for reference. In this country particularly, we need to give consideration to this subject. There is scarcely an allusion made in the work under review to recent meteorological work in the United States, not because it has not been published, but because it has not been issued in a suitable form. In order to compare our statistics with those of other countries, it is necessary first to re-arrange and classify them. The international meteorological committee has recommended forms of publication, the adoption of which will add greatly to the facility with which corresponding data can be compared. But even these forms do not give all the data which the climatologist would like to have; and meteorological observations could be made more available for studies in climate by attention to the author's treatment of the subject. There is also need of deducing more results from the immense collection of data which is daily accumulating all over the world, to check the prevailing tendency of heaping up observations for no useful purpose. If this work shall have the effect of stimulating research, and promoting a more intelligent use of meteorological observations, it will do much good. It is to be hoped that it will be translated into English to reach a wider circle of readers.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Ottawa field-naturalists' club, Canada.

Jan. 31. — Mr. W. L. Scott read the report of the ornithological and oölogical branch, showing that a number of rare birds had been secured, that thirteen species had been added to the published lists, and that other good work had been done. Among specimens exhibited was a great white egret, in full breeding-plumage, which had been shot on the Upper Ottawa, — a locality far north of its usual range, but where it is stated to be a not uncommon visitor. Its name, however, will not appear in the lists of the club, as the locality is considered beyond the limits of its district.

Prof. J. Macoun read a practical paper on the 'Edible and poisonous fungi' of the vicinity. He pointed out, that while at present the only fungus collected for food is the common mushroom, Agaricus campestris, there are other equally nutritious and palatable forms which exist in far greater abundance; as, for instance, Coprinus comatus, which grows in great profusion about the city during Sep-

tember. Two species of morel, Morchella esculenta and Gyromitra esculenta, are also common, and are very desirable food-supplies; while the Lycoperdons, or puff-balls, are found in immense numbers, and often of large dimensions, and, when young, are excellent for the table. Among poisonous forms, the fly-agaric, Amanita muscaria, was instanced as one of the most highly organized, most widely distributed, most beautiful, and most dangerous of the agarics. The difficulty of distinguishing by sight between many edible and non-edible or poisonous species was stated; and it was explained that those having a pleasant odor and taste were always likely to be eatable and harmless, while others would be more or less injurious. It is, however, always advisable, at first, to eat but a small quantity of any untried species. Professor Macoun, as botanist to the Geological survey, is now working at the fungi of Canada, and is preparing a report thereon for publication. Beautiful plates to illustrate this report have been drawn by Mrs. Chamberlin, a member of the club; and such as related to the forms discussed were exhibited by her, to the great gratification of the members. — The secretary laid on the table advance copies of the Transactions of the club for 1882–83, and announced that they would be ready for distribution in a few days.

Princeton science club.

Jan. 25. — Professor Rockwood gave a paper on the mutual relations of the conics, discussing especially the changes by which the different curves turn one into another through their limiting forms. He traced the various curves represented by the equation $A^2y^2 + B^2x^2 = A^2B^2$, when A^2 is constant, and B^2 assumes all possible values, showing them to include all the varieties of the ellipse and hyperbola. In the same way the equation $y^2 = \frac{2B^2}{A}x - \frac{B^2}{A^2}x^2$ was shown to include *all* forms of the conic when A and B assume various values, — zero, infinite, or finite. In tracing the movement of the foci, he showed that in the series of ellipses and hyperbolas the foci come first to coincide at the centre; afterward their distance from the centre becomes $c\sqrt{-1}$, which, by interpreting the imaginary factor as indicating revolution through a right angle, changes the foci from the horizontal to the vertical axis, on which they then recede to infinity, returning from infinity on the horizontal axis when the ellipses change through two parallels to the series of hyperbolas. The changes were also followed out with focus and directrix fixed and eccentricity varying, with focus and focal ordinate fixed and eccentricity varying, etc.

Professor Scott reported that he had just discovered a rudimentary pollex in Oreodon of the White River miocene. The carpus is very primitive in arrangement, and a trapezium is present.

New-York academy of sciences.

Jan. 21. — Two specimens of corundum from western North Carolina were exhibited by G. F. Kunz. One was a crystal weighing 13 grams: the other, weighing $3\frac{5}{16}$ carats, was cut *en cabachon*, and by the exhibiter was said to be the most perfect star-sapphire probably yet found in the United States. Both pieces were a rich light-brown color, very compact, and resembled a variety of sapphire from the hills of precious stones in Siam. Prof. H. L. Fairchild delivered a lecture on methods of animal self-defence, which was well illustrated with a large series of well-selected lantern-slides. Remarks were made by President Newberry and Prof. W. P. Trowbridge.

Canadian institute, Toronto.

Jan. 19. — Prof. R. Ramsay Wright gave an account of researches on the skin and nervous system of Amiurus catus, which will shortly be published in the Proceedings. Special attention was devoted to the 'clavate' cells of the epidermis, to the branching of the fifth nerve, and to the relationship between the air-bladder and auditory organ.

Natural science association of Staten Island, New Brighton.

Jan. 12. — Mr. C. W. Leng read a paper on the Cicindelidae of Staten Island. The beetles live all summer in sunny places in the woods, roadsides, and on the sands at the seashore. They are able to make short flights, which they do at the least alarm, flying a few paces at a foot or two from the ground, and then dropping quite suddenly. Their colors always mimic the places at which they are found, which makes it difficult to distinguish them after they alight. During the night and rainy days they hide in holes dug in the sand, or among piles of chips and bark. The following eight species have been found on Staten Island: C. sexguttata, purpurea, generosa, tranquebarica, repanda, hirticollis, dorsalis, punctulata.

Remarks were made by Mr. Sechusen on a very interesting series of precious stones, their particular characters, and the localities from which they came.

Society of arts, Massachusetts institute of technology.

Jan. 10. — Dr. Charles S. Minot, of the Harvard medical school, read a paper giving an account of his researches on growth and death. Dr. Minot has undertaken an extensive series of experiments, which will occupy many years, on senescence, or the process of growing old; and he presented in this paper the results of one branch of his investigations, in which he had studied the growth of the guinea-pig from birth until the attainment of the full size, having made about fifty-five hundred weighings of these animals, the weight being the function of growth best adapted for study.

In 151 recorded births, the proportion of males to females was found to be 119 to 100. The average weight at birth was about 72.5 grams, and was about the same for males and females. The range was from 42 to 99 for the males, and 46 to 111 for the females. The most potent influence on the weight at birth was found to be the number in a litter; the larger the litter, the less the average weight. The period of gestation was found to average 67 days; and the longer the period, the greater the weight at birth

This weight was also greater in summer than in winter. Notwithstanding the great variation of weight at birth, the difference diminished with age, all the animals thus tending to approach a certain standard size. One of the most important facts discovered was, that the rate of growth diminishes continuously from the time when the animal recovers from the loss of weight at birth; this diminution being rapid at first, and slower afterward. By rate is here meant, not the absolute increment in weight in a given period, but the per cent of the weight at the beginning of the period, which is added to said initial weight during the period. A discussion of the best available data indicates the result to be also true of man.

Dr. Minot had also made some experiments with rabbits, and compared the results with those for guinea-pigs and for man. He found that the guinea-pig grows on an average, until it is full-grown, 1.73 grams per diem, the rabbit 6.20, and man 6.60 grams. Men are therefore larger than rabbits, not because they grow faster, but because they grow longer; while rabbits are larger than guinea-pigs because they grow faster. The *rate* of growth, however, as above defined, is very different; being 4.6 % in the guinea-pig, 5 % in the rabbit, and 0.02 % in man.

Philosophical society of Washington.

Jan. 5. — Prof. J. R. Eastman discussed the Rochester (Minn.) tornado of Aug. 21, 1883, describing the ground as it appeared a few days after the storm, and showing that the phenomena did not indicate cyclonic motion. All disturbed objects were thrown in essentially the same direction, and were pressed down rather than lifted. In the course of the ensuing discussion, Mr. W. H. Dall described similar phenomena in the Escanaba region, where he observed storm-tracks consisting of swathes of prostrate trees, the trunks of which pointed uniformly in one direction.

Mr. Dall then read a paper on Recent advances in our knowledge of the limpets, summarizing the researches of Spengel on the sensory organs or osphradia; Cunningham, on the renal organ and renopericardial pore in Patella and Patina; Fraissé, on the eye in Patina, Fissurella, and Haliotis; and the speaker, on the presence of an intromittent male organ in Cocculina. He stated that among the Acmaeidae and Patellidae the type of eye differs; and while in Patina it is of a very rudimentary character, in other genera it might be well developed, — as, for instance, in Ancistromesus, which has as well developed eyes as Fissurella. He also alluded to the gradual progress in classification afforded by anatomical investigation during the past few years, and observed that nearly all the known forms except Propilidium and Scutellina were amenable to classification; our ignorance of the branchiae in the former, and the dentition in the latter, operating to prevent a final classification in these two cases until more is known. Those authors who study the embryology and histology usually from a single species generally ignore the wide differences of adult anatomy between the genera of limpets, and sow their generalizations on a basis of classification which is little in advance of that of Lamarck and his immediate successors.

The president of the society, Dr. James C. Welling, announced the death, since the last meeting, of Gen. A. A. Humphreys, one of the founders of the society, and pronounced a brief eulogy on his character.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Geological notes. — Prof. I. C. Chamberlin and his assistants, during December, 1883, were engaged in field-work in Illinois and in Missouri. Professor Chamberlin devoted his personal attention mainly to the borders of the newer drift, the concentric morainic belts that lie within it, and the contiguous old drift without it, in north-eastern Illinois. Mr. R. R. Salisbury continued his previous observations of the residuary clays and loess and drift-borders in eastern and central Missouri.

The revision of the manuscript of a report by Mr. J. S. Curtis on the Eureka mines has been completed by Mr. G. F. Becker and Mr. Curtis, and will soon be ready for the printer.

Since the beginning of Prof. R. D. Irving's study of the metamorphic rocks in 1882, he and his assistants have made five hundred thin rock-sections. Of this number, written descriptions of three hundred have been prepared. They include rocks from the original Huronian, the Huronian of the Marquette and Menominee regions, the Animikie group of the national boundary, the folded schists of the same region, and the crystalline rocks of the Minnesota and Mississippi valleys.

Assistant John Chaplin at Denver has prepared thin sections of all the eruptive rocks collected in the Rocky-mountain district during the past season.

Paleontology. — Prof. L. F. Ward has completed the work of preparing index slips for a catalogue of fossil plants. He has so arranged all of the fossil plants collected from the Laramie and Fort Union groups, that they are in a convenient form for future detailed investigation.

Chemical division. — The analyses of waters from Walker Lake and Walker River have been completed by Prof. F. W. Clarke.

Mr. J. W. McGee, in his examination of the subterranean forest exposed by an excavation on Connecticut Avenue, Washington, D.C. (referred to in *Science* of Nov. 30, 1883), discovered an earthy blue mineral, which was abundantly distributed throughout the

stratum of clay, at the bottom of which the remains of wood were found. This blue earthy mineral has been identified as vivianite by Professor Clarke.

Mr. Hillebrand, in the laboratory at Denver, has been examining the Leadville porphyries with respect to the proportion of precious metals contained in them. He has prepared a new gravity-solution, the borotungstate of cadmium, designed to replace in part the Thoulet solution, which is in some cases inapplicable in the separation of the mineral constituents of rocks. He has also made various qualitative examinations of several minerals new to the west, — tantalates, columbates, and phosphates of rare earths.

Dr. Mellville and Mr. G. F. Becker, at San Francisco, have been investigating some of the chemical relations of quicksilver.

In the laboratory at New Haven, Dr. William Hallock, at the suggestion of Mr. Arnold Hague, has begun a series of experiments upon the artificial production of geysers. Small models have been made that worked admirably with regular periods. An artificial geyser, with a reservoir twenty-five feet deep, has been constructed, and will soon be in working-order. The study of this model will be of exceeding interest.

Topographical notes. — It was hoped that topographical work could be carried on through the winter in Massachusetts; but owing to the continued bad weather through December, especially in the latter part of the month, the work was greatly delayed; and about the middle of the month it was decided to postpone further field-work in the state until spring.

Mr. Willard D. Johnson, assistant topographer, who has been preparing several small local maps in the Mono basin, California, has completed a map of the Parker-creek moraines, and began one of the Leevining-creek moraines. He has been unable to complete the latter on account of unfavorable weather. The map of the Parker creek moraines includes an area of about seventeen square miles, on a scale of four inches to the mile. The general map of the Mono basin covers some two thousand square miles, and the field sheets of the map are upon an approximate scale of one inch to one and three quarters miles. Several points of the transcontinental triangulation of the coast and geodetic survey are included. They give it scale and position. The vertical relief is derived mainly from angles, and a line of levels connects the work with a determined point on the Carson and Colorado railroad. The map exhibits the outline of the ancient expansion of Mono Lake; the outlines of the ancient ice-stream of the adjacent Sierras with their present remnants. Agricultural and grazing lands are shown, and the areas of timber lines also indicated.

Mr. J. D. Hoffmann, in the division of the Pacific, was busy during December, carrying on the detailed survey of the new Idria quicksilver district in California.

Prof. A. H. Thompson, geographer, was occupied during December in the determination of the latitude and longitude of Fort Wingate, New Mexico, which work has been satisfactorily completed.

PUBLIC AND PRIVATE INSTITUTIONS.

Harvard college observatory.

Funds. — In his report to the president of the university, the director of the observatory states that the annual subscription of five thousand dollars, which has been in force for five years, has expired by limitation, and that an attempt to raise a fund of one hundred thousand is meeting with good success, about half having been already obtained.

Variable stars. — The study of the variable stars has been continued by Mr. Chandler. The bibliography is nearly completed, so far as the first extraction of references is concerned. Notes have been prepared to exhibit the evidence of variability which has been published with regard to about twelve hundred stars. This list excludes many cases in which the evidence is entirely inadequate. A table, giving all the published maxima and minima of each of the variables of long period, is now in process of construction. The preparation of this table has led to the important result that an interval of several years occurs in which no observations appear to have been made of about thirty of these objects. About one hundred and forty stars belong to this class; and, since last April, all of them have been observed by Mr. Chandler with the six-inch Clacey equatorial mounted in the west dome. Charts of the vicinity of these variables have been prepared, and some progress made towards their completion. Similar charts have been made for about seventy telescopic stars suspected of variability, and nearly two hundred observations of these stars have been obtained. The color of the variable stars is also estimated, about three hundred observations of this class having already been made. The circular distributed, asking the aid of amateurs and others, in the observation of stars known or suspected to be variable, has, it is believed, secured much valuable co-operation. Numerous replies have been received, and important results have been obtained, especially by Mr. H. M. Parkhurst of New York, and by the Rev. J. Hagen, S.J., of Prairie du Chien, Wis. The great difficulty encountered by most of the observers was that of identifying with certainty the fainter stars, although this is one of the first things that should be learned by any person desiring to do useful astronomical work.

Astronomical photography. — With the assistance of Mr. W. H. Pickering, an investigation was undertaken in astronomical photography. Two objects were kept in view, — first, the determination of the light and color of the brighter stars; and, secondly, the construction of a photographic map of the whole heavens. After numerous preliminary observations, a method was employed by which a photograph of the brighter stars included in about one-twelfth of the entire heavens could be obtained on a single plate. Maps were also obtained, containing a region of about fifteen degrees square, containing stars as faint as the eighth magnitude. The color exercised a marked influence on the intensity of the photographic images, in some cases producing a difference equivalent to four magnitudes. It is thought that

photography may offer the most delicate test we yet have of the color of a star, — differences too small to be perceptible by the eye, becoming distinctly visible in the photographic images.

NOTES AND NEWS.

PROFESSOR MILNE-EDWARDS writes to the Société de géographie in regard to the scientific work of the expedition on the Talisman. After having studied the profiles from the African coast into deep water, the vessel recruited at San Jago, Cape Verde Islands, and later at San Vincente; soundings being carried on during the various movements of the vessel, and proving of great interest, as in some cases they did not accord with those on the charts. Branco Island, which has never been visited by naturalists, was carefully explored. The shores are very rocky, and it became necessary to swim ashore, which the temperature rendered rather agreeable. The island is entirely volcanic, and the rocks of a singular nature. Those near the shore were blocks of lava cemented by a sort of calcareous coquina, containing many shells, into a kind of pudding-stone. Others consisted of sea-sand, drifted by the winds to an altitude sometimes of a thousand feet, and changed into solid layers by calcareous infiltration. Vegetation is very sparse, yet the great lizards peculiar to this island were found to be herbivorous. The Sargasso Sea was then examined, and proved to be of great depth, reaching nearly thirty-three hundred fathoms, and the bottom entirely volcanic, with a rather poor fauna. A collection of lava and scoriae was obtained, some of which appeared to be of quite recent origin. There is probably in the Atlantic an immense band of volcanoes extending parallel with the Andean system, perhaps to Iceland, and of which the culminating peaks form the Cape Verde, Canary, and Azores islands.

More than two hundred deep-sea soundings were made before the return of the expedition *viâ* San Miguel, Azores. Wonderfully rich collections were made, and specimens of the bottom throughout the whole region traversed. The topography of the ocean-bottom hitherto accepted will be considerably modified by these researches. It was expected that Professor Milne-Edwards would address the society on the general results of the work before a general session about Jan. 21, and exhibit at the same time some of the treasures obtained.

— At the meeting of the Paris academy of sciences, Dec. 10, Dr. Hyades gave a summary report on the geological, botanical, zoölogical, and anthropological work accomplished by the French mission to Cape Horn. In the southern islands of the Fuegian Archipelago the prevailing rocks were found to be schists and granites, greatly weathered wherever unprotected by vegetation. The dwarf Antarctic beech is limited to an altitude of four hundred metres, the Fagus betuloides to three hundred, forming with the Drimys and Berberis a forest zone with a humid soil poor in vegetable humus, and covered with mosses, heaths, and a considerable variety of small plants. The marine flora abounds in all kinds of algae (the most common being the Macrocystis pyrifera), affording a shelter to numerous zoophytes, annelids, mollusks, crustaceans, and migratory fishes of eight or ten species. Of the shell-fish, which abound on most of the seaboard, all the large species are edible. Although poorer than the marine, the land fauna includes several species of Coleoptera, Lepidoptera, Arachnida, some forty species of birds, but no reptiles or frogs. The mammals are represented by only one species of fox, two rodents, and an otter, besides the domestic dog. The natives all belong to the Tekeenika stock of Fitzroy, called Yahgans by the present English missionaries. They speak an agglutinating language, current from the middle of Beagle passage to the southernmost islands about Cape Horn. About one thousand words of this language were collected, including some abstract terms, such as *tree*, *flower*, *fish*, *shell*. The numerals get no farther than three, although the natives count also on the fingers. Over a hundred anthropometric observations were taken on individuals of all ages and both sexes. Good photographs were also obtained of a large number of Fuegians, besides numerous castings of all parts of the body, some skeletons, and a great variety of ethnological materials.

— Besides the analyses of snow made at Madrid and in Holland (in which was observed volcanic sediment similar to that of the ashes found in Java after the eruption of the volcano), mentioned by Mr. Upton in his article on the 'Red skies,' in *Science* of Jan. 11, *Nature* of Dec. 20–Jan. 3 contains a number of letters in which mention is made of a grayish volcanic (?) sediment having been found at several points in England after rain-storms in December.

— The International congress of geologists will meet at Berlin on the 25th of September next, and last five days; then a grand geological excursion will be made through the Hartz Mountains, Saxon Switzerland, from the 1st of October to the 5th, ending at Dresden by a visit to the Royal museum, under the guidance of its celebrated director, Prof. Dr. H. B. Geinitz.

— In Oregon City there is a large apple-tree in the Methodist-church lot, planted in 1842 by W. S. Moss, Esq., for Rev. G. Hines, who was then living there. The tree bears two kinds of fruit, but only one kind each year, and the different kinds appear on alternate years. It is still a vigorous, healthy tree.

— It is understood that the outer satellite of Mars, Deinos, has been observed by Professor Hall during the present opposition. As the planet Mars is now near its aphelion, its visibility would seem to show that the satellite can be observed at every opposition of Mars with the great telescopes which have recently been constructed.

— The Pi eta scientific society of Troy, N.Y., has changed its name to Rensselaer society of engineers.

SCIENCE.

FRIDAY, FEBRUARY 15, 1884.

COMMENT AND CRITICISM.

It may not be generally known that it is the duty of the National academy of sciences to examine and report upon such matters as may be submitted to it by the proper authorities of the national government. The problem is referred by the academy to a committee, composed of such of its members as are specially skilled in the science to which the subject appertains; and they consider it in the light of all accessible data, and, where necessary, submit the problem to experimental investigation and study. It is not unusual, also, to call into council experts in good standing who are not members of the academy. All these services are rendered gratuitously, only the actual expenses incurred being defrayed. It would seem as if no fairer way could be devised for obtaining an honest and intelligent opinion on the question at issue; since the government is unbiassed, and the jury untramelled, while it consists of men whose ability and attainments are guaranteed.

Many reports have thus been presented to the government during the existence of the academy; but few seem to have attracted as much attention, or to have aroused as much feeling, as a recent report made to the commissioner of internal revenue upon the question as to the wholesomeness of glucose as an article of food. The conclusions reached are, 1°, that the manufacture of sugar from starch is a long-established industry, scientifically valuable and commercially important; 2°, that the processes which it employs at the present time are unobjectionable in their character, and leave the product uncontaminated; 3°, that the starch-sugar thus made and sent into commerce is of exceptionable purity and uniformity of composition, and contains no injurious substances; and, 4°, that though having at best only about two-thirds the sweetening-power of cane-sugar, yet starch-sugar is in no way inferior to cane-sugar in healthfulness; there being no evidence before the committee, that maize starch-sugar, either in its normal condition or fermented, has any deleterious effect upon the system, even when taken in large quantities.

For reporting these conclusions, the members of the committee have been most severely attacked, and their honesty impugned. One of the most bitter and partisan of these attacks is contained in a recent 'leader' in the Washington *Evening star*, in which it is distinctly implied that this report favors the use of glucose in adulteration. Inspection of the report shows this deduction to be entirely without foundation; and the attack reveals the most unpardonable ignorance, or a deliberate intention to deceive. The use of glucose in adulteration is a well-known fact, and it is the duty of the commercial and legal fraternities to devise means for its prevention. The wholesomeness of glucose was a matter about which nothing was definitely known, and the fact of its being largely used in food made the matter of the gravest consequence. The consideration of this fact was the most important duty of the committee.

The action of the New-England fish and game convention, recently assembled in Boston, should meet with cordial support in all quarters. The object of the convention was to secure uniformity in the fish and game laws of all the New-England states, and to see that these laws are so worded that they may be enforced. The present game laws, of Massachusetts at least, are in great measure a farce, as under them convictions are often impossible, even when infringement of the law is clearly proved. This is due, in part, to the varying close times in different states, — a condition of things which encourages the smuggling of ille-

gally acquired game into a neighboring state. A carefully considered draught of the proposed uniform laws has been presented to the Massachusetts legislature; and since it would be difficult to find, in all New England, persons more competent to draught such laws than those who recently came together for this purpose, it is hoped that the draught, without material change, will be accepted by the legislature. Provision is made for the granting of special licenses only to actual students, cutting off the nearly indiscriminate license-giving to young men who wish to form collections for their personal gratification, and not for true scientific study. The lobster question has become far more serious than most persons are aware. This important crustacean is now nearly extinct on our shores; so that the proposed close time, and the prohibition of the capture and sale of any lobster under one foot in length, are wise additions to the existing laws. The proposal to intrust the duties of game commissioners to the commissioners on inland fisheries, as is done in some states, is another important provision of the proposed law.

The movement which within the last few years has caused a rapid organization of agricultural experiment-stations in various parts of the United States has developed another phase of the problem concerning the distribution of work in botanical research. The very marked development of botanical science within the last ten or fifteen years has necessitated specialization in several directions, and renders it necessary to consider which of the particular fields inviting research should remain identified with our higher institutions of learning. One of the most promising fields at the present time is to be found in vegetable physiology; but this is discovered to be naturally gravitating towards the experiment-stations and away from the colleges. This is a phase of the problem which should be carefully considered by those who have in hand the interests both of the science and of the stations; and care should be taken not only that those who are called to the charge of these important institutions should be capable of fully appreciating the importance of the interests involved in this particular branch, but that they should secure to it a position commensurate with its high character and the great possibilities which it offers in the way of practical results.

The present season is remarkable for the brilliancy of the evening sky; the four brightest planets, Venus, Mars, Jupiter, and Saturn, being all above the horizon at once. To add to the brilliancy of the spectacle, this takes place at a time when Orion, Taurus, and others of the brightest constellations, are near the meridian, and nine stars of the first magnitude above the horizon. An additional point of interest to possessors of telescopes is, that Saturn is approaching both his perihelion and the point of greatest opening of his rings, and is therefore in that part of his orbit most favorable for study. About the middle of April an addition will be made by the simultaneous appearance of Uranus, Neptune, and Mercury, so that all eight of the major planets will be visible at the same moment. Of course a telescope will be required to see Uranus and Neptune, but the six others will be visible to the naked eye.

England has been rejoicing in a piece of elephant worship since Mr. Barnum placed at the zoölogical gardens in London the white elephant which he recently procured from Burmah. The natives of the east affirm, and the Europeans are willing to corroborate their statements, that the body of a dead elephant, except of such as die by the rifle, is never found. Whether they never die, or betake themselves to some remote body of water before they depart this life, is a disputed point. The great esteem in which the elephant is held is said to be due to the last incarnation of Gautama, before he was born as Buddha, being that of an elephant; yet, as the Buddhists' idea of the path of beings is on through at least seven heavens to the final total annihilation, it is not perfectly clear why they should not suppose the soul to finally take refuge in an old elephant, to rest with it in its unknown grave.

LETTERS TO THE EDITOR.

Deafness in white cats.

I AM engaged upon an investigation concerning the causes of deafness; and I have therefore naturally been much interested in Mr Lawson Tait's paper concerning deafness in white cats, published in *Nature* (vol. xxix. p. 164), and in the letter of Mr. Joseph Stevens, published in the same journal, concerning his father's breed of deaf white cats (vol. xxix. p. 237).

I have myself come across three instances of white cats with blue eyes (two in Europe and one in America), and in each case the animal was deaf.

Mr. Tait's statement, that "congenital deafness is not known to occur in any animal but the cat" is a most extraordinary one, in view of the great prevalence of congenital deafness among human beings.

Of the 33,878 deaf-mutes in the United States, more than one-half are congenitally deaf;[1] and in Europe (excepting Germany) the proportion of congenitally deaf appears to be much greater, — about four to one, according to the late Dr. Harvey L. Peet (1854).[2]

Why should congenital deafness among the lower animals be confined to cats, and why only to white cats?

Mr. Tait notes also an apparent association between epilepsy and whiteness in animals. He says, "Every kind of white animal I have kept as a pet has been the subject of epilepsy; and the association is suggestive when we are told, as I have been frequently, that the disease is unknown among negroes."

It is worthy of note, that deafness also appears to be less common among negroes than among white people. According to the recent census, the total white population of this country amounts to 43,402,970, and the total number of white deaf-mutes is 30,661. The colored population is given as 6,580,793, with 3,177 colored deaf-mutes (not including Chinese and Indians).

Thus, while we have one deaf-mute for every 1,416 of the white population, we have only one deaf-mute for every 2,070 of the colored people. It would be interesting to know whether the proportion of congenitally deaf is less among the colored than the white deaf-mutes.

The pallid complexion of many deaf-mutes has often been commented upon by strangers as an apparent indication of ill health. While I cannot say that I have myself observed this as a common characteristic, still my attention has never been specifically called to the point. It would be easy to test the matter by collecting into one room all the congenitally deaf pupils of some large institution, excluding those pupils who became deaf from accidental causes. A cursory examination would probably show whether there is or is not, in the human race, an association between congenital deafness and the absence of coloring-matter from the skin and hair. I trust that some of your readers may be able to throw light upon these points.

ALEXANDER GRAHAM BELL.

Washington, D.C., Feb. 4, 1884.

[1] See Compendium of the tenth census (1880), part ii. p. 1664.
[2] See American annals of the deaf and dumb, vol. vi. p. 237.

Radiant heat.

In a letter to *Science* of Jan. 25, Mr. Fitzgerald thinks it is possible that I am misled as to the manner in which my rotating-screens work, by reason of the complication of the arrangement. I must nevertheless continue to assert, that I think I understand how the process I have invented operates, and cannot admit that I am in error in this until such error is pointed out. Now, Mr. Fitzgerald's demand that I should show that the heat which originally came from B is returned to B *in the same direction* as the heat coming from A, would incorrectly lead the reader to suppose that I made some such statement or supposition in the original paper, and that consequently I was misled, as he suggests. But the most superficial examination of the paper shows that I have not for a moment supposed this; as I have simply proposed to so arrange the reflecting surfaces as to return radiations from B through some one or more of the apertures in the screen b, and not necessarily through the apertures from which they originated. It necessarily follows, that I did not suppose them to be returned in a direction parallel to the radiations from A.

I think, then, that Mr. Fitzgerald must certainly admit that I have not made the blunder which is implied in his letter.

Again: Mr. Fitzgerald takes it for granted, apparently, that this want of coincidence in direction would be fatal to the process; whereas, in my estimation, the only question is, whether the radiations which originally came from B are returned to B or not. What their direction may be appears to me entirely immaterial.

If it is possible to show that the want of coincidence in the direction of all the rays coming to B invalidates the process, as Mr. Fitzgerald implies, he will no doubt be able to give a direct proof of the fact. Such proof, however, seems to me impossible; for, after the energy reaches B, the path by which it has arrived is of no consequence.

It goes without saying, that in this view of the matter it is quite impossible to substitute the process proposed by Mr. Fitzgerald in place of mine; as in his process these directions necessarily coincide, which in mine cannot coincide.

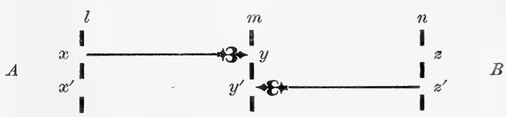

FIG. 1.

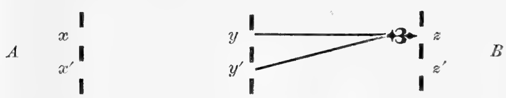

FIG. 2.

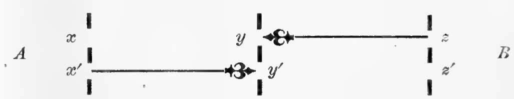

FIG. 3.

FIG. 4.

It does seem possible, however, to employ two sets of openings such as Mr. Fitzgerald has proposed, in such a way that they shall together accomplish what neither of them can effect singly. For example: let there be three fixed screens, l, m, n, with two sets of openings, $x\ y\ z$, $x'\ y'\ z'$, which can be opened or closed instantly; and let them all be closed except when the contrary is explicitly stated. Let each of the four equal intervals of time which we shall speak

of be the time required by the front of a ray in moving from n to m, or *vice versa*. During the first interval let x and z' alone be open. The rays between the screens at the conclusion of the first interval are shown in the first diagram. During the second interval let y alone be open, and let the reflector at y' send the ray impinging on it towards z. The situation of the rays at the end of the second interval are shown in the second diagram. During the third interval let x' and z alone be open. The rays between the screens at the end of this interval are represented in the third diagram. During the fourth interval let y' alone be open, and let the reflector at y send the ray from that point toward z'. The next interval is a repetition of the first, and so on.

It is seen that, in fact, the difference in the directions of the two rays arriving at B can be made less than any assigned finite angle, however small, by sufficiently increasing the distance between the screens, or sufficiently decreasing the space between the openings, or both.

It is possible that the above process may, from its comparative simplicity, conduce to a clearer understanding of the relations involved, though it seems inferior to the one originally proposed in some important particulars. H. T. EDDY.

University of Cincinnati, Feb. 2, 1884.

The Greely relief expedition.

In view of the comment upon the Greely relief expedition, it may not be out of place at this early date to call attention to a neglected principle of arctic navigation which bears with full force upon the navigation of the route in question. To its adoption may be traced the success of Nares with the Alert and Discovery, and of Nordenskiöld with the Vega; to its neglect, the wreck of the Jeannette and the Proteus among a host of others.

Simply stated, it is, under all circumstances, to cling to the coast, and among its islands find protection against the floating ice. To coast along the edge of the floe, and follow the openings it offers, is a veritable siren. Of course, the principle is not applicable till after Jones's Sound is passed; but here the course is usually free.

The Eskimo knew me as TILITOIANIAC.

New Haven, Conn., Feb. 2.

The red skies.

I have only time to-day to reply very briefly to your editorial inquiry on p. 30, as to previous instances of red skies and volcanic eruptions.

You will find a West India instance in 1831 on p. 165 of the *Meteorological magazine* for 1883; but the most striking parallel has been pointed out by Professor Karsten of Kiel as occurring in 1783, lasting about four months, and spreading over the whole of Europe, northern Africa, and eastern Asia.

Arrangements are being made for the concentration of all collectible information upon the subject, and I shall be proud to act as the receiver of copies of any notes or records which your readers may intrust to me. G. J. SYMONS, F.R.S.

62 Camden Sq., London, N.W.,
Jan. 25, 1884.

[We shall publish Professor Karsten's article next week.]

Aeolian ripple-marks.

On the evening of June 11, 1883, after a severe rain-storm, during which large quantities of soil were washed from adjacent fields and deposited along the roadside, I noticed near Brodhead, Wis., a peculiar phenomenon, which may be worth recording. The mud, deposited only a few hours before, was still very mobile, and, at the point where best seen, covered an area a rod or more wide and three or four long, presenting a perfectly plane surface. The steady force of the strong wind was interrupted by occasional gusts of greater violence, each of which raised on the plastic mud-surface corrugations, which, in every detail that could be caught during their momentary existence, resembled ripple-marks formed by water, being a beautiful and distinct series of parallel ridges slightly concave toward the direction of the moulding-force. The outlines of these aeolian ripples were no sooner defined than they began to dissolve, and a minute or two sufficed to obliterate all trace of them. The phenomenon was observed several times on the same surface, and also in adjacent localities, where the consistence of the mud, and therefore the duration of the ridges, varied slightly. The ripples were best defined in the thinnest mud, though this was most favorably situated for their production; and they disappeared less rapidly where formed in the more viscous material.

This, of course, is not a radically new phenomenon, but a rare phase of the familiar action of wind on liquid surfaces. R. D. SALISBURY.

Winchell's 'World-life.'

Will you permit me to announce that a number of errata, attributable both to author and proof-reader, have found their way into my late work on 'World-life;' and I will be glad to mail slips of corrections to any who will kindly notify me by simple postal-card that they so desire?

ALEXANDER WINCHELL.

Ann Arbor, Mich.

THE LABORATORY IN MODERN SCIENCE.

THE material circumstances under which scientific discovery is prosecuted have been completely revolutionized during the last forty years. Of the immense changes that have occurred, the majority have fallen within the last fifteen, one might almost say dozen, years. It is interesting and profitable to contrast the past with the present in this respect.

Forty years ago there were very few, more properly no laboratories which we of to-day would consider even tolerable. Now every university of importance and high repute, the world over, has large suites of rooms for each department of science, and often numerous great buildings within whose walls thousands and thousands of students are daily brought face to face with the facts and laws of nature. The generation that is now gone pursued its scientific studies in incommodious quarters, and even those were destined for the use of the professors rather than the students. Many a small, dingy, and ill-lighted room is still to be seen, where some illustrious *savant* created new knowledge,— a small square chamber, with crooked walls, low ceiling, undulating floor,

and an insufficient window: what scientific traveller abroad has not seen that working-place, where his predecessors labored at the foundations of our existing science? Is not each of its forlorn details examined with a curiosity which is half wonder, half pity? Yet in such places were made the commencements of modern science.

Nowadays discovery has more seemly abodes. The great institutes which make the pride and glory of German universities are the models now being copied everywhere. By a guess we may estimate the number of laboratories equipped and intended for research at four or five hundred. The modern laboratory is a really new institution, the evolution of which still awaits its historian. Its origin appears to have been twofold: it grew, on the one hand, out of the museums; on the other, from the private collections of apparatus and materials belonging to the professors. The earliest museums were storehouses of curiosities,[1] but during the eighteenth century they gradually acquired a more scientific character. Not, however, until this century, did any of the museums attain great size; while the gigantic dimensions which a few, like those of Berlin, London, Paris, and Washington, have reached, are the result of very recent growth. Of course, special work-rooms have to be provided for those in charge of, or who come to study, such large collections; and, since the majority of scientific museums are connected with universities, the work-rooms in many of these institutions have become laboratories for students.

A great many of the older scientific men now living, and of the previous generation, got their little and imperfect practical training in private laboratories, which were the only ones existing in the earlier part of this century. Before long a few professors introduced, through their private energy, better equipment for the benefit of their laboratory students; and, when the demands exceeded their resources, these early enthusiasts obtained subventions from the university authorities. As these appropriations were increased, the private laboratory gradually became a university enterprise. Thus, Purkinje established his physiological laboratory at Breslau; Magnus, the physical laboratory at Berlin; and Liebig, the chemical at Giessen.

A good museum is very valuable, but a good laboratory is many times more valuable. Collections of any kind have, as such, a very limited utility, and even that only in very few sciences. The modern laboratory is almost unrestricted in its scope and possibilities. It is the most remarkable and influential creation of science in our time. It is a place well supplied with the necessary conveniences for watching and recording the special class of natural phenomena belonging to the science to which the particular laboratory is dedicated. Experience has shown that the appliances necessary for the exact observation of nature are numerous, varied, and costly: indeed, the thorough pursuit of any branch of science requires ample resources. Now, pure science does not lead to wealth: therefore students and investigators are compelled to rely upon the concentration of means and appliances in endowed laboratories to render their work possible. Association and co-operation, the characteristic social forces of our epoch, nowhere achieve more important results than in these laboratories, in which are produced the majority of current contributions to knowledge.

The expense of establishing and maintaining a good laboratory of any kind is far greater than is usually conceived. There are weights and volumes and temperatures to be measured, requiring delicate balances, graduated glasses, and fine thermometers; a great variety of glassware, lamps, stands, etc., is necessary; also reagents, standard fluids, and the like; next come the special supplies needed for the science to which the laboratory is devoted. It is astonishing how much like an assemblage of machinery the stock becomes even in those departments which require least. Next to be named is the material to work upon, which, in the natural-history sciences, is extensive, and has to be gathered from far and near. Finally, we mention as indispensable a small working-library, which ought to contain at least all those books that need to be frequently consulted, and sets of a few of the most valuable special journals. These conditions are more than fulfilled in many European laboratories, but by very, very few in this country. The architectural conditions are, on the whole, of subsidiary importance. There is no more common or egregious error than to suppose the erection of a building establishes a laboratory. In a handsome edifice something essential is often sacrificed to appearance: outside beauty is not indispensable to inside convenience. Half the cost of a building, given to endow the running-expenses of a laboratory, would in the majority of cases prove many fold more valuable.

A good scientific laboratory — that is to say, one in which original researches, as well as

[1] Of course the original 'musaeum' at the palace of Alexandria was altogether different.

mere teaching, may be undertaken (such a one as is found at universities, *de facto*) cannot be carried on properly and successfully by less than three persons. The highest officer must be the responsible director, — a man of superior ability, extensive attainments, and prolonged experience: one, in short, who has mastered his department of science, knows its possibilities and deficiencies, and is therefore capable of judging what work is most feasible and instructive for students, and what problems are best adapted for investigation. It is sheer waste for a man of such high capacity to sacrifice his whole time to the arrangement of apparatus, or the preparation of experiments for his lectures or his students: therefore it is desirable, we prefer to say indispensable, that he should have an assistant, preferably a young devotee of science, who will be fitted by his experience as an assistant to ultimately become himself director of a similar laboratory. The third person is the laboratory keeper (*diener*), who needs must be a man of some mechanical skill, so that the precious instruments may be safely intrusted to his care. He should be something more than a servant, and less than an assistant. A laboratory without this working-force cannot do much for the promotion of science, although even more modest ones may be valuable for simple instruction. A first-class laboratory, and in Germany are many such, has always a larger number of officers. There are few persons among us who appreciate the magnitude of a scientific laboratory: were it otherwise, there would not be so many petty substitutes for them.

Existing laboratories fulfil two functions, — giving education to students, and opportunity to investigators. The multiplication and enlargement of laboratories depend chiefly upon the growing recognition of the truth that first-hand knowledge is the only real knowledge. The student must see, and not rest satisfied with being told. Translated into a pedagogic law, it reads, 'To teach science, have a laboratory; to learn a science, go to a laboratory.' He who has never learned to appreciate a laboratory in its highest sense does not know even the meaning of 'I know.' We do not consider those liberally educated who have never had even a single thorough course of laboratory training. It is the laboratory which gives strength to the movement in favor of scientific education, for it opens to all the road to real living knowledge; while books by themselves lead off to the by-ways of what other men thought they knew at the time they wrote. Life and death are not more different than are, in their ways, real and book knowledge of nature. A book, at best, is but a useful adjunct in science.

To the investigator the laboratory is, or ought to be, all in all, providing him with every thing wherewith to experiment and observe. Not only should there be on hand all the paraphernalia of research, but it must also be possible to purchase or construct the new apparatus which may be devised to meet the new requirements. Yet in no respect, perhaps, do laboratories maintain a more efficient utility than in fostering technique, by the development of new methods, and by gathering from all sources complete information concerning the available processes and means of work. Only the daily laborer at science can adequately value the knowledge of methods which is concentrated in every well-managed laboratory. In places where these requirements are fulfilled, discovery makes rapid progress; and their existence explains the present immense rapidity of scientific progress.

What a contrast between the magnificent opportunities we enjoy to-day and the meagre possibilities of fifty years ago! The change has been rendered possible by the establishment of well-fitted laboratories for the promotion of science.

TESTS OF ELECTRIC-LIGHT SYSTEMS AT THE CINCINNATI EXPOSITION.

THE commissioners of the eleventh industrial exposition held in Cincinnati in September and October, 1883, determined to undertake a series of tests of the efficiency of electrical lighting systems, and so advertised in their circulars, which were widely distributed. Special premiums were offered for the best system of arc-lighting, the best system of incandescent lighting, the best dynamo machine for arc and incandescent lighting respectively, and for the best lamp in each system.

A jury was appointed by the commissioners, consisting of T. C. Mendenhall, chairman, H. T. Eddy, Thomas French, jun., and Walter Laidlaw. The jury was instructed to make such tests and measurements as seemed desirable and were possible under the circumstances, and which would aid in arriving at a verdict upon the relative merits of the different exhibits.

The opening of the exposition took place on Sept. 5, and the close on Oct. 6. The jury was requested to make its report of the awards one week before the close of the exposition.

In response to the proposal of the commis-

sioners, four systems of electric lighting were entered for competition. The Thomson-Houston electric-lighting company submitted a system of arc-lighting; the Edison electric-lighting company, a system of incandescent lighting; and the U. S. electric-lighting company offered a system of arc-lighting, and also one for incandescent lighting. Several things conspired to make the tests less complete in some respects than was desired by those interested. The members of the jury were all engaged in professional work, and were therefore unable to devote their entire time to the tests. The dynamometers used were built after the exposition opened, and were not completed until after many vexatious delays. One of them, that upon which the most reliance was placed, was of a form recently devised, and the principles of which had never been realized in practice, except in an experimental model constructed by its inventor. Its construction on a large scale necessarily involved a good deal of experimentation. In spite of these delays, the jury was enabled to begin regular work on the evening of Sept. 25, and to make, during the succeeding ten days, such tests of the most important features of the various systems as to justify them in making the awards, whatever difference might have existed in reference to minor points, which, for lack of time, were not thoroughly investigated.

The plan adopted was substantially that upon which nearly all similar trials have been conducted. The energy consumed by the dynamo was measured by means of the dynamometers, and the electrical energy in the circuit was determined by well-known methods. This gave the efficiency of the machine as a generator. The illuminating-power of the lamps was compared, and at the same time the electrical energy which they consumed was measured. A combination of the results obtained by these two processes gives the relative illuminating-power per unit of energy consumed by the dynamo, which represents the relative commercial efficiencies of the systems. The measurements made, therefore, were of three kinds, — dynamometric, electric, and photometric; and they will be considered in the order mentioned.

Dynamometric measurements.

Two separate dynamometers were simultaneously employed in measuring the mechanical energy expended in running the armatures of the four dynamos which were tested. They have been called, from the manner of their operation, the 'belt' and 'cradle' dynamometers respectively.

The belt dynamometer has been frequently employed before; and its manner of operation is explained by Dr. Hopkinson in *Engineering*, vol. 27, p. 403, where he gives a figure of it, and the formulae used by him in determining the power expended in certain electric-light tests. These formulae tacitly assume that the belt is perfectly flexible and without weight: for otherwise terms must be introduced into the formulae to take account of the differences of tension in the belt caused by passing the dynamometer-pulleys, and the centrifugal force generated in the belt as it leaves the various pulleys. The velocity of the belt being great, it is more than probable that such terms are required in order to deduce accurate results from this form of dynamometer.

Under these circumstances the computation of the power expended from the observations of the belt dynamometer by the theory as at present known was wholly unsatisfactory, giving results, in all except the first few tests, considerably less than the truth, and in some cases less than the electrical power in the circuit.

The cradle dynamometer, however, gave results of a much more satisfactory character. The principle of this dynamometer is a recent invention of Professor Brackett of Princeton, N.J., and, owing to its novelty and great accuracy, merits a somewhat minute description. It was built at the machine-shops of Messrs. Lane & Bodley, Cincinnati, under the superintendence of Mr. Laidlaw, from designs made by Mr. Eddy, to whom is due the arrangement of its various parts.

It consisted of a substantial platform, *cc*, fig. 1, seven feet long by four and a half feet wide, hung at each end by iron rods, *ee*, from an axis consisting of a short piece of two-and-a-half-inch shafting, *a*, which rested upon a supporting-girder, *gg*. Fig. 1 represents the framework, etc., at one end of the platform, to facilitate raising and lowering the girder *gg*, which carried the platform *cc* by means of the jackscrews *jj*, upon which *gg* rests. The uprights *bb* are guides passing through the openings *bb*, shown in fig. 2, which is intended to represent the ground-plan of *gg*, and adjacent parts of the cradle. Each girder, *gg*, was composed of two planks, held at a distance of three inches apart by blocks, *dd*, and bolted firmly together. The rods *ee* passed between the planks *gg*, and were forged to an eye which fitted the axis *a*. The axis *a* rested upon pieces of smooth boiler-plate in the upper surface of *gg*.

The uprights *bb* form part of a rigid framework, well bolted together, one side of which is seen in outline on a smaller scale in fig. 3.

A scale-beam, *ff*, made in the form of an inverted L, and graduated to fractions of an inch, had the lower extremity of its vertical arm fastened to the platform *cc;* while at the angle was an eye which was centred upon *a* by the screws *iii*.

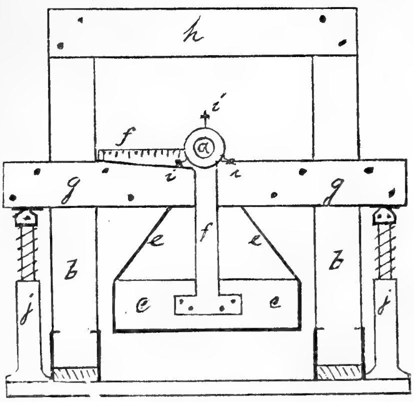

FIG. 1.

It is readily seen that the platform, when it was raised from the ground, as shown in fig. 1, was free to swing through a limited space, either to the right or left, and that any eccentric weight or force so applied as to tend to swing it to the left could be compensated by a weight upon the scale-beam, *ff*, which swings with it; so that the platform could be still kept in its horizontal position.

The axis about which the swinging tends to occur is the line of contact between *aa* and *gg*, which line we shall for brevity henceforth call the axis *aa*.

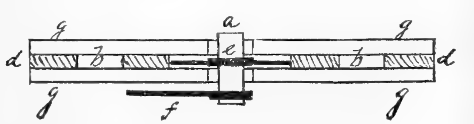

FIG. 2.

In setting up the dynamometer, it was so placed that the axis *aa* was directly below the axis of the driving-pulley, and in the same vertical plane with it. The dynamo to be tested was placed upon the platform *cc*, while *cc* was resting upon the ground; and it was blocked up on *cc* to such a height, that the axis of the armature was as nearly at the same height as the axis *aa* as could be readily done by direct measurement. This adjustment could be effected with all necessary exactness once for all; for, even though the armature were slightly above or below the axis *aa*, no error would thereby be introduced into the observations.

The axis of the armature was also set, as nearly as it could be conveniently, in line with the axis *aa;* but the final adjustment, so that the centre of the armature-pulley was neither to the right nor left of the axis *aa*, was made mechanically as follows. The platform and dynamo were raised from the ground, and the girders *gg* carefully levelled by means of the jackscrews. The platform was then brought to a horizontal position by placing compensating weights upon it. The belt was next adjusted, and was tightened by lowering the platform. It was then found, that, in case the axis of the armature was to the right or left of *aa*, the tension of the belt exerted a force to tip the platform, and it no longer stood horizontal. This was corrected, — one half, by shifting compensating weights; and the other half, by moving the dynamo to the right or left. The belt was then slackened by raising the platform, and a similar adjustment again made to bring the platform to the horizontal position. This was repeated until the platform stood horizontal, whether the belt was tight or loose; both girders being at the same height, and both accurately levelled, account being taken of the bending.

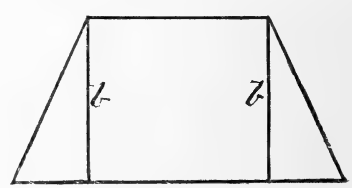

FIG. 3.

A further application of compensating weights was employed to render the balance sensitive. With the Edison dynamo, which is top-heavy (i.e., its centre of gravity is above the axis of the armature), more than a ton was hung on the sides of the platform to bring the centre of gravity of the whole down to the axis *aa*. With the other dynamos, whose centres of gravity are below the axis of their armatures, compensating weights of smaller amount were placed upon a staging built on the platform above the dynamos, in order to bring the centre of gravity of the whole up nearly to the axis *aa*.

In making the tests, the power was applied to turn the armatures clockwise in fig. 1. This caused the horizontal scale-beam *f* to rise; and weights were placed upon it to bring it back to the horizontal position. The moment of

the couple, got by multiplying the weight so applied by its distance from the axis *aa* as read upon the scale-beam, is evidently equal and opposite to the moment of the couple with which the armature is turned. Thus the moment of the force applied to run the armature was measured in foot-pounds. This moment, multiplied by the number of revolutions per minute and by 2π, is the work expended in driving the armature, in foot-pounds per minute.

It was found convenient to use a weight having a moment somewhat less than sufficient to bring the scale-beam to the horizontal, and employ a Chattillon spring-balance with a dial-face reading to 2 oz. to furnish the remaining part of the couple. This balance was fastened to a vertical cord passing around a small winch, which enabled the observer to bring the scale-beam to the horizontal with facility.

The principal difficulty to be apprehended in testing with this dynamometer was a possible tendency to oscillation, which might be caused by running the belt. Had this existed, it might have been checked by a dash-pot; but the weight of the platform and dynamo was sufficient to almost entirely obviate any such difficulty, and give very considerable steadiness of position. Indeed, the jarring seemed to increase its sensitiveness, and evidently enabled the platform to come to rest in its position of equilibrium by overcoming any initial friction existing.

The structure was mostly built of three-inch plank, ten or twelve inches wide. The platform was designed to safely carry five tons at its centre.

For permission to make use of the cradle dynamometer, the jury is indebted to the kindness of Professor Brackett.

In addition to the use of the two dynamometers described, indicator-diagrams were taken from the steam-engine furnishing the power for driving the dynamo machines. Throughout the dynamometric tests the machines were driven by a Cummer engine of about a hundred horse-power, which furnished power for other dynamos than that upon the cradle, as well as for two or three pieces of machinery on exhibition in Power Hall. It was thus impossible to make the taking of indicator-diagrams contemporaneous with the regular tests, owing to the large load which the engine carried; and they were generally taken after ten o'clock at night, at which hour the remainder of the load was thrown off. Although these indicator-cards were not used in the final computations, they furnished valuable checks upon the performance of the dynamometers.

The electrical measurements.

For the purpose of making the electrical measurements as free from disturbance as possible, a small room, about twenty feet long and ten feet wide, was fitted up in the basement of the central part of the large exposition building. In this, three brick piers were built upon solid foundations, and two or three wooden brackets were firmly secured to the walls, so as to furnish firm resting-places for the galvanometers. The main lines of the arc-lighting systems were run through this room, and very heavy copper conductors connected the room with the space in which the dynamos were exhibited; so that the entire current from the incandescent machines could be introduced when desired.

The electric measurements consisted in the determination of the strength of the current, and the electromotive force between two points in the circuit. For this purpose several galvanometers of different kinds were employed. For the measurement of current strength the principal instrument used was one of Sir William Thomson's current galvanometers, made by White of Glasgow. Although of recent invention and construction, the instrument is probably so well known as not to require any detailed description. It consists essentially of a magnetometer, and a coil of very low resistance. In the magnetometer four short magnets are combined to form a needle, the position of which is indicated by a very light yet very rigid aluminum index. A steel magnet, bent in the shape of a semicircle, is placed in a vertical plane over the needle, so that the latter is approximately at the centre of the circle of which the magnet forms a part. One end of the magnet is furnished with a cross-piece of brass, from one extremity of which projects a pin which rests in a conical hole, and upon the other extremity is a 'button;' so that freedom of motion around the pin as an axis is allowed. The opposite end of the magnet rests in a groove cut around the end of a screw, by the movement of which the plane of the magnet can be shifted towards the east or towards the west.

The coil is fixed in a vertical plane at one end of a wooden table whose length is about one foot, and breadth about five inches. The table is furnished with levelling-screws, and a V-groove is cut lengthwise through the centre, at right angles to the plane of the coil. In

this groove the magnetometer, with its attached magnet, slides; so that, by placing the needle at different distances from the centre of the coil, the instrument may be used for measuring currents differing very greatly in strength.

The adjustment of the instrument consists in placing the magnetometer upon the table, without the field-magnet, and adjusting the whole so that the index is at zero of its scale; after which the magnet is put in its place, and, if necessary, one end is moved by means of the screw until the index again points to zero.

The interpretation of the reading of the instrument is a very simple operation. A scale along the edge of the V-groove shows the position of the magnetometer. It is necessary to know the strength of field at the needle, which is, of course, that due to the magnet, plus the horizontal component of the earth's magnetism; and then, if this strength of field in C.G.S. units be multiplied by the reading of the needle, and divided by the scale-reading of the magnetometer, the result will be the current in ampères.

This galvanometer was permanently mounted on one of the stone piers, and its connections were so arranged that it could be quickly thrown in or out of the circuit without interfering with the continuity of the same. The direction of the current through the galvanometer could be instantly reversed; and throughout the observations reversals were regularly made, so as to eliminate error arising from displacement of the zero. The zero-point was adjusted, however, at the beginning of every series of observations, and examined at frequent intervals during the same.

A differential galvanometer was also used in measuring current strength. This instrument was kindly loaned to the jury by Professor Brackett of Princeton, by whom it was devised and constructed. A description of it will be found in the *American journal of science*, vol. xxi. p. 395. It consists essentially of two heavy rings, one within the other, through which the current goes in opposite directions. The needle in the centre has a silk-fibre suspension. The radii of the rings being given, the constant of the instrument can be readily calculated. It was especially constructed for the measurement of strong currents, ten ampères giving a deflection of fourteen to fifteen degrees when the value of H is a little more than .2. When the current was steady, it behaved admirably; but with a fluctuating current it became extremely difficult to get trustworthy readings, owing to the constant vibration of the needle. The graduated circle was so small that the estimation of fractions of a degree was quite uncertain. Even with steady currents, more time was required for reading the Brackett than the Thomson, owing to the length of time needed for the needle to come to rest after a reversal of current. For these reasons its use was not continued throughout the test. It was observed continuously during the tests of the Thomson-Houston dynamo, and during a part of the tests of the Weston dynamo, when, owing to fluctuation in the current, its use was necessarily discontinued. It served a useful purpose, however, as a check upon the indications of the Thomson instrument, the close agreement of the two justifying confidence in the indications of the latter. The most carefully made series of comparisons was that of Sept. 20. During the afternoon of that day, eight simultaneous readings of the two instruments were made; the current, which was remarkably steady, being furnished by the Thomson-Houston dynamo. The means gave 9.92 ampères as indicated by the Thomson, and 9.93 ampères for the Brackett. The regular tests were begun on Sept. 25, and in the mean time several additional conducting-wires had been brought into the testing-room. The indications of the Brackett galvanometer were, after this, constantly somewhat less than those of the Thomson, which was doubtless due to the alteration of the field by the presence of the currents. The difference was quite constant, and amounted to about two per cent. Thus, on Sept. 25 the Thomson gave 9.97 ampères, and the Brackett 9.77. On the 26th the Thomson indicated 10.0, and the Brackett 9.80, and on the 27th, with the Weston arc dynamo, showed 18.6 ampères, and the Brackett 18.3. That this discrepancy could be accounted for by the effect of the current upon the strength of field was established by vibrating a needle under two conditions, — with and without the currents. Herein is shown the advantage of a strong, permanent magnetic field, such as exists in the Thomson instrument. An alteration of the field, which might considerably influence the results from the Brackett, would hardly be perceptible with the Thomson.

During the tests of the arc-light machines the whole current was taken through the galvanometers. With the incandescent systems, however, in which the current was sometimes as high as 170 ampères, this was impossible; as the coils and connections would have been greatly heated. The current might possibly have been safely divided between four or five instruments; but, these not being at hand, it became necessary to make use of a shunt.

For this purpose the heavy main conductor was cut, and the two ends were inserted into large mercury-cups, cut out in a block of wood an inch and a half thick. These cups were also connected by about forty feet of number 0 copper wire, the ends of both main and shunt wire being well immersed in the mercury, and pressed close together. These mercury-cups were connected with two others by means of short copper wires, and into the second pair the ends of the galvanometer wires were plunged. As thus arranged, about one-fifth of the current was taken through the galvanometer. Even with this division of the current, it was found, that, when using the strong current from the Weston dynamo, the wires of the galvanometer were somewhat heated; and in order to avoid this result, a short piece of number 0 wire, not more than two or three inches in length, was bent so that it could be inserted in the mercury-cups, and thus cut the galvanometer out, except during the few moments necessary for taking a reading. During all of the 'resting' periods this short wire carried by far the greater portion of the current, and thus tended to prevent the heating of the shunt wire proper as well as of the galvanometer.

The determination of the ratio of the two parts into which the current was divided, or the value of the 'shunt multiplier,' was, of course, a matter of great importance. In the preliminary measurement of this ratio the current from the Thomson-Houston machine was of great service on account of its steadiness. To begin with, a number of tests were made to discover if the connection resistances were of such importance that any accidental variation in them would perceptibly alter the shunt ratio. The shunt was repeatedly lifted out of the cups and replaced, and the galvanometer connections were broken and remade. Every thing that could be disturbed was disturbed; but, upon reconstruction, the result was found in all cases to be practically unaltered. On Sept. 28 a series of twenty measurements was made with the shunt alternately in and out, using a current of 10 ampères. The results agreed closely with each other, and gave 4.6 as the value of the shunt multiplier. On the following day the tests of the incandescent machines began; and the shunt was not moved from its position, nor disturbed, until after the conclusion of the entire work. On Oct. 3, after all of the regular tests had been completed, another test of the shunt was made, with a current of 10 ampères, as before. Ten observations were made, all of which agreed in giving a ratio of a little more than 5.0. This result was quite unexpected, and the discrepancy between it and that obtained from the first test was entirely too great to be accounted for by errors of observation. As circumstances prevented further tests in Cincinnati, it was determined to remove the shunt and all connections to the physical laboratory of the Ohio state university, where a thorough examination of the cause of the difference could be made. This was done; but, before any experimental examination had been undertaken, the origin of the difficulty suggested itself. The two short wires connecting the mercury-cups had been in one case thrown with the galvanometer doubtless, and in the other with the shunt. It was perfectly certain, however, that throughout the tests they had formed a part of the galvanometer. Upon examination, this explanation was at once found to be correct. The shunt and galvanometer were connected up precisely as they had been in Cincinnati: and a series of twenty-five observations gave, when the small wires were a part of the shunt, a multiplier of 4.60; and, when they formed a part of the galvanometer circuit, it was 5.01. The measurements were made by comparing the resistance of the two parts of the circuit by means of the fall in potential, as shown by a Thomson's reflecting galvanometer of high resistance. While in use in Cincinnati, the shunt was constantly carrying a portion of the current; and its temperature was therefore always slightly higher than that of the galvanometer. The difference was small, and it could not be measured accurately; but, on account of its existence, it was thought proper to adjust the shunt multiplier. An excess of heat in the shunt would throw a greater amount of the current through the galvanometer than would go there if the two were at the same temperature: accordingly, the value accepted was 4.9 instead of 5.0, as indicated by the comparison, in which the currents used were much weaker than those transmitted during the tests. It will be observed, the existence of an excess of temperature in the shunt favors somewhat the system in which the stronger current was transmitted.

In the measurements of electromotive force, Thomson's potential galvanometer, by White, was used. In the beginning a large number of comparison observations were made, in which the same electromotive force was measured by this instrument and by the well-known method of discharging a condenser through a high-resistance galvanometer.

A condenser of one-half micro-farad capacity, and a reflecting galvanometer of nearly seven thousand ohms resistance, both by Elliot Broth-

ers, were used with a battery of ten Daniell cells in good condition. These comparisons proved that the indications of the potential galvanometer could be relied upon as trustworthy within practical limits, and in the actual tests it alone was used on account of the greater convenience and rapidity with which observations could be made. Further tests of its accuracy were made, however, which will be referred to later. It is sufficient to say, that this instrument, in form and construction, is quite similar to the current galvanometer already described, except that the coil has a resistance of nearly seven thousand ohms. A key is placed in the circuit, so that the current passes through the coil only during the few moments necessary to secure a reading, thus preventing the heating of the coil. The difference of potential in volts, between the two points to which the leading wires are connected, is found by the same process as is used for reducing the readings of the current galvanometer to ampères. In measuring the efficiency of the dynamos, wires were brought from their binding-posts to the galvanometer. In the arc-light machines the electromotive force was high, amounting to more than twelve hundred volts in the Thomson-Houston dynamo; and it was therefore desirable to introduce extra resistance in the galvanometer circuit. From resistance-boxes made by Elliot Brothers, an amount equal to seventeen times the resistance of the galvanometer was thrown in, thus bringing the fall in potential in the galvanometer within easy range. Great care was taken to see that the coils were not heated during these measurements; and for this purpose the boxes were opened, and the coils exposed to the air, frequent examination being made to see that no rise in temperature took place. Precisely the same arrangement existed throughout the tests of both arc systems. During the photometric tests the wires of the potential galvanometer were attached directly to the lamp under test, so that the fall in potential through the lamp only was measured.

Photometric measurements.

Unquestionably, the most difficult question to deal with, in work of this kind, is the question of photometry. The expression of illuminating-power in 'candles' is a matter of great uncertainty, arising from the uncertain character of the standard, and also from the great inequality existing in the intensity and composition of the lights which are brought into comparison. As the test was intended to be purely competitive, the jury decided to ignore the question of 'candle-power' entirely, and confine itself to a comparison of the lights under consideration. It is believed that the adoption of this plan rendered the results free from many errors to which they would otherwise have been liable.

The photometric comparisons were made by means of the ordinary Bunsen disk photometer, as modified by Letheby. Some preliminary experiments were made with one of Glan's spectrum photometers, for the use of which the jury was again indebted to the kindness of Professor Brackett. The adjustments of this instrument are delicate, and observations cannot be made so rapidly with it as with the ordinary disk photometer; so that, in consideration of the limited time at the disposal of the jury, it was decided not to attempt its general use throughout the tests. It was hoped and intended, in the beginning, to make a thorough examination of the composition of the different lights; but unforeseen delays in the preparation of other portions of the machinery of the test forbade this. As the candle was not made use of, all the lights which were compared were more nearly of the same composition, and thus much of the difficulty in the use of the disk photometer did not appear.

It was found most convenient to make the comparison of the arc-lights through one of the incandescent lamps, as the steadiness and constancy of these could be depended upon during the time necessary for a comparison. In these measurements, a long gallery in the basement of the main building, and adjoining the testing-room, made it possible to place the two lights which were being compared at a distance of fifty feet from each other. The line extended into the testing-room, where the photometer-bar, ten feet in length, was placed. An Edison incandescent lamp, nominally of sixteen candle-power, was used as a standard. In the first series of experiments, comparisons were made with the arc-lamps in three different positions; five readings of the position of the photometer-box and of the galvanometers being made at each position. The lamp was first suspended in its normal, vertical position; then afterwards it was inclined at an angle of forty-five degrees, first with its base away from the photometer-box, and afterwards with its base towards the same. After such a series had been completed with one of the two lamps in competition, it was at once removed, and its place was supplied by the other. On the following night the comparison was continued, other lamps having been selected; but the lamps were tested in only two

positions, — the normal position, and that in which the base of the lamp was towards the photometer-box; these being regarded as the positions of the greatest importance. Altogether, twenty-five photometric observations were made in comparing the arc-lamps. The lamps compared were taken at random from those in use by the exhibiters.

The comparison of incandescent lamps presents questions of far greater delicacy and difficulty. There is one element, in the economy of an incandescent lamp, which does not enter to any extent in the consideration of arc-lamps; that is, the life of the lamp. Although of great importance, it did not seem possible, in the limited time which was at the disposal of the jury, to investigate this point. The only fair and impartial method of making such an investigation, involved, in the opinion of the jury, the continuous and prolonged burning of a large number of lamps belonging to the different competing systems. Under the circumstances, it was absolutely impossible to make use of this method.

There exists, also, difference of opinion as to the proper method of comparing the efficiency of two incandescent lamps. They may be reduced to the same illuminating-power, and the electrical energy consumed by each may be compared; they may be brought to a condition in which they consume the same electrical energy, and their illuminating-power compared; or they may be allowed to differ in both of these elements, and comparisons be made in both.

The first method has been pursued in several tests which have been made both in Europe and in this country.

Incandescent lamps are generally made to be equal, nominally, to a given number of standard candles; but, by modifying the consumption of energy, a lamp of nominally low candle-power can be made to produce almost any degree of illumination, from nothing up to the equivalent of several hundred candles, the high illumination being, of course, at the expense of the life of the lamp. If this element is left out of consideration, the efficiency of a lamp increases rapidly with its degree of incandescence. As it is by no means necessary that incandescent lamps should run at a fixed 'candle-power,' it will follow that the temperature at which a lamp will show greatest efficiency (including the life element) will depend greatly upon its construction.

Taking two lamps of radically different construction, however, there will be for each a certain set of conditions as to current strength and electromotive force, and including the element of life, under which it would show its highest efficiency and economy. After such conditions were determined for each lamp, a strict comparison would be possible. The reduction of two such lamps to the same degree of illumination would probably be unfair to one or the other, or possibly to both, if the element of life is not considered.

Suppose that a lamp in one system is at its best, *all things considered*, at fifteen candle-power, and that one in another reaches its highest degree of efficiency at sixteen candle-power. If they are both brought to fifteen candle-power, the second must suffer in the comparison; and if both are brought to sixteen candle-power, *and the element of life is not considered*, it will again suffer, for the apparent efficiency of the first will be increased by its higher incandescence.

As the labor of determining the most favorable conditions for each lamp would be so great as to necessarily throw that method out of consideration, the jury felt constrained to adopt the last of the three methods mentioned above. The jury assumed, in fact, that the exhibiters of the different systems had already determined these favorable conditions in their own interest; and that in putting their lamps before the public for the entire period of the exposition, each maintaining more than two hundred lamps in different parts of the exposition building, they would operate them as nearly as possible in accordance therewith. In other words, it was decided to compare the lamps as they were used in the exhibit, determining the ratio of their illuminating-power, and measuring the electrical energy consumed by each. It is proper to state, that the lamps of both systems were spoken of by their respective representatives as sixteen candle-power lamps, although certain marks on the lamps which were supposed by the jury to refer to candle-power did not exactly agree.

To secure impartiality of selection, the jury requested permission to have access to the supply of lamps kept by each company for use in the exhibit, which permission was freely granted. From each, ten or twelve were selected at random, and carried to the testing-room; and from these the lamps which were compared were taken. They were placed upon the photometer-bar at a distance of a hundred and twenty-five inches from each other, and a system of switches was arranged, so that the galvanometers could be quickly connected with one or the other. Measures of current and electromotive force were made

rapidly and continuously during the photometric comparison.

Neither of the two lamps under test illuminated equally in all directions. They were therefore compared in nine different positions, each lamp assuming three, which were designated respectively, 'flat,' 'edgewise,' and 'forty-five degrees;' and each position of one was compared with all of the other. Five sets of readings were made at each position, making, in all, forty-five comparisons of the two lamps. A number of preliminary comparisons were made, which were not considered as forming a part of the actual test. The latter was made on the evening of Sept. 29.

The determination of the efficiency of the dynamos consisted in measuring the power consumed, as shown by the dynamometer, on the cradle of which the dynamo was placed, and at the same time measuring the current and the electromotive force at the binding-posts of the machine. The speed of the main shaft being nearly uniform, it was necessary to place different pulleys upon it, in order to secure the necessary speed for the armatures of the different machines. The speed of running being a matter which concerned the exhibiters rather than the jury, they were requested to furnish the dimensions of these pulleys, and accordingly did so. The average speed of the armature of the Weston dynamo for incandescent lamps was a little above ten hundred and thirty revolutions per minute, during three different series of observations made while the machine was on the cradle. The Edison dynamo was placed on the cradle on the afternoon of Oct. 2, when a series of measurements was made with an average speed of ten hundred and sixty-eight revolutions. This was above what may be called the 'normal speed,' which was due partly to the size of the pulley, and partly to the fact that the engine was doing but little other work, and was probably running a little above its normal rate. In the evening the tests were continued, the speed of the armature being a little below a thousand revolutions, the electromotive force being also less. It will be observed that the 'efficiency' of this dynamo, under the latter conditions, differs from that under the former by only two-tenths of one per cent. Particular attention is called to the fact, that no photometric measurements were made with lamps on the circuit of the Edison machine, which was on the dynamometer; those used being supplied from another similar dynamo, which was run by an Armington and Sims engine, which formed a part of the Edison exhibit. A glance at the results given below will show that the electromotive force in the latter case was much lower than in the former.

Tests of the galvanometers.

Although the jury was satisfied of the accuracy of the Thomson galvanometers, within all practical limits, before deciding to rely upon their indications, for reasons that need not be referred to here, it was considered desirable, after the conclusion of the tests, to make such an examination of them as would leave no doubt as to the correctness of this opinion. The chief cause of error in these instruments, and in all of a similar construction, is the possible variation in the strength of the permanent magnets which establish the field in which the needles move. The existence of a strong field is a great advantage, as has already been pointed out, provided its value is known. An examination of the instruments was made before they were taken to Cincinnati; and then, again, when they were mounted in the testing-room, they were compared with others not liable to such alterations, as before related. Numerous tests were made to ascertain if each instrument was consistent with itself by measuring the same quantity with the magnetometer at different points of its scale, thus varying the position of the needle; and the results were satisfactory. Finally, after the instruments were returned to the physical laboratory of the Ohio state university, they were subjected to tests, a brief account of which is as follows: —

For the potential galvanometer, ten cells of the 'gravity battery,' — the elements of which were zinc, zinc sulphate, copper sulphate, and copper, — in good condition, were individually compared by the condenser method with a standard Daniell cell set up for the purpose. They differed very little among themselves; and when the electromotive force of the ten, in series, was measured by means of the Thomson instrument, the resulting electromotive force of the Daniell was 1.106 volts. The instrument was also compared with one of Ayrton and Perry's voltmeters, kindly furnished for the purpose by the Electric supply company of New-York City. For this purpose recourse was had to an Edison lighting-plant, the instruments being applied to the same lamp. The fall in potential in the lamp was at first 110 volts, which was beyond the range of the Ayrton and Perry instrument; but it was reduced a little below 100 volts, and two measurements were taken with each instrument.

The Thomson read the same in both measurements, making the electromotive force 97.6 volts. The divisions on the scale of the Ayrton and Perry were very small, making the reading quite difficult. From it were obtained, in the two measurements, 96.1 and 95.5 volts.

Assuming that the field of the potential galvanometer is known, it is easy to determine that of the current galvanometer, as the magnets are interchangeable. A series of observations was made in which a practically constant quantity was measured, first with one of these magnets on the magnetometer, and then with the other, alternating throughout the series. Twelve observations made in this way show a mean difference of 1.75% between the two magnetic fields. In the numbers used in these tests the difference is 2%.

The current galvanometer was also compared with an Ayrton and Perry ammeter at the same time at which the potential instruments were compared. The circumstances did not allow the use of a stronger current than that passing through a single Edison lamp. The result was therefore not of great value. The Thomson showed 1.05 ampères, and the Ayrton and Perry gave 1.03 for the same current.

Several tests of the current galvanometer were made by means of a battery of five Grove cells, which were freshly set up. The reading of the galvanometer was noted, and then a resistance of one ohm was introduced into the circuit. The first reading was 19, and the second was 9.5; showing that the resistance of the battery and galvanometer was one ohm. The electromotive force of the battery was then determined by means of the potential galvanometer. Two measurements were made; the first giving 9.43 volts, and the second 9.56 volts. Assuming the resistance to be one ohm, as shown above, these numbers would represent, in accordance with Ohm's law, the current in ampères. The current, as calculated from the galvanometer reading, was 9.5 ampères.

Many other tests of a similar character were made, all of which showed that the galvanometers must be admitted to be what they were assumed to be during the tests, — practically correct. But, even if they were somewhat in error, the similarity of conditions under which the competing systems were tested was such that all would be affected alike.

Results.

In determining the efficiency of the dynamos, after every thing was found to be in good order, a run of about half an hour was made; during which time readings were taken every two minutes, as nearly as could be, of the dynamometers and electrical instruments. Generally from ten to twenty sets of readings were secured. In most cases two or more 'runs' were made; the repetition being in some instances the desire of the jury, and in others of the exhibiters. Sometimes the conditions under which the dynamo was running were changed by the exhibiters, with the expectation, doubtless, of increasing its efficiency thereby. In the following summary of results, the numbers showing the electromotive force, current strength, power consumed, etc., are means of a number of observations.

Photometry of arc-lamps.

The table on the next page shows the results of the photometric comparison of the two arc-lamps, and will be easily understood. The arrows show the direction of the light measured in each series: thus, ← means a horizontal measurement; ↖ means that the measurement was of the light going upward at an angle of forty-five degrees; and ↙ refers to the light going downward at an angle of forty-five degrees. For convenience, the intensity in terms of the standard (an Edison incandescent lamp) is multiplied by 1,000 before dividing by the number of Watts.

It will be seen that the different lamps differed from each other considerably in their efficiency. This was especially true of the Weston lamp, which was irregular in its ac-

tion. The numbers under the head of 'General means' show the average light in terms of the standard, in all directions measured, and the relative illuminating-power per unit of energy. There is a difference of more than forty per cent in favor of the Thomson-Houston.

Photometry of incandescent lamps.

The table below, showing the results of the photometric comparison of the incandescent lamps, will need but little explanation. In the first column the relative position of the carbon filaments is shown: thus, | | means that they were parallel to each other, and at right angles to the photometer-bar. The three positions of a lamp were designated as 'flat' (|), 'edgewise' (—), and 'forty-five degrees' (\ or /). $\frac{W_E}{W_M}$ denotes the Watts of the Edison divided by the Watts of the Maxim. The column headed $\frac{E}{M}$ shows the actual illuminating-power of the Edison, compared with the Maxim as a unit; and the numbers are the squares of the ratios of their respective distances from the photometer-box. The numbers in this column, divided by those in the one preceding, give the numbers in the last column, headed $\frac{E_E}{M_E}$, or the

Incandescent lamps.

—	\	.622	115.4	71.8	.853	62.2	53.0	1.35	1.65	1.22
—	—	.631	115.4	72.8	.853	61.4	52.3	1.39	4.58	3.29
/	—	.631	116.1	73.3	.887	63.0	55.8	1.31	3.96	3.02
|	—	.631	115.7	73.0	.870	62.6	54.4	1.34	3.74	2.79
|	\	.639	116.5	74.5	.887	63.0	55.8	1.33	1.35	1.02
/	\	.648	114.7	73.5	.853	62.6	53.4	1.38	1.66	1.21

light from the Edison per unit of energy as compared with the Maxim.

The results of these comparisons in nine different positions make it possible to establish certain comparison equations, from which means may be obtained which will serve to eliminate, to some extent, the errors of experiment.

Let a = the light from the Maxim lamp 'edgewise;' then, by working through the different positions of the Edison, the above results give —

Maxim	—	a	a	a
	/	$2.77a$	$2.39a$	$2.77a$
	|	$3.58a$	$3.50a$	$3.37a$

and for means —

Maxim	—	a
	/	$2.64a$
	|	$3.48a$

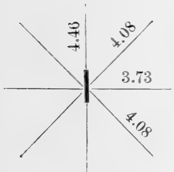
By a similar computation it is found that—

Edison	—	$4.58a$	$4.45a$	$4.36a$
	/	$3.96a$	$3.93a$	$4.38a$
	|	$3.74a$	$3.58a$	$3.86a$

the means of which give —

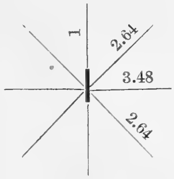
Edison	—	$4.46a$
	/	$4.08a$
	|	$3.73a$

Fig. 1.



Edison.

Fig. 2.



Maxim.

Figs. 1 and 2 show the arrangement of these intensities of illumination around the carbon filament; the plane of the filament being vertical, and Maxim edgewise being taken as unity.

For the mean all round, the result is —

$$\text{Edison} = 4.09 \qquad \text{Maxim} = 2.44$$

$$\frac{4.09}{2.44} = 1.676 = \frac{\text{E}}{\text{M}} \text{ in light.}$$

But from the previous table,

$$1.336 = \frac{\text{E}}{\text{M}} \text{ in energy:}$$

therefore $\frac{1.676}{1.336} = 1.25 = \frac{\text{E}}{\text{M}}$ *in light per electrical horse-power.*

It seems evident that this difference of twenty-five per cent in favor of the Edison lamp is largely due to the form of the incandescent filament as compared with that of the Maxim lamp. The latter shows great inequality in illumination in different directions, the light measured from the flat side being about three and one-half times as great as that obtained when the lamp is edgewise. The effect of this increased radiating surface is shown in the last column of the above table, from which it appears, that in the comparison of the Maxim, 'flat,' with the Edison in all positions, the former shows a higher actual efficiency than the latter. If this large radiating surface could be made to distribute its effect around the circumference, the lamp would, in the opinion of many, be greatly improved. It is fair to say, however, that the unequal distribution of light is claimed, by at least some of the representatives of this lamp, to be an important advantage. It was not so considered by the jury.

The form of the carbon filament in the Edison lamp is such that a much greater uniformity of illumination results. While the Maxim form has the advantage of concentrating the radiating surface, the arrangement of the carbon to accomplish this greatly diminishes its effectiveness in the 'edgewise' position. In the Edison there is but a single loop; and, furthermore, this is generally curved, so that it does not lie in one plane. As a result, one side of the loop never exactly hides the other, and there is but little loss from that source. It will be seen in the above figure that the illuminating-power of the lamp edgewise actually exceeded that in any other direction. This difference was too constant and too great to be attributed to error in experiment. It is attributable, no doubt, to the fact, that in this position the luminous lines lie nearly in the axis of the pear-shaped glass containing them, as viewed from the photometer-box; there being, therefore, less scattering of the light in transmission, and possibly some gain on account of reflection. Of course, if a lamp were used in which one of the branches of the loop exactly or nearly covered the other in this position, a different ratio of illumination might follow.

Throughout the entire series of tests the jury was fortunate in having the assistance of Mr. A. L. Rohrer, a student in physics in the Ohio state university.

In the distribution of work, Mr. Eddy and Mr. Laidlaw made the observations, and kept the records of the dynamometer work; Mr. Laidlaw also taking and reducing the indicator-cards. Mr. French made the readings of the position of the photometer-box, and set the same. Mr. Mendenhall generally read one of the galvanometers, and Mr. Rohrer the other; the latter generally keeping the notes of the electrical work, although this was done on several occasions by Mr. French and by Mr. Laidlaw.

The results of these tests seem to point to one conclusion of very considerable interest. It happened that the competition in both the arc and incandescent systems was between low electromotive force and great strength of current, on the one hand, and high electromotive force, with weaker current, on the other. In one arc system the electromotive force was almost exactly double, and the current almost exactly half, that of the other. In the incandescent systems, the contrast, although not so great, was very marked. In these trials the advantage was decidedly on the side of high electromotive force.

NOTES ON THE VOLCANIC ERUPTION OF MOUNT ST. AUGUSTIN, ALASKA, OCT. 6, 1883.[1]

On the western side of the entrance to Cook's Inlet (forty-five miles wide) lies Cape Douglas; and to the northward of the cape the shore recedes over twenty miles, forming the Bay of Kamishak. In the northern part of this bay lies the Island of Chernaboura ('black-brown'), otherwise called Augustin Island. It is eight or nine miles in diameter, and near its north-eastern part rises to a peak called by Cook, Mount St. Augustin. As laid down by Tebenkoff, the island is nearly round. The northern shores are high, rocky, and forbidding, and are bordered by vast numbers of rocks and hidden dangers. The southern shore is comparatively low.

Mount St. Augustin was discovered and named by Capt. Cook, May 26, 1778; and he describes it as having 'a conical figure, and of very considerable height.' In 1794 Puget describes it as

> "A very remarkable mountain, rising with a uniform ascent from the shores to its lofty summit, which is nearly perpendicular to the centre of the island, inclining somewhat to its eastern side. . . . Towards the seaside it is very low, from whence it rises, though regular, with a rather steep ascent, and forms a lofty, uniform, and conical mountain, presenting nearly the same appearance from every point of view, and clothed with snow and ice, through which neither tree nor shrub were seen to protrude; so that, if it did produce any, they must either have been very small, or the snow must have been sufficiently deep to have concealed them."

At that time there were native hunters, under the direction of two Russians, hunting or living in the vicinity of the north-eastern point of the island.

Vancouver placed the peak of this mountain in latitude 59° 22′: Tebenkoff places it in latitude 59° 24′.

The peak of St. Augustin is distant forty-nine miles nearly due west (true) from the settlement on the southern point of Port Graham, or, as it is sometimes called, English Harbor. This harbor is situated on the eastern side of Cook's Inlet, near Cape Elizabeth.

In connection with the fall of pumice-dust at Iliuliuk on Oct. 16, 1883, it may be of interest to observe, that the peak of Augustin is over seven hundred miles to the north-eastward of Bogosloff Island, off Unalashka (see map).

About eight o'clock on the morning of Oct. 6, 1883, the weather being beautifully clear, the wind light from the south-westward (compass), and the tide at dead low water, the settlers and fishing-parties at English Harbor heard a heavy report to windward (Augustin bearing south-west by west three-fourths west by compass). So clear was the atmosphere that the opposite or north-western coast of the inlet was in clear view at a distance of more than sixty miles.

When the heavy explosion was heard, vast and dense volumes of smoke were seen rolling out of the summit of St. Augustin, and moving to the north-eastward (or up the inlet) under the influence of the lower stratum of wind; and, at the same time (according to the statements of a hunting-party of natives in Kamishak Bay), a column of white vapor arose from the sea near the island, slowly ascending, and gradually blending with the clouds. The sea was also greatly agitated and boiling, making it impossible for boats to land upon or to leave the island.

From English Harbor (Port Graham) it was noticed that the columns of smoke, as they gradually rose, spread over the visible heavens, and obscured the sky, doubtless under the influence of a higher current (probably north or north-east). Fine pumice-dust soon began to fall, but gently, some of it being very fine, and some very soft, without grit.

At about twenty-five minutes past eight A.M., or twenty-five minutes after the great eruption, a great 'earthquake wave,' estimated as from twenty-five to thirty feet high, came upon Port Graham like a wall of water. It carried off all the fishing-boats from the point, and deluged the houses. This was followed, at intervals of about five minutes, by two other large waves, estimated at eighteen and fifteen feet; and during the day several large and irregular waves came into the harbor. The first wave took all the boats into the harbor, the receding wave swept them back again to the inlet,

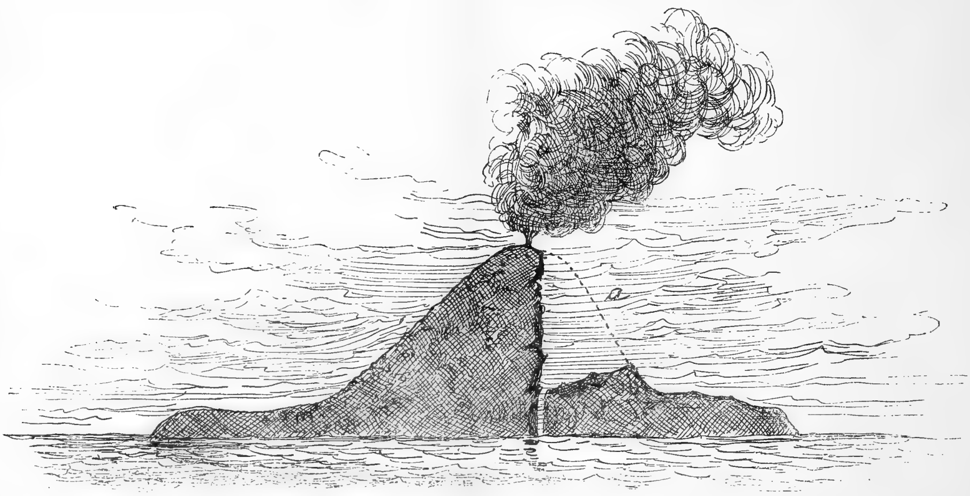
and they were finally stranded. Fortunately it was low water, or all of the people at the settlement must inevitably have been lost. The tides rise and fall about fourteen feet.

These earthquake waves were felt at Kadiak, and are doubtless recorded on the register of the coast-survey tide-gauge at that place. Also the pumice-ashes fell to the depth of four or five inches, and a specimen of the deposit was given to the tidal observer at St. Paul. It will be interesting to compare these ashes with those collected at Iliuliuk on the 16th of October, and which, from a confusion of dates, were supposed to have come from the new Bogosloff volcanic island. I am of the opinion that they came from St. Augustin.

The condition of the Island of Augustin or Chernaboura, according to the latest accounts, is this: —

At night, from a distance of fifty or sixty miles, flames can be seen issuing from the summit of the volcano; and in the day-time vast volumes of smoke roll from it. Upon nearer approach from English Harbor, it was found that the mountain had been split in two from peak to base by a great rupture extending across it from east to west, and that the northern slope of the mountain had sunk away to the level of the northern cliff.[1] This is corroborated by the statement of the hunting-party in Kamishak Bay. Smoke issued from the peak at a very short distance to the southward of the rupture.

The party of natives on Kamishak did not approach the islet, though they gave clear and distinct accounts of its eruption and subsequent appearance; but Capt. C. T. Sands, who was at English Harbor, gave the Alaska company a full description; and Capt. Cullie of the Kodiak states, that, if there were plenty of water in the line of rupture, it would be possible for a vessel to sail through (see figure). At the time of Capt. Sands's observations the low ground of the island was visible, and seemed to be a vast crater, from which smoke and flames were issuing.



MOUNT ST. AUGUSTIN AFTER THE ERUPTION, AS SEEN BY CAPT. CULLIE, Nov. 10, 1883. *a*, THE ORIGINAL OUTLINE.

But beyond all these phenomena, apart from the volcanic eruption and the rupture of the island, we have the report of Capt. Cullie of the schooner Kodiak (from whom we also obtain a statement in regard to the rupture), who approached the island from English Harbor on the 10th of November, and found that a new island, about a mile and a half long and seventy-five feet high, had been upheaved in the ten-fathom passage between Augustin and the mainland to the westward. This passage is from six to eight miles wide, and was sailed through by Puget in Vancouver's voyages of discovery.

This new island (also reported by the hunting-party in Kamishak) would appear to have arisen during the late volcanic activity. It lies to the north-westward of Chernaboura Island (Augustin), and was distinctly seen from the Kodiak, as that vessel lay ten miles to the north-eastward, and had clear weather.

To show the violence of the volcanic convulsions at this time, two extinct volcanoes on the Alaska peninsula, which are reported to be about west (true) from the active volcano Iliamna (twelve thousand feet high), had burst

[1] Capt. Cullie's account.

into activity; and during the day volumes of smoke were distinctly seen, and columns of flame at night. Usually, at that season, Augustin and the peak are covered with deep snow. On the 10th of November, however, when Capt. Cullie approached the island, while there was a depth of four feet of snow at Port Graham (English Harbor), Mount St. Augustin was bare and black.

During this same season, a party of seven or eight Aleuts had established themselves on Chernaboura (Augustin) Island to hunt the otter during the winter. Two of the women refused to remain on account of the violent noises inside Mount St. Augustin; and they were taken to St. Paul, Kadiak. Since the eruption no one of this party has been seen, nor any signs of their bidarkas, although a rescuing party of natives had gone along the coast to learn of their whereabouts. It is feared, therefore, that they have been destroyed. In confirmation of this report of the native women, Capt. Sands says that he and others noticed that St. Augustin was emitting smoke as far back as August; but no other signs were observed before the heavy report of Oct. 6.

George Davidson,
Assistant U. S. coast and geodetic survey.

THE COD-HATCHING EXPERIMENTS AT GLOUCESTER BY THE FISH COMMISSION.

In the winter of 1878 and 1879 the Fish-commission at that time having a station at Gloucester, Mass., made very extensive experiments upon the hatching of certain salt-water fish, but more especially of the cod (Gadus morrhua). For years the cod has been almost entirely confined to the deeper waters on the coast, having been driven there by many causes, sewerage being the most probable and potent; and it has been since the discovery of America that these fish, at that time extremely abundant everywhere along the shore, even to such an extent that they could be caught in great numbers from any point of rocks, have become reduced in numbers to their present comparative scarceness, and at the same time driven from their former haunts to the deeper waters. Taking into account this remarkable decrease in numbers, and change of habitat, Professor Baird conceived the idea that the former abundance of cod could in part be restored by means of artificial propagation, which had proved so successful with the fresh-water species of fish. Many difficulties stood in the way, — difficulties which had never been encountered in any previous experiments. The principal trouble which was experienced resulted from the floating of the eggs, and it was only after many trials and numerous failures that an apparatus was invented which in part prevented the eggs from clogging the screen placed over the overflow-pipe.

The location for the primary experiments was fixed at Gloucester, on account of the great industry of catching and preparing these fish, which is centred there. Vessels and boats arrive every day during the winter months, bringing in fresh cod, many of them containing spawn. By the request of the commissioner, such fish were kept alive until they could be put into the live-box at the hatchery. It was also possible, and this was the most important reason for the choice, to carry on important investigations into the natural history of the deep-sea food-fishes, and to gather valuable statistics concerning the fisheries; it being impossible to get such information in any other place.

Many obstacles arose, owing to the location. A temperature of 30° F. is fatal to cod; and, as the surface-water in the harbor is liable to reach this point at any time during two or three months of the winter, it was necessary that the car containing the live fish from which spawn was to be taken should be constantly watched, and sunk to the bottom during every cold snap. The filthiness of the water caused by decaying waste portions of fish thrown into the docks — these being common receptacles for all dirt and refuse formed by the dressing-process — was such, that, even after the most careful filtering, the water was in a decidedly impure condition. The north-east storms so prevalent on the Massachusetts coast, especially during winter, kept the water in a roiled condition for a greater part of the time; so that when it reached the aquaria, although a great part of the mud had been filtered out, still the mudiness was apparent. Such a condition could not be other than an unhealthy one for young fish whose parents had been accustomed to the clear, cool, outer waters. When there were no storms, the great rise and fall of tide, about eleven feet, sufficed to keep the finer mud in constant circulation. But, notwithstanding these numerous obstacles, over one million and a half young cod were successfully hatched, and placed in the clearer waters of the outer harbor at Gloucester. On account of the impurity of the water even there, and the adverse conditions under which they were hatched, it was scarcely expected that any

practical increase in the number of cod would be noticed as the result of these experiments. However, the results obtained proved conclusively, that if carried on under favorable circumstances, and with the experience gained at Gloucester, hatching deep-sea fish could be successfully engaged in, and made a great success. It was with this belief that an appropriation was obtained from Congress for building the extensive hatching houses and basins which are in progress of erection at Wood's Holl, Mass. Here the harbor is very pure, there being no city emptying its refuse into the immediate waters. The bottom is composed of clean sand; while the water is pure and not too cold, receiving an offshoot of the Gulf Stream, instead of the Labrador current, as is the case at Gloucester. Here the tides, although forming swift currents by the pouring of immense quantities of water through narrow outlets, rise but two feet, which is a decided advantage. Within forty miles of the hatchery, fish can be caught in sufficient abundance to supply the wants of the commission; and it is to be expected that results of great importance will be obtained by hatching and placing young food-fish in the water at various points along the New-England coast.

For at least a year, reports have been prevalent to the effect that small cod belonging to the deep-sea species have been, and are at present, very abundant in the harbor at Gloucester. In order to find out definitely, Professor Baird asked me to inquire, and collect specimens if possible, while I was at Gloucester, in October. I ascertained, that, since the winter of 1882, 'silver-gray cod' (G. morrhua) have been caught in abundance, and of just the size that the artificially hatched fish would naturally be at this time. Not only are cod obtained in the outer harbor by the fishermen, but even in the impure waters of the extreme inner harbor, where they are frequently caught by boys fishing for flounders. A specimen taken in this manner was found by Capt. Collins in the taxidermist's store, and forwarded to Professor Baird. It proved to be the true deep-sea cod. One fisherman, while obtaining bait for his lobster-pots, during the early spring of 1883, frequently caught as many as a hundred pounds of these fish in a single catch. This same fisherman informed me that at least three or four generations were plainly distinguished, the smaller being much more abundant. From only one other point along the coast was I able to find this species of cod reported in the shallow water. A school was encountered by a Gloucester vessel close in by Mount Desert, and fourteen barrels obtained. They all measured within an inch or two of fourteen inches, — just the size of those reported from Gloucester, and exactly as long as the specimen obtained from that locality. I obtained two specimens from the Mount Desert school, which are at present in the National museum. Here we find, in a limited area, great numbers of a fish now inhabiting only the deeper waters; this fish for many years having been a total stranger to the locality in which it is at present so abundant, and not found, so far as is known after many inquiries, in other similar places, with but a single exception. The oldest and most observing fishermen never remember a similar instance; and all come to the conclusion, that they are the result of the hatching operations in 1879, those from Mount Desert being but a small portion of the larger school migrating from their given home. Certainly other than natural causes must be looked for to explain this sudden increase in a small, unfavorable locality: so, as a very convenient and satisfactory explanation is found, with evidence to back it, we will say with the fishermen, 'These must be Fish-commission cod.' They will of course migrate in time; for it is hardly to be expected that they will return to their first home after once finding purer water outside.

Undoubted good must come of the future operations, for millions and millions of eggs which would otherwise be spoiled will be hatched; the young reared, and placed in the water to live and reproduce; and thus the waters will become restocked with a species of fish which is growing scarcer every year with frightful rapidity. These unexpected results of the experiments prove beyond a doubt that even deep-sea fish can be kept under control by the same means that the stock of river-fish is regulated.

While at Gloucester, Professor Farlow, by request of Professor Baird, investigated the nature of the so-called 'reddening' of salted cod, which caused such ravages during the warm months, with the idea of furnishing a remedy. This peculiar 'reddening' was found to be caused by an alga (Clathrocystis roseo-persicina) which was abundant on the marshes near Gloucester. In many of the fish-houses the alga was present in large quantities on the walls, on the flakes, and even in the vessels, probably having been introduced there by the fishermen on their clothes, or from the mud on their boots. Furthermore, it existed to a considerable extent in the Cadiz salt, which was used in preference to Trepani

salt on account of the cheapness of the former. Trepani was, on the contrary, found to contain very little. Dr. Farlow advocated that the walls and all the wood-work be scraped, and washed in hot water to kill the plant, and that painted wood be used in preference to the rough natural walls in order to afford as little room as possible for the Clathrocystis to lodge itself. He further advised that Trepani salt be used instead of Cadiz. A number of fish-dealers have adopted his suggestion in regard to the salt, and they all inform me that for two summers not a single fish has been lost by 'reddening.' The wood-work contained the plant; and in warm weather old butts turned red on the outside, while the new ones, in which no pickle made from Cadiz salt had been kept, remained perfectly intact. The fish saved by this means more than paid for the difference in price between the two salts. Trepani salt seems to prevent the rapid growth of the plant, while Cadiz rather favors it. Here, as in many other cases, we see that a little scientific thought will accomplish that which would never be brought about without it.

RALPH S. TARR.

MUSEUMS OF NATURAL HISTORY IN THE UNITED STATES.[1]

THE state of its public museums, laboratories, and other scientific institutions, gives a very reliable measure of the appreciation and culture of science by a nation. We are often inclined to consider America as a country where money-making suppresses all other interests, where learning, art, poetry, — in one word, all the finer manifestations of the human mind, — can enjoy even a poor existence only in a few places, and find in general very unfavorable ground. One, however, who has had an opportunity of carefully observing American literature during recent years, could certainly not help seeing its intellectual activity; most of all, perhaps, in the case of the sciences, they being intimately connected with practical life, and among these especially those of geology and paleontology. Most of the states created geological surveys for the investigation of the country, and the publication of maps and other results: the general government extended these investigations to the territories. The elegant publications of these geographical and geological institutions, distributed with the greatest liberality, form already a library which contains information of the greatest value concerning the vast country of the United States.

We have often enough heard that they were founding public museums in America, and that, together with their indigenous treasures, they were desirous of obtaining the material of the old world for comparison, if, as now and then happened, a valuable private collection had to make its way across the ocean. It would form a long 'list of the missing,' should we enumerate all the valuable scientific objects, which, during the last thirty years, have gone to America from Germany alone. The contributions of England and France towards the enrichment of the transatlantic museums are, of course, not less. But, in spite of all this, the American museums are hardly known among us. While among the eminent learned men of America there are only a very few who have not travelled in Europe at least once, the new world is usually not studied with the same care by the learned men of the mother-countries. The Americans, however, have begun to make their treasures in natural science accessible to the public, as well as to the specialist, in a way which in many respects deserves admiration and imitation.

The following observations on some of the most prominent museums of natural history, made during a short stay in North America, will undoubtedly prove to be incomplete, one-sided, and perhaps in many respects even inaccurate. Their main object is merely to call the attention to those institutions more carefully than has hitherto been done.

Up to the middle of this century, Philadelphia was at the head of scientific investigation in America; and even to-day, when the principal city of Pennsylvania has almost lost its leading position, a visit at the fine museum of natural history will show everywhere the traces of a celebrated past, and of a comparatively old civilization. Among all the larger museums of North America, the museum of Philadelphia shows the strongest European influence in its whole organization, and in the arrangement of the collections. The handsome building belonging to the Academy of natural sciences is in the centre of the city, near one of those beautiful squares full of trees which are the pride of Philadelphia. The first floor contains a rich library, the meeting-rooms of the academy, rooms for officials and for special investigators. The collections are in the upper part of the building, in one large hall surrounded by wide galleries. Stuffed mammals, skeletons, and several large fossil vertebrates occupy the centre of the vast room. Among them a fossil gigantic saurian, with its strong hind-legs and short fore-legs, is conspicuous by its enormous size. The bones which were found at the 'Hopkins' farm in New Jersey, and which furnished the material for the restored skeleton of the Hadrosaurus, have been well prepared, and are now kept in show-cases near by, together with the remnants of another gigantic fossil lacertian (Laelaps), and together with the nearly complete skeleton of an Elasmosaurus, found in the chalk of Kansas, which has much resemblance to Plesiosaurus. The restoration of the Hadrosaurus was made before the time of Marsh's great discoveries, and before the twenty-four skeletons of Iguanodons had been found near Bernissart in Belgium. We must therefore not too severely criticise a few errors made by the restorer in the restoration of the missing parts. By the purchase of the collection of birds from the famous

[1] By Prof. K. A. ZITTEL of the University of Munich. Translated from the supplement to the *Allgemeine zeitung* of Dec. 16.

ornithologist, Gould, Philadelphia got a first-class ornithological museum. For craniologists, Dr. Morton's collection of about twelve hundred skulls is of interest. The collection of recent shells is said to be second in completeness only to that of the British museum, and is rich in originals used in the publications of a large number of active scientific men in Philadelphia.

Through Professor Joseph Leidy, the director of the museum, Philadelphia was the first place to procure the remains of fossil mammals from the territories of Wyoming, Dakota, and Nebraska. By this excellent *savant*, attention was called to those inexhaustible treasure-houses in the far west from which, since that time, a whole world of marvellous fossil animals has been unearthed. The interest of the specialist will be attracted by Professor Gabb's collections made in California and Nevada, and by the petrifactions from the tertiary formation in Georgia and Alabama. The museum is also rich in European objects.

The interior arrangement is simple but practical. Sometimes the show-cases are rather crowded, and stand so near together that the light is not everywhere sufficient, in spite of the high windows on all sides of the hall. Already in this comparatively new building there is, as in nearly all European museums, a lack of space.

Naturalists will not leave Philadelphia without having seen Prof. E. D. Cope's celebrated collection of fossil vertebrates. During my stay in Philadelphia, this indefatigable investigator was in New Mexico in order to continue the exhumations with which he now has been occupied for many years at a heavy expense, and with much personal hardship. Very soon his elegant house in Pine Street became too small for the collected treasures, the house next to it had to be bought, and now it is filled from top to bottom with fossil bones. And again no space was left: the larger specimens, therefore, had to be placed in the cellars of a public building. Mr. Wortman, a former pupil and assistant of Professor Cope, was my amiable and well-informed guide through this improvised museum, where almost all the rooms are filled nearly up to the ceiling with cases, shelves, drawers, trunks, and boxes, where one finds piled on the floor, or along the walls, enormous skulls of mastodons and Dinocerata, or bones of gigantic saurians, and where the visitor's eyes are delighted with several complete skeletons of mammals still remaining in their stony matrix. Besides a number of forms already known by way of pictures or descriptions, one may see here the remnants of several hundred fossil vertebrates of which we in Europe know hardly more than the names. Comparing the fossil mammals of the Paris basin with those found in North America in strata of the same period, we discover a striking difference between the two faunas.

The regions of geographical distribution for vertebrates were just as sharply limited during the tertiary period as nowadays. This is the reason why we find a nearly inexhaustible abundance of new orders and species in the so-called Bad Lands of western America. Professor Cope is one of the most eminent authorities of our time in comparative anatomy and paleontology: he has bought the fine osteological collection of Hyrtl at Vienna, and is now busy in editing an extensive work, in which he intends to give descriptions, as well as pictures, of the numerous fossil mammals discovered by him.

While Philadelphia has the oldest museum of North America, Washington is arranging the newest one. In the elegant, beautifully situated capital of the country, with its wide and clean but hardly animated streets, with its vast parks and magnificent edifices, the visitor will be surprised to find unfinished, not only the Washington monument, but also various other edifices. But if once all the enterprises which are now going on are finished, Washington will be one of the most beautiful cities of the world. Not far from the simple home of the President there is a park of about fifty acres, in which we find most imposing public buildings, among them the greenhouses of the botanical garden, the Smithsonian institution, and the National museum. The latter is in a palace of red sandstone. The interior of the tasteful building, in Normano-Gothic style,[1] contains in the centre a dome-like hall two hundred feet long, where various collections in a somewhat strange mixture are accommodated. Large glass cases with stuffed animals are put together with Indian curiosities, models, and relief-maps, together with samples of building-materials and ores. Part of the hall and a wing of the building are given to the geological survey. In the other wing we find the excellently arranged prehistoric and ethnographical collection, under the direction of our countryman Karl Rau. The great variety of the tools and weapons made of stone, still used among some Indian tribes, which are exhibited here, is hardly less remarkable than the ability with which these savages work the brittle material. In this respect the American autochthones have undoubtedly attained a higher civilization than the inhabitants of Europe during the stone period. For the present, the National museum, as a whole, can be considered merely as the beginning of a museum of almost universal character; but, with the enormous means which are at the disposal of the central government, it needs only a few influential and energetic men to develop great things out of this promising germ.

A glance at the growth of the American museum of natural history in New York shows what energy, and readiness to sacrifice, may accomplish within a few years. In January, 1869, a few scientific friends met, and decided to found in New York, the metropolis of North America, a museum of natural history, which was to correspond with the means and the importance of this city, and to give its inhabitants an opportunity for recreation and instruction. Within a few weeks forty-four thousand dollars were subscribed. Out of this money the collection of birds made by Prince Maximilian of Wied was bought. Many other objects were given; and very soon the

[1] The writer has here confused the Smithsonian and museum buildings.

halls of an armory, assigned by the city to the museum, proved to be too small. Thereupon the trustees thought of having a home of its own for their collections; and to that end the city government not only gave Manhattan Square, an estate of eighteen acres and a quarter, in the immediate vicinity of Central Park, but also decreed the necessary means for the projected building.

In June, 1874, the corner-stone was laid, in the presence of President Grant, the governor of the state, the mayor of the city, and a number of prominent persons from Boston and New Haven. As early as December, 1877, the large fire-proof building, consisting of nothing but stone and iron, was finished so far that it was possible to transfer the collections, and to make them accessible to the public. To-day the museum is already filled to such an extent, that the trustees ask for three hundred thousand dollars more, in order to put up an additional building of the same size. In regard to the excellent adaptation of the building to its purposes, and also in regard to the practical interior arrangement, the New-York museum deserves to be called a model institution. The exterior of the red-brick building is without any ornamentation. The entrance at the narrow side leads to the basement: the large staircase is opposite. Each floor contains, besides one single large hall of a hundred and seventy by sixty feet, only a few small laboratories near the stairs. Wide and high windows on both sides furnish plenty of light. Between them the walls have openings like loopholes, through which the interior of the cases, which are in a rectangular position against the side-walls, get the necessary light. The wide, well-ventilated halls, provided with heating-apparatus and gas, make a grand impression. On all the floors the main cases are arranged in the same way, and are of the same size; so that it would be easy to move the contents of one hall into another. The rooms, as well as the cases, are well protected against dust. The cases are made of iron; their doors, of a single pane of glass. The tasteful and appropriate furnishings correspond with the contents. In the basement there is a rather small collection of mammals. We do not see here those shabby skins, half-destroyed by moths, nor those ill-shaped, four-legged straw bags which disfigure so many museums of older date. Every thing is new and clean; and some groups — as, for example, the family of orang-outangs, or the Ornithorhynchus, with its surroundings — may well be called pictures borrowed from nature. The collection of birds on the first floor deserves similar praise. The laymen will be pleased with the birds of paradise, the macaws, the parrots, and the humming-birds, which display here the beauty of their feathers. The hall of the first floor is thirty feet high, with a wide gallery, forming, so to speak, a floor for itself, with its own windows. Here we find a rich ethnographic and prehistoric collection. American objects predominate; but there is no want of foreign material for comparison, and especially one interested in the European stone period could find here very many valuable things. The next floor contains the geologico-paleontological and the mineralogical collection. The nucleus of this division is a collection bought for sixty-eight thousand dollars, from Prof. J. Hall in Albany, the Nestor of American geologists. The typical objects, as given in Hall's voluminous work on the state of New York, are arranged here in a way that affords an excellent view of the whole; and I do not think that the enormous mass of paleozoic petrifactions of America is better exhibited in any other museum. On the highest floor there is a library, a hall for public lectures, laboratories, and a number of rooms for various specialists and their private collections. A freight-elevator runs from the cellar to the highest floor in an American museum, as a matter of course.

If we consider what has been done in New York within less than fifteen years, we have, indeed, to admire the energy of the superintendent, Prof. A. S. Bickmore. He not only knew how to get some of the richest and most influential citizens interested in his work, but also formed, with the means at his disposal, an institution unrivalled in many respects. The American museum of natural history is open to the public daily; and, on an average, about fifteen thousand persons a week make use of this privilege. The city of New York pays to the museum annually fifteen thousand dollars. All the expenses above that are paid by subscription. Should the plan, as exhibited in the basement, be carried out, the museum wolud have twelve buildings of the size of the present, which, together with six connecting wings, would cover the whole of Manhattan Square. An enormous cupola would form the centre of the whole. Then New York would decidedly have the largest museum of natural history in the world.

The museum of the state of New York, at Albany, is on a smaller scale. This institution has been founded by the celebrated geologist, J. Hall. During fifty years of investigation he has unearthed the geological and paleontological treasures of his state; and, besides a private collection, he has created a public museum, where the products of the state of New York are exhibited in a fine arrangement. In Germany we have only one local collection, the 'Württembergisches landes museum,' at Stuttgart, which is ahead of the museum of the state of New York in regard to arrangement and completeness.

For study and investigations, the capital of the state of New York, with its unpleasant political life, is not a very favorable place. The university towns of New Haven and Cambridge are far better homes for intellectual culture in North America. There is no better introduction into society than a diploma from Yale or Harvard. These universities are partly imitations of English colleges, partly of German institutions; and for decades there have been first-class learned men among their teachers. The scientific life of America is under the influence of these universities and these independent corporations are so popular that they receive considerable legacies nearly every year. The numerous handsome buildings of Yale college at New Haven show the wealth of this institution. Among the simple dormitories and buildings for lecture-rooms, the museum of

natural history attracts the attention by its height and a fine Gothic front. It owes its existence to a gift of Peabody, the well-known philanthropist. The first story is occupied by a collection of minerals most excellently arranged, by the private laboratories of Professors Dana and Brush, and by lecture-rooms and common laboratories. The middle floor contains the geological and paleontological collection. The highest floor contains collections for zoölogy and prehistoric ethnography.

The centre of interest at New Haven is a collection of fossil vertebrates founded by Prof. O. C. Marsh. Not only the whole first story, but also cellar and attic, are filled with fossil bones. Long rows of piled-up boxes contain the paleontological treasures. Only a very strict order makes it possible to find every thing in these crowded rooms, where a number of assistants are busy in preparing and combining the objects which so often arrive in fragments. In a small additional building a German modeller forms casts of the finest specimens, and afterwards these casts are sent with the greatest liberality to American and foreign museums. To a large extent, the Peabody museum owes its fine condition to the self-sacrificing activity of Professor Marsh.

What at the beginning of this century Cuvier did in Europe for the knowledge of antediluvian vertebrates, has been done in America by Professor Marsh, and his not less active rival Professor Cope in Philadelphia. The great variety of fossil vertebrates in America corresponds with the vastness of the country. Whole cartloads of bones have been dug out in the Bad Lands of the far west: they were carried on the backs of mules hundreds of miles, before they reached the railroads which brought them eastward. For months Professor Marsh and his assistants were camping in the reservations of the Indians, protected by an escort of cavalry. With the great chiefs of the Sioux, 'Red Cloud,' 'Red Dog,' he used to smoke the pipe of peace: against others he had to defend himself, revolver in hand. Professor Marsh's collection of fossil remains of vertebrates, brought together within about fifteen years, is not less complete, and not inferior in value to the collection of the British museum in London. It is infinitely more than all the material ever seen and studied by Cuvier during his whole life. During my visit at New Haven there were about twenty-five gigantic skulls of Dinocerata in the professor's laboratories. Several lithographers were occupied in making plates for the publications in which the fossil mammals and reptiles of America will be described. In an adjoining room a whole series of teeth, and bones of the foot, illustrate the development of the horse species. Though the Indians made the acquaintance of the horse only through the Spanish 'conquistadores,' there is no country where remains of antediluvian horses are so often found as in America. A series of fossil species shows the changes which the ancestors of the horse underwent, before the present type of the solidungulate was attained. Europe, also, has some of the intermediate forms, but not so many. The American predecessors form a nearly uninterrupted series. From the enormous mass of antediluvian mammals I can mention here only the oldest forms from Jura and tertiary strata, which have been discovered lately in America. Up to that time we knew only several lower jaws found in England, and a few teeth from the keuper of Wurttemberg.

Professor Marsh has brought from Wyoming remnants of at least three hundred specimens, and not only lower jaws, but also skulls, and other parts of the skeleton. They belong, without exception, to little marsupial-like species, usually of the size of a rat or squirrel. In contrast with these dwarfish forms, the reptiles of the Jura and chalk formations excel usually by their gigantic size; and it is just the largest and the clumsiest of them that show a remarkable combination of reptilian and avian peculiarities. New Haven has the largest collection of such dinosaurians. There you may see a complete skeleton of the curious Brontosaurus, — an animal with a small head, a long neck, long tail, high hind-legs, and short fore-legs.

The upper part of the femur of the gigantic Atlantosaurus is about twice as long as the corresponding bone of an elephant. The curious Stegosaurus, thirty feet long, was covered with an armor of enormous bone plates, and armed with thick spines. The cavity of its brain was of a minimum capacity; but, in compensation therefor, the spinal marrow in the os sacrum is swollen into a second brain-like enlargement. Another little saurian (Coelurus) has ring-shaped vertebrae which are entirely hollow. Hadrosaurus has shining teeth, jagged on the sides like shark's teeth, in several rows above each other, and side by side, so that they come into use only one after another. Besides these dinosaurians, some snake-like saurians of the sea, with short swimming-feet (Mosasauridae), attract our attention. A slab three metres high contains a complete well-preserved skeleton of such an animal. On the whole, Professor Marsh may have parts of about sixteen hundred specimens.

America has also flying saurians; though the skeletons are not often so completely preserved as those in the lithographic slate of Bavaria, but they are of considerably larger size. The skull of a Pteranodon, for instance, is three feet long. While this flying saurian differs from its European relatives by toothless jaws, there are in the chalk strata of America a number of birds with well-developed teeth. Professor Marsh has given a description of these curious creatures in a very elegantly executed monograph.

A visit at the Peabody museum, under Professor Marsh's guidance, arouses very mixed feelings in a European colleague. Together with sincere admiration, he necessarily has the disheartening conviction, that, whereas the time of great discoveries has begun in America, it is over in Europe. The character of greatness and magnitude which we find in many conditions of American existence is also prominent here. Compared with the paucity of the discoveries in our own country, the virgin soil of America furnishes, uninterruptedly, new and unexpected objects

It is beyond question that the future development of geology and paleontology will be essentially influenced by America; but it seems to me, that, for zoölogy also, a model institution for the future, in many respects, has been created in the celebrated Agassiz museum in Cambridge, near Boston, which probably will not be without influence on the development of museums of natural history in Europe. On an extensive plot near Harvard university there has been erected a five-story brick building with numerous windows, but with no ornamentation, and with an almost barrack-like appearance. The simple staircase corresponds with the modest exterior and with the whole interior arrangement. The genial founder of the 'Museum of comparative zoölogy,' as he called it, did not intend to have a brilliant exhibition, but a place for serious labor and study. And the great enterprise called into existence in 1860 by Louis Agassiz has now been nearly completed, according to the ideas of the father, by the energy and the organizing talent of the son. Over three hundred thousand dollars were subscribed in a short time, when Louis Agassiz, twenty-four years ago, came to America, and announced a plan for the erection of his museum. Nobody knew better than he how to arouse the enthusiasm of others for ideal purposes by the power of words; and we may well say that he originated that new movement in the descriptive natural sciences which continues up to the present day. A whole school of young zoölogists grew up at Cambridge. Collections of all kinds were bought in the old and in the new world, expeditions were sent to far-away countries, and the depths of the sea were investigated. The ingenious investigator, who was always full of new ideas, had neither time nor patience for the sifting and arrangement of the extremely rich material: his son and successor undertook this task. As an administrator, Alexander Agassiz may be equalled only by a few; as a naturalist, he belongs, as his father did, to the first names of America. A large fortune, acquired in the copper-mines of Calumet and Hecla, near Lake Superior, makes it also possible for him to promote the interests of the museum financially. To him it must be attributed, that the museum has been entirely withdrawn from the influence of an often-changing government, and has been transferred to Harvard university.

In the well-lighted basement of the museum there are eight rooms assigned to the collections in alcohol, which consist not only of lower animals and fishes, but also of numerous mammals, birds, and reptiles in metal boxes filled with alcohol. A seawater aquarium, a room for the preservation of living animals, and various other storerooms, occupy the rest of the basement.

On the first floor, there are the paleontological and geological collections, together with the necessary laboratories and lecture-rooms. The parts of the collection devoted to scientific investigations are separated from the collections for the show-cases proper; and in those, only a comparatively small selection of objects is exhibi ed. The second floor contains the rooms of the curator, a rich library, laboratories for anatomical and physiological investigations, and other workrooms for more advanced students and specialists. Besides the rooms already mentioned, there is on each floor a so-called synoptic room, through which every visitor of the museum has first to pass. A small but well-selected collection gives here a general view of the most important representatives from all classes of the animal kingdom. Large inscriptions on the walls and on the cases make it easier to find one's way. All the specimens are accurately labelled. Dissected preparations explain the anatomical structure of crabs, insects, echini, starfishes, etc. The synoptic room for zoölogy may well be called a model of a collection for purposes of instruction. A similar collection for geology and paleontology is in preparation.

While the two lower floors are chiefly devoted to purposes of instruction, the specialist will find in the three upper stories abundant material for his investigations. The third floor contains a zoölogical collection accessible to the public. In five halls all the more important species and varieties are exhibited in systematic order, and not crowded together. For the vertebrates the stuffed skins, as well as the skeletons, are given.

The zoögeographical collection is a specialty of the Cambridge museum. In two well-lighted halls one finds the whole fauna of America. The typical specimens of the animal kingdom of Africa, of India, of Europe and Siberia, and of Australia, are represented in their respective rooms. A special hall has been reserved for the inhabitants of the ocean; and here it is intended to place the rich treasures acquired by the investigations of the depths of the American seas. Most probably several years will pass by before the arrangement of this extremely interesting division of the museum will be finished, — a collection which will be unique in its way.

In the two highest stories the large and strictly systematic main collection of geology is stored in simple but appropriate cases with glass doors. Thousands of skins of mammals and birds are stored up in drawers. The lower animals are deposited in a similar manner. Every case and every drawer bears a label showing its contents. In many departments Cambridge is said to be even ahead of the British museum. Excellent methods of preparation have been applied with fishes and reptiles. The collection of insects, under the direction of the German entomologist, Dr. Hagen, excels by reason of its abundance of beautiful preparations, showing the whole development of the more important species and varieties.

By a mere hasty visit to the exhibition-rooms no one will get an idea of the magnificence of the Museum of comparative zoölogy. Neither the building, nor the rooms inside, nor the exhibited objects, will make an especially imposing impression. But the strong point of this institution lies in the peculiar arrangement of the collection for the public, and in the strict separation of the large material for scientific investigations. By the constant development of science, by the improved accessibility of distant continents

and islands, by the investigations of the depths of the ocean, collections of natural history will be enlarged almost to infinity; and it will be harder and harder to place them in our museums, and to preserve them. Everywhere buildings begin to be insufficient; and if we were to stick to the old system, according to which a museum exhibits nearly all its objects, the large central depositories of natural history would grow to an enormous extent. The organization of the Cambridge museum tries to meet equally the demands of science and the wants of the public which comes for information; and in this sense I have called the Agassiz museum a model museum for the future.

Besides the institutions here mentioned, there are in many other cities of the United States — as Chicago, San Francisco, St. Louis, Cincinnati, Princeton, Baltimore, Charleston, Providence, etc. — smaller museums of natural history. They are almost all supported by societies or schools. There is, therefore, no lack of interest in scientific studies; nor is money wanting. But still the number of those is very small, who, out of pure enthusiasm for science, prefer the modest existence of a learned man to a materially better-paying occupation. In this respect Europe is still far ahead. Circumstances, however, will change, together with the great development of North America; and in some of the Eastern States an alteration can already be noticed. We must therefore keep our eyes open, if we do not wish the experience of having our young cousins across the ocean outstrip us in a field the thorough culture of which, so far, has been the glory of old Europe.

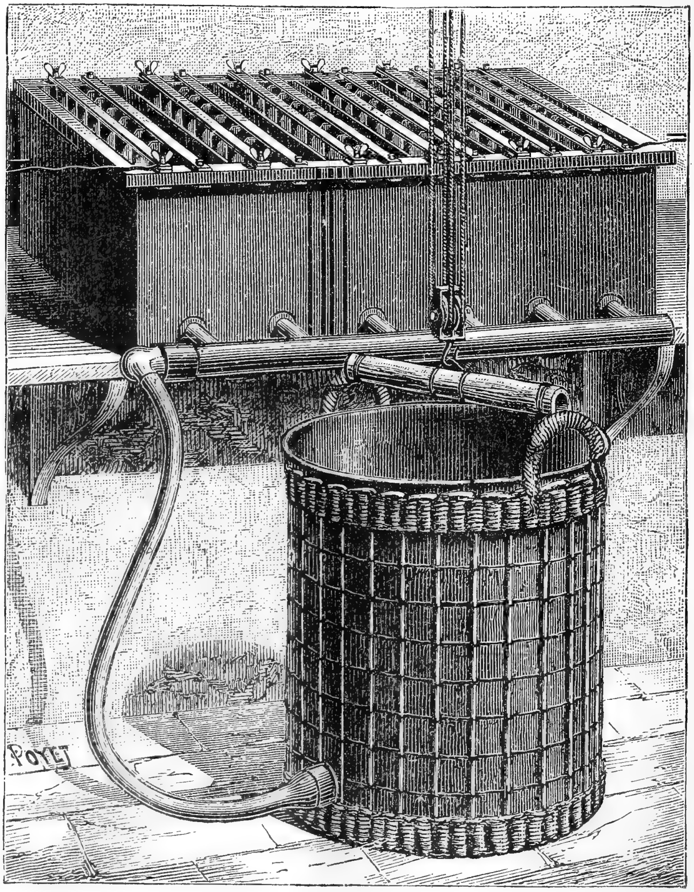


FIG. 3.—Batteries for Tissandier's balloon.

TISSANDIER'S ELECTRIC BALLOON.[1]—II.

As we have described our apparatus as a whole, we will now give some details concerning the various parts, and especially concerning the dynamo-electric motor and the bichromate of potassium battery, which was prepared with a view to our experiments.

The motor is a Siemens new model machine, made at Paris especially for us, consisting of a bobbin very long in proportion to its diameter, and mounted on a light wood frame. This machine weighs only fifty-

[1] Concluded from No. 53.

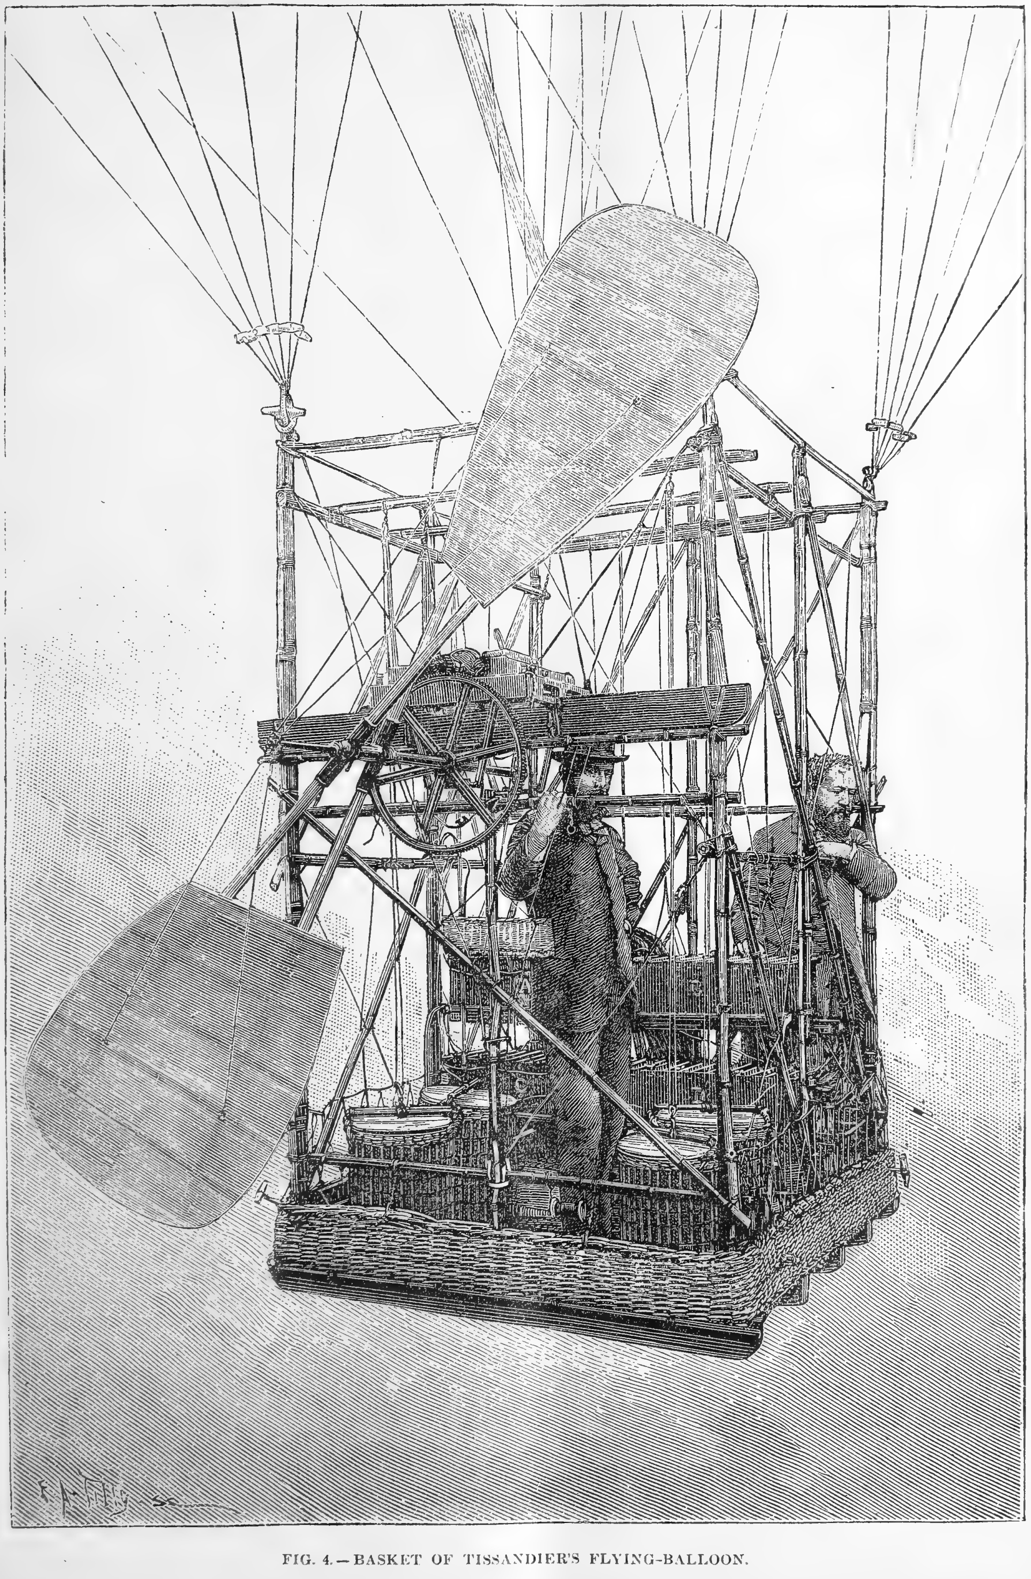

FIG. 4.—BASKET OF TISSANDIER'S FLYING-BALLOON.

four kilograms. The screw consists of two helicoidal pallets covered with varnished silk, the deformation of which is guarded against by the action of coils of steel wire. This screw is 2.85 metres in diameter: it is attached to the machine by a transfer and by gearing, and makes a hundred and eighty revolutions per minute, while the bobbin makes eighteen hundred.

The electric battery, which may be called the generator of the screw balloon, has the same surface of zinc and carbon as our trial batteries, the measurement of which has already been given elsewhere (*La Nature*, May 20, 1882), the same number of cells, the same volume of liquid. We are able to considerably reduce its capacity by using four ebonite troughs with six compartments, instead of twenty-four separate receivers. Besides, we use slightly higher vessels, which also gives greater breadth. Fig. 3 presents one of the four batteries used in the electric balloon as it was tried in the laboratory. It consists, as may be seen, of one large trough with six divisions; each compartment forming an element of the pile, enclosed and mounted on copper legs, having eleven thin carbons and ten zincs arranged alternately. The zincs are held in place from above by flexible pincers, and may easily be renewed after each experiment: they are .15 of a centimetre thick, sufficient to work the battery for three hours. They must be perfectly amalgamated. Each compartment is provided at its lower part with a slender ebonite tube, which communicates to a lateral conduit connected by a caoutchouc tube with a large and very light ebonite vessel containing the acid solution of bichromate of potassium. If the pail is raised by means of a string passing into the blocks above the level of the battery, the latter is filled by the chief communicating vessel, the liquid acts on the zincs, and the current passes: if the pail is lowered, so that it occupies the position seen in fig. 3, the liquid enters by the caoutchouc tube, the battery becomes empty, and ceases to act. By this system it is apparent that the piles communicate with each other solely by the narrow conduits. The resistance of the liquid is great enough for this communication to have no effect on the current, although the elements are in series. In the car there are four batteries like that shown in the figure, of twenty-four elements, in series, and fed by four pails of ebonite, each containing thirty litres of the bichromate of potassium solution. The batteries are stowed away in the car (which is 1.9 metres long and 1.45 metres broad) so as to occupy the least possible room. Two ebonite troughs of twelve elements are placed cross-wise about .35 of a metre from the bottom of the car, and there are two more .15 of a metre higher. The ebonite reservoirs at the two back corners of the car feed the upper piles; and the other two reservoirs, nearer the battery, feed the lower piles (fig 4). A vacant space is left between the four pails for the operator, who controls every thing, having at hand the cords to raise the pails, the hooks to hold the cords at the desired height, the commutator with the cup of mercury to start the current, and the cords the rudder.

The bichromate of potassium used to work the battery is concentrated and very acid: it is turned into the pails at a temperature of about 40°, which permits of a considerable increase in the quantity of dissolved salt. The commutator is so arranged that a current of six, twelve, eighteen, or twenty-four elements may pass; and thus the screw has four velocities. The four pails are covered with a sheet of caoutchouc, pierced with one small hole, which allows the air to pass when the liquid is flowing, and is bound around the pail by a copper thread sheathed in gutta-percha. This manner of closing is very secure; and, in case of a shock, not a drop of the liquid can escape. The pails, when empty, weigh only three kilograms each: they are strengthened by basket-work, which also serves as a support. Cords passing into the pulleys raise them above the piles in order to fill them, and lower them to empty them. The bottom of the car holds a caoutchouc cistern to receive the liquid in case of accident. The pile with the liquid weighs about a hundred and eighty kilograms. A little willow basket — easily seen in our illustration — is placed under the motor. It contains an oil-can for the motor, a little bottle of mercury to supply the cups of the commutator sunk into a block of box-wood, and also the tools necessary to discharge the pile in case of accident. All this occupies the back of the car. In the front, space is reserved for the ballast-bags and for the implements used in the descent.

Our illustration was made with great exactness: it presents all the details of the arrangement of the car, and shows the attachment of the motor. The

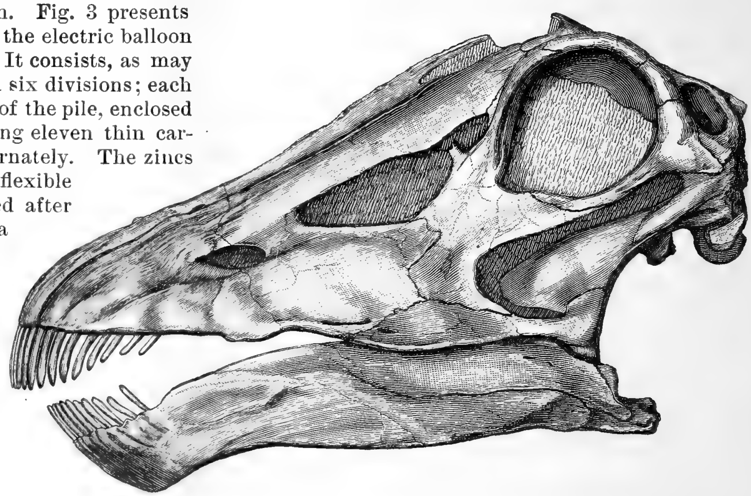

Fig. 1. — Skull of Diplodocus longus Marsh, side view.

Siemens machine, and the spring which it works, are arranged on a walnut cross-piece. In addition, it is held by stretched ropes, which may be tightened at pleasure by tension, and which connect the four extremities of the framework with the upper and lower cross-pieces of the car. When rotating with great velocity, the vibrations are avoided by this method of attachment.

The use of such a machine in the car of a balloon is comparatively simple. When every thing has been prepared on the ground, there is nothing to do but to plunge a little copper fork into the mercury-cup of the commutator, and the screw begins to turn.

From fear of fire, and from the change of position, which affects the altitude of the balloon when once poised in the air, the operator must have no manual work to do: electricity alone supplies all the fundamental conditions of the aerostatic motor-force. After the winter, when favorable weather comes, the first electric balloon will again take its flight.

GASTON TISSANDIER.

A NEW AND STRANGE DINOSAUR.

PROFESSOR MARSH continues his studies of the Jurassic dinosaurs of America by giving, in the last number of the *American journal of science*, an account of a new family of Sauropoda founded upon the genus Diplodocus, which he places between the Atlantosauridae and the Morosauridae. The chevrons of the caudal vertebrae, which have both anterior and posterior branches, have suggested the name Diplodocus; and the ischia of the pelvic girdle are intermediate in form and position between the families heretofore recognized, the shaft being straight, and not twisted nor apically expanded.

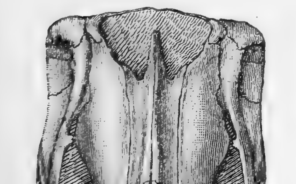

FIG. 2. — The same skull, front view.

But the best preserved portion is the skull, of which we reproduce Professor Marsh's excellent figures. It was of moderate size, the figures being one-sixth the natural size, and showing clearly the characteristic features. It has two pairs of ante-orbital openings, the small front pair not having been seen before in dinosaurs. The brain inclines backward, and has a very large pituitary body, enclosed in a capacious fossa below the main brain-case, — a very different condition from that holding in the other families of Sauropoda. The size of the skull indicates an animal probably forty or fifty feet long: the weak dentition shows that it was herbivorous, and its food was probably such succulent vegetation as an aquatic life would enable it to procure.

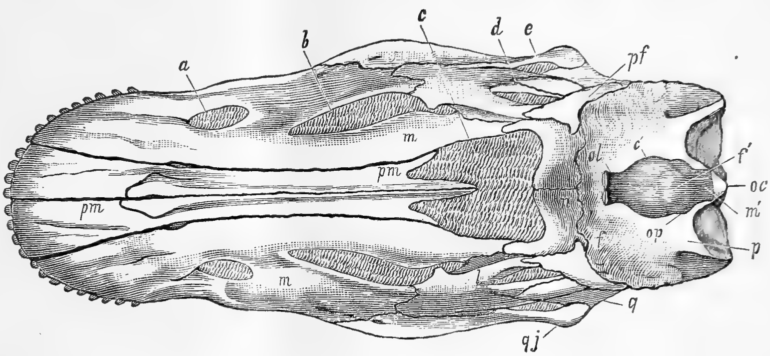

FIG. 3. — Skull and brain cast of the same, seen from above. *a*, aperture in maxillary; *b*, ante-orbital opening; *c*, nasal opening; *c'*, cerebral hemispheres; *d*, orbit; *e*, lower temporal fossa; *f*, frontal bone; *f'*, fontanelle; *m*, maxillary bone; *m'*, medulla; *n*, nasal opening; *oc*, occipital condyle; *ol*, olfactory lobes; *op*, optic lobe; *p*, parietal bone; *pf*, pre-frontal bone; *pm*, pre-maxillary bone; *q*, quadrate bone; *qj*, quadrato-jugal bone.

In looking at these figures, and noting their strange resemblance to a horse's skull, one finds it hard at first to recall the fact that the nearest living allies of Diplodocus are the crocodiles.

THE FALSE PROPHET OF THE SUDAN.

THE religious movement in the Sudan has a special interest for ethnologists on account of its parallelism with the events by which the faith of Islam was originally propagated. A recent letter from Khartum informs us that Mohamed Ahmed, the Mahdi, was born at Dongola in the year 1260 of the hegira. His parents, Abdellahi and Amina, were poor, and had two older sons. From the age of seven he was taught in a Mussulman school to read, write, and commit to memory the Koran. At the age of twelve he knew the latter perfectly. In the same year his father died; but his brothers continued his education while he pursued studies of the Mussulman law, foreseeing eminence in store for him. After the death of his mother, having completed his studies, he repaired to the Isle of Aba on the White Nile, to be near his brothers, who were boat-builders. For nearly fifteen years he inhabited the isle, venerated as a holy man by all who knew him, before making claim to the title of Mahdi or Mussulman Messiah. He then wrote to all sheiks and grand dervishes of the region, that the prophet

Mohamed had appeared to him in a dream, and informed him, as from Allah, that he was the long-promised Mahdi; that the Turkish supremacy was at an end, the reign of the Mahdi begun; requesting their assistance, and further predicting wars and insurrections for the Sudan. For himself, at the proper time, he proposed to go to Mecca to receive recognition from the grand sheriff. These predictions were circulated at Khartum a year before they came to the knowledge of the local authorities. Finally Raüf Pasha, governor-general, decided to send a deputation, headed by the famous Abu Suüd, to confer with the new prophet. The latter was found in a large hut surrounded by his dervishes, but declined to go to Khartum or to perform miracles, the time for which, he said, was not come. Abu informed him that he would be forcibly taken to the governor if he did not come willingly; but, discovering several men with drawn swords in his rear, he retreated precipitately to his despatch-boat and to Khartum. He was sent back with two hundred soldiers, commanded by an adjutant-major, to bring the Mahdi forcibly. These soldiers landed at night in mud up to their middles, lost all courage, and, arriving at the hut, were confronted by a mob of whirling dervishes. One of these was shot by the commander as a signal for attack, when the remainder, with thousands of Arabs who had remained in ambush, threw themselves upon the little troop, and exterminated them. The boat was next attacked, and was obliged to retreat to Cava. On the 20th of August, 1881, a large force was collected at Cava to crush the insurrection before it gathered strength. Meanwhile the Mahdi and his people left the Isle of Aba under the very eyes of troops who dared not oppose him, and made his way toward the mountains of Gadir. Here, in November, 1881, he was attacked by Rashid Bey and the king of the Shiluk tribe with five hundred soldiers, who were destroyed, almost to a man, in a few moments as it were. Raüf Pasha being superseded, Giegler Pasha, a European civil officer temporarily in charge, declared that he could preserve order with the troops at his command, and declined re-enforcements. In order to carry out this boast, he concentrated the garrisons of Kordofan, Kashoda, Sennaar, and Khartum, and despatched them from the latter place against the Mahdi, under command of Yusuf Pasha. They comprised about seven thousand men, mostly untrained conscripts, with six cannon.

Three days after their arrival at Gadir they were attacked by fifty thousand insurgents, commanded by the brothers of the Mahdi; and only about a hundred and twenty-four private soldiers escaped from the general massacre. The troops of the Mahdi suffered severely, and both his brothers were killed. Meanwhile the other provinces, from which the garrisons had been withdrawn, began to rise against the authorities. Sennaar revolted: the few soldiers there were slain, with all the Europeans, and their goods looted. El Kerim Bey came to the rescue of the government with three thousand Arabs. He was killed, his men slain or dispersed, his villages were burned, and all the inhabitants put to the sword, without regard to age or sex.

At this juncture Abdelkader Pasha was named to the governorship; and the Mahdi marched on El Obeid, capital of Kordofan, putting the inhabitants of the villages on his way to the edge of the sword. A Catholic mission, consisting of two priests, two sisters, and two lay brothers, were taken prisoners by the Mahdi, and tortured for three days, in a vain attempt to force them to renounce their religion. In September the Mahdi attacked El Obeid with a hundred and ninety-two thousand insurgents. Assisted by a trench, the defenders held their ground for two hours, after which the Mahdi retired, leaving twelve thousand of his men on the battle-field. He proceeded to invest the town, and in four months and a half reduced it by famine, on Jan. 17, 1883. All the Europeans were obliged to embrace Islamism to escape death. Their goods were confiscated. The mission was demolished; the missionaries, male and female, put to the torture. The archives were burned; the merchants of the town, and all the principal functionaries, sold into the interior as slaves. The females suffered rapine.

Before this, thirty-seven hundred soldiers, commanded by Ali Bey, had been sent to succor El Obeid. They were attacked by thirty thousand insurgents under Mama, the grand-vizier of the Mahdi. A thousand escaped to Bara, where they capitulated to the rebels two weeks before El Obeid. But the career of victory was not wholly unchecked. Karkodi on the Blue Nile, the headquarters of the trade in gum and lentils, was captured by the rebels, and partly burned. Four hundred soldiers and merchants were massacred. However, in thirty-five days, the rebels were driven out by the Egyptian troops, and order re-established. A revolt on the White Nile at two large villages, ten hours from Khartum, was crushed, with heavy loss to the rebels, and the death of their leader and his three sons.

Up to this time the insurrection had cost more than a hundred thousand lives in the Sudan. At the time this letter was written, Hicks Pasha and his army were just arrived, and were expected to restore order. Their rout and massacre occurred later. At this date the Egyptian government, under pressure from England, is about to abandon the Sudan to the hordes of the Mahdi; and the unfortunates who are holding a few outposts in the faith of rescue will be left to their fate. The story reads like a page from the middle ages; and it seems hardly credible that such events can characterize any part of the nineteenth century. Unless the strong arm of Abyssinia intervenes against the forces of the false prophet, it is quite possible that even for Egypt proper the end is not yet.

THE GEOGRAPHISCHES JAHRBUCH.

Geographisches jahrbuch. Vol. ix., 1882. Gotha, *Perthes*, 1883. 16 + 719 p. 12°.

THIS *jahrbuch*, an outgrowth of Petermann's *Geographische mittheilungen*, was first pub-

lished in 1866, under the editorship of E. Behm. On the death of Petermann, in 1878, Behm took charge of the *Mittheilungen*, and H. Wagner succeeded him in the preparation of the *Jahrbuch*, of which the ninth biennial volume has recently been issued. It is about double the size of the first number, and, as now conducted, covers a broad field in geography and allied departments of study, as the following abstract of the contents will show. Indeed, the range of topics reported upon by the thirteen specialists who aid Wagner in its preparation is now so extensive that the seven hundred pages of the present volume are no longer sufficient to contain abstracts of all of the three thousand papers quoted.

The more directly geographical part of the volume contains chapters on the exploration of Africa (42 pages), Asia (35), the polar regions (27), and the oceans (25), by Zöppritz and Lullies of Königsberg, Wichmann of Gotha, and v. Boguslawski of Berlin. From the last of these, we may note the following maps, as embodying the present state of our knowledge concerning the form of the sea-floor. An atlas of thirty-six maps, showing the physical relations of the Atlantic Ocean, was published in 1882 by the German 'Seewarte' at Hamburg. Its first plate shows the depth by eight contour lines at two hundred, a thousand, two thousand, etc., to seven thousand metres, the old fathom measure being discarded. The northernmost Atlantic and adjoining Arctic Ocean are represented in the maps by Mohn, published in supplement No. 63 to Petermann's *Mittheilungen* (1880). The Indian Ocean and the several seas between Asia and Australia are shown in two maps by Krümmel in Kettler's *Zeitschrift für wissenschaftliche geographie* for 1881 and 1882. The latter is especially valuable in illustrating the distribution of temperatures in the sea.

A very considerable share of the work is allowed to questions not simply geographical. Geological investigation is reviewed by v. Fritsch of Halle in seventy-one pages; but only three of these are allowed to the United States, showing a decided inequality of treatment. Studies on the distribution of plants (83 pp.) and animals (71 pp.) are summarized by Grube of Dresden and Schmarda of Vienna; and Gerland of Strassburg reports on ethnology (95 pp.) with satisfactory detail. Geographic meteorology (71 pp.) is safely intrusted to Hann of Vienna. Among the many important memoirs referred to, we may mention Supan's, on the distribution of annual variations of temperature; those by Teisserence de Bort and Wild, on the relation between isobars and thermic isabnormals; Spindler's paper on the strength and inclination of the wind in storms; and several others on meteorological cycles. Concerning the latter, Hann says, in effect, that the hope that such cycles might afford a foundation for long-range prognostics has proved delusive, and the problem is at present of purely scientific, not practical, interest. Whipple's inquiry into the periodicity of rainfall is quoted as proving the absence of any short cycles of between five and thirteen years' duration, so that it can be definitely said that predictions of wet or dry years on the basis of previous observations are quite worthless. So, also, Hoffmeyer's study of the North Atlantic tempests serves to show the inaccuracy, to say the least, of the *New-York herald's* cable-warnings to western Europe. Forty-four pages are devoted to questions of regional climate.

Dr. Zöppritz of Königsberg is allowed forty-two pages for the progress of terrestrial physics (*geophysik*). In commenting on Professor George Darwin's work on the effect of the tides upon the moon's distance, and on Mr. Ball's entertaining lecture, 'A glimpse through the corridors of time,' on the same subject, the reviewer accepts Professor Newberry's conclusion that the moon must have already attained its actual distance from us when our oldest Cambrian and Silurian strata were deposited. This seems an unnecessary adherence to doctrines of uniformity: for, in the spread of our paleozoic strata, there is evidence of much stronger submarine transportation than we now find; and even in Jurassic times there is a surprising area of cross-bedded sandstones in the region of the Colorado plateau. We agree more fully with the author, in his opinion that Mr. O. Fisher has, in his 'Physics of the earth's crust,' rather overvalued the strength of his conclusions, and again in objecting to the theory of the permanence of continents. Under glaciers, the discussion by Forel, of their periodic variations in Switzerland as dependent on preceding and not contemporaneous climatic irregularities, is regarded as of especial importance. Forel was preceded in this idea by Güssfeldt.[1]

Geodesy and cartography are also discussed; and a list is given of geographic societies, which now number seventy-nine, and of geographic journals, which have recently increased rapidly to the number of one hundred and nineteen. Among the societies, the Royal geographical society of London leads the list

[1] Ueber die eisverhältnisse der hochgebirge. Verh. ges. erdk. Berlin, vi., 1879, 86.

with a membership of 3,373, and an income of about nine thousand pounds sterling.

There remain still two chapters to which we hope later to call attention in special notices, — one by Egli of Zurich on the present condition of geographic onomatology, or the study of names; the other, by the editor, on the development of the study and method of teaching of geography, a matter discussed with much seriousness in Germany, though receiving small attention here.

In concluding the present notice, it may be said, that while the *Geographisches jahrbuch*, like other works of its class, by no means serves the purpose of final reference, it is of the greatest value as an aid in all geographic studies; and the special feature of arrangement according to place makes it a most valuable supplement to other bibliographic works in which the classification is according to subjects.

MASCART'S ELECTRICITY AND MAGNETISM.

Leçons sur l'électricité et le magnétisme. Par E. MASCART et J. JOUBERT. vol. i. Paris, 1882. 8°.
A treatise on electricity and magnetism. By the same; translated by E. ATKINSON. vol. i. London, *De la Rue*, 1883. 662 pp. 8°.

ONE feels, in reading Maxwell's treatise on electricity and magnetism, that the author had a grip upon the subject which has only been approximately attained by other writers. Although the style is obscure, and the arrangement often merits the word 'atrocious,' — for equations are taken for granted which are afterwards proved, and other equations are referred to in general without particular specification; so that the student who comes to the book with mediocre preparation, and is determined to master it, cannot fail to have a feeling allied to bitterness with the author who has led him over such a corduroy road to a promised land, — nevertheless, the grip is there, and one always feels it; and each paragraph is full of suggestion.

The treatise of Mascart and Joubert is Maxwell's treatise very much simplified. It has the Gallic flow, but it has not the Scottish grip. It is Cummings's admirable little elementary treatise on electricity, treated by the calculus, and amplified with some of the harder portions of Maxwell. It has the appearance of a collection of excellent professorial notes on Maxwell's book.

The volume now printed contains the mechanical theory of electricity; and a second volume on the phenomena and electrical apparatus is promised. The portion on thermo-electricity is more extended than the chapter on the same subject in Maxwell's treatise; although, curiously enough, Tait's ingenious method of measuring thermo-electric relations is not given. Much space is devoted to the propagation of what are termed, for convenience, 'electrical waves;' and the action of the telephone is theoretically considered. In the treatment of electro-dynamics the principle of symmetry is often employed in a clear manner. It is noticeable throughout the work that the authors are patriotic, and the special investigations of Frenchmen are often alluded to. We miss, however, full notices of contemporaneous investigations by Germans and by Americans. Perhaps these will appear in the following volume. The chapters on magnetism are very suggestive, and in them the various theories are presented in a clear manner. Thomson's papers on magnetism are given at considerable length, mainly as they are contained in his 'Papers on electro-statics and electro-magnetism.' The view that diamagnetism is merely the difference between the magnetic character of the medium in which the small diamagnetic substance is suspended, and the magnetic character of the substance itself, is popularized by presenting the analogy between this phenomenon of magnetism and the action of bodies floating in fluids of different specific gravities. This hypothesis makes the ether of space a magnetic medium, with a greater coefficient of magnetization than that of any known diamagnetic substance. The analytic processes of the authors are, in general, simple. Laplace's and Legendre's coefficients are used only in a limited way in the subject of magnetism. Perhaps this may be regarded as an advantage in the treatment. What is needed at present is an extended treatise on the application of spherical harmonics to practical problems in electricity and magnetism, and to problems of attracting forces in general, in order to show the availability of this method of analysis.

The authors treat the subject of electro-magnetic induction in a clear way. The retarding effect of induction on the swing of a galvanometer needle is clearly set forth, and the work of electrical motors receives some attention. More will probably be given in the next volume. Hall's phenomenon is treated in a far-off manner. The authors state that "Hall's phenomenon would seem to be in contradiction with the opinion generally adopted, that in electro-magnetic phenomena the action

is exerted on the *supports* of the currents, and not on the currents themselves. But, however we may explain the experiment, it follows that a magnetic field in the stationary state develops an electromotive force which tends to move electricity in the direction of the electro-magnetic action; that is, to the left of an observer placed in the current, and who is looking in the direction of the magnetic force." Perhaps one cannot do more than make the above statement in the present state of our knowledge; but the fact that the phenomenon in question is different in different metals shows the influence of the *supports*. In general, we like the arrangements of the topics treated better than that of Maxwell; and we hope that this book marks the revival of a period of graceful and lucid treatises on mathematical physics which we have a right to expect from Frenchmen.

The English translation of this work by Dr. Atkinson is well executed, and is revised by the authors, who have added certain portions to it which are not contained in the French treatise. We have noticed here and there faults in punctuation which add to the difficulty of comprehending certain relations.

LARISON'S TENTING-SCHOOL.

The tenting-school: a description of the tours taken and the field-work done by the class in geography, in the Academy of science and art at Ringos, N.J., during the year 1882. By C. W. LARISON, M.D., principal of the academy, etc. Ringos, N.J., *Larison*, 1883. 292 p. 12°.

THIS is an amazingly queer little book, — so full, indeed, of oddities, that one is at a loss where to begin an account of them. In the first place, the author is evidently one of our orthoepomaniacs. Nearly all the vowels, and many of the consonants, are decorated with diacritical points. The result is, that the pages have a singularly bristling and formidable aspect. But we advise the reader to discipline his eye to this painful amelioration of the written speech, for a reward awaits him. Behind this printed '*chevaux-de-frise*' there is a lot of things worth reading. The first effort of the author is to tell just how he managed for the conveyance and camping of a party of students, boys and girls. Every little detail for the construction and equipment of a wagon and camp for eighteen persons is carefully set forth. The most trifling articles are figured in rude woodcuts. All this, though in its way useful, would be tedious but for the *naïve* though often cumbrous language in which it is given, and the strangely complicated ways of meeting simple needs. When, for instance, he comes to the making of the camp-fire, which the untutored campaigner accomplishes as best he may, our author tells his very ingenious way. The plan is so altogether good, that we give it in full, unhappily omitting the diacritical accents, which are beyond the resources of an ordinary press.

"To kindle fire, we use a kind of strong iron cup, fastened to an iron handle about three feet long. This cup is very wide at the top and will hold about a quart. In this cup, we place a handful or more of resin, a gill or more of kerosene, and about a tablespoonful of a mixture, consisting of one part of ether and four parts of alcohol. At first thought, this may seem to be a very incompatible mixture; but, of its practical value, we have much evidence. To start a fire in wet wood, during a rainy day, under ordinary circumstances, is not easy; but with the arrangement, and the fuel above named, it is readily effected.

"To ignite resin, in the open air, with an ordinary match, is almost impossible. To ignite kerosene in the open air with a match, is not easy; and to fire alcohol in an open pan, with a match, is not done at every trial. Each of these substances require (*sic*) to be heated up to a certain point, — the kindling point, before they will ignite. To raise the temperature of either of these to the kindling point, requires more heat than is developed by the burning of a match; but, ether is so volatile, that when poured out, its vapor instantly rises. This vapor fires at so low a temperature, that when a burning match is brought in contact with it, it ignites with explosive violence, and continues to burn with vigor until consumed. While burning, the heat generated, evaporates the alcohol, raises the temperature of the alcoholic vapor to the burning point, and ignites it. By the burning of the alcohol, the kerosene vapor is raised to the kindling point, and is ignited. The burning of the kerosene soon develops heat enough to liquify (*sic*) the resin, evaporates it and ignites it. At this juncture, a part of the kerosene and resin begins to be converted into a gas that makes a hotter blaze than that made by burning either kerosene or resin alone; besides, attending this fire is much less smoke than is made by the burning of resin alone.

"The cup of burning kerosene and resin, when placed under a heap of wood that is not too wet, soon raises the fuel to the kindling point, ignites it and gives to the fire such impetuosity that it makes water boil quickly, and butter to fry and sputter furiously.

"With the cup alone, charged as above directed, I have boiled a two gallon tea kettle of water in eight minutes. But, this could not have been done in a windy day.

"It would be criminal to make the above statement, respecting the iron cup and the fuel to be used with it, without informing the tiro that it is very dangerous. Should any one attempt to use it, he cannot be too careful. The act of touching it off with a match, unless circumspectly done, may prove very disastrous. The results of using this mixture without sufficient circumspection we have seen. Suffice it to say, they were terrible."

Unhappily, our author does not give a picture showing the effects of these occasional catastrophes on the camp of innocents; but

at least he might have told us how to apply the circumspection.

Like many another victualler of youth, he has very dark views about the hungry camper, or, as he sadly calls him, the 'stomach-man.' He thus exhorts him by picturing the perfect primal man: —

"In reference to this subject, this fact should be kept in view. The type man, the formative man, was symmetrical. Neither his intellectual, nor his sensual, faculties predominated. Temperate in all things, he appreciated and enjoyed the beautiful, the euphonic, the fragrant, the relishful and the eupathic. He suffered, — but to him his task was not onerous; he enjoyed, — but his fruition did not engender ecstasy. Virtuous, — he met what was before him with fortitude. Brave, — he triumphed in every struggle for right. From birth till death, all was satisfactory, all was enjoyable."

The most of the book is filled with accounts of short excursions in New Jersey. They are commonplace enough in their matter, and are only interesting from the indescribably queer tone that pervades them. There are many singular criticisms on the manners and customs of the folk at the summer resorts on the Jersey coast: they are vulgar enough, but the pervading queerness of the text makes them interesting.

This essentially worthless little book meets a growing interest in the free life that the camp alone can give the summerer. Our country with its abundant wildernesses, with the tolerance of its country folk for what would in other lands be called trespasses, lends itself to this charming method of travel. It is much to be desired that some master of the fine art of decent living in rough conditions should give us a manual for the guidance of beginners in its mysteries.

ETHNOLOGICAL PSYCHOLOGY.

Zur naturwissenschaftlichen behandlungsweise der psychologie durch und für die völkerkunde. Von A. BASTIAN. Berlin, 1883. 234 p. 8°.

THE idea pervading all of the more recent publications of Adolf Bastian is to establish a science of psychology of nations upon the data of modern ethnography. The all-pervading influence of nature forms and shapes peoples, nationalities, and their customs and habits; and therefore ethnology must become a natural science, — the physical science of the mind as manifested in the development of each nation in particular, and all the nations taken as a whole. The withdrawing of ethnology from metaphysical influences, under which it has labored since it was made a scientific study, is possible only when a sufficiently large material has been collected among the nations of the globe and the records of history to establish on it incontrovertibly general principles, which will be found to rest on natural science, and not on philosophic speculation. Some parts of the vast field of ethnology are still obscure as to their real significance, because the material to judge from is too scattering and scanty. Bastian's most recent work contains a series of seven articles, mainly on Polynesian subjects, which uphold and illustrate his ideas concerning ethnology, as stated above, with a full array of the most erudite comparisons. The author's extensive travels have furnished him with a stock of ethnographic facts which none has equalled in our century, and which he readily compares on almost every page with notices derived from the classic writers. Concerning the progress traceable on the social development of man, the writer shows, that, considered as an individual, the single man is of very small account in the primitive horde. The first stage is the tribe, based on consanguinity with exogamic marriage. This stage passes into that of *civitas*, or citizenship, whenever the country becomes agricultural. Social connection is no longer determined by family ties, but by the extent of the district, country, or commonwealth to which the individual belongs. When tribal organization becomes loose, then blood-revenge, and similar primeval customs, also disappear. The concise style of Bastian is not always what we should desire: at times it becomes rambling, a heavy phraseology obscures its lucidity, and the pressure of thoughts cannot find words enough to give vent to their rapid flow. Such defects as these are more prejudicial to the literary success of Bastian's numerous publications than the typographic errors which the proof-reader has allowed to disfigure their texts, especially the classic quotations.

STOKES'S SCIENTIFIC PAPERS.

Mathematical and physical papers. By GEORGE GABRIEL STOKES, M. A., D. C. L., L L. D., F. R. S., professor of mathematics in the University of Cambridge. Reprinted from the original journals and transactions, with additional notes by the author. Vol. ii. Cambridge, *University press*, 1883. 366 p. 8°.

VOL. i. (328 pages) appeared in 1880, and contains the papers, arranged in chronological order, which were published by the author between April, 1842, and December, 1847. The earliest date in vol. ii. is March, 1848, and

the latest, March, 1850. Vol. iii. is stated by the publishers to be in press.

Of the papers reprinted in these first two volumes, only two of the more important are of a purely mathematical character, and these treat of the properties and methods of computation of infinite periodic series such as arise in many physical problems, which series were first systematically employed and explained by Fourier in 1822. Fourier's treatise [1] is to-day the best introduction to a knowledge of this kind of analysis, besides being one of the most brilliant expositions, in any branch of science, in existence. With the exception of a single paper of 42 pages, upon a differential equation relating to the breaking of railway bridges under loads moving at high speeds, the remaining papers all come under the head of fluid motion in one way or another, and include extensive discussions of the fundamental dynamical equations of motion of perfect fluids, of viscous fluids, and of elastic solids. These discussions treat, among other subjects, the theory of oscillatory waves, the equilibrium of the earth in a fluid state, the variation of the force of gravity on its surface, and the undulatory theory of light.

The work of Professor Stokes in hydrodynamics is of special importance in correcting and rediscussing the results obtained by Lagrange and Poisson, and in paving the way for the more modern developments of Helmholtz and Thomson in vortex motion, and of Maxwell in electricity and magnetism.

[1] Analytical theory of heat. By JOSEPH FOURIER. Translated, with notes, by Alexander Freeman. Cambridge, 1878.

But the papers of Stokes which are probably of most interest to the mathematical physicist of to-day are those upon the undulatory theory of light, in which he has added essentially to our knowledge of the constitution of the luminiferous ether by showing how the phenomena of aberration may remain unaffected by the fixity or motion of the ether, as also by his investigation of the theory of diffraction, by which he has sought to decide whether the vibratory motion of a plane polarized ray lies in the plane of polarization or at right angles to it.

By these investigations, and by others, among which may be noticed that of the colored rings of Newton, he has explained difficulties in Fresnel's undulatory theory, and essentially improved it.

The treatise of Verdet,[1] which is the most complete and important exposition of the undulatory theory yet written, gives a complete bibliography of this subject, extending to many hundred titles, from which the reader can correctly estimate the labors of Professor Stokes in this field.

The lifelong labors of Professor Stokes have given an immense impulse to mathematico-physical research in England; and the republication of these papers by the syndics of the Cambridge university press is a graceful and well-deserved tribute to the Nestor of the greatest mathematical school in the world.

[1] Leçons d'optique physique par E. Verdet. Paris, tome. i., 1869; tome ii., 1872. The following translation and revision to date is in process of publication: Vorlesungen über die wellentheorie des lichtes, von E. Verdet. Herausg. von Dr. Karl Exner, Braunschweig. Bd. i. 1881.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Geologic work in the South Atlantic district.— Owing to the as yet incomplete state of the topographic work in the southern Appalachians, the systematic geologic survey of that section has not yet been commenced. However, several geologic reconnaissances have been made, and considerable collections of paleontologic material have been sent into the main office of the survey. During the season of 1883 Prof. H. R. Geiger examined the geologic structure of a considerable portion of Virginia and West Virginia. During the latter part of July he was in the eastern part of Virginia, but in August transferred his field of work to Greenbrier county, W. Va., where he studied the formations that are exposed between the Greenbrier River and the Lewis Tunnel, just east of Alleghany station, W. Va. A collection of Devonian fossils was made. In September his work was carried into Alleghany county, Va., where a careful examination was made of the rocks so well shown there. The thickness, dip, etc., of the beds were obtained, and an excellent series of typical specimens secured. In October the field was extended northward to Rockingham county, but bad weather impeded the operations. Through November a special study was made of the foldings in the limestones that lie between the Blue Ridge and North Mountain, and a careful comparative examination made of the limestones of Rockingham and Rockbridge counties, Va.

Professor Ira Sayles was assigned to the northeastern part of Tennessee, and adjacent portions of Virginia and Kentucky. The early part of July was spent by him in the examination of the caves near

Clinch River in Virginia. He next examined the coal-beds on Big Yellow Creek in Bell county, Ky., and the Dyestone iron-ore beds a few miles farther down Poor valley. The following month the work on Clinch River was continued in Hancock county, Tenn., especially with the object of ascertaining and more accurately defining the extent and direction of the faulting so well displayed in that section. The upper coal-measures were also examined, and a running field-chart of the county made. In the latter part of the month, Professor Sayles discovered some very interesting cave-deposits in a quarry in Hawkins county, Tenn. The formations of this county were carefully studied during September and October, and large collections of fossils obtained. The latter part of October found Professor Sayles at Knoxville, in accordance with his orders, to examine the vicinity of Knoxville and Centreville for Potsdam fossils to supplement Mr. Walcott's paleontologic work. He was engaged in this region through November and December.

Topographic work in eastern Tennessee. — With a view to facilitate future geologic work, the division for the topographic survey of the southern Appalachian region was organized upon a considerably enlarged scale for the season of 1883. As already noted in *Science*, five topographic and two triangulation parties were put in this field.

Topographic party No. 3, in charge of Mr. Frank M. Pearson, was assigned to the valley of East Tennessee. The territory covered by his party includes about five thousand square miles, lying between parallels 36° and 36° 35′, and between meridians 82° 15′ and 84° 30′. This area is the northern half of the valley of East Tennessee; extending from the summit of the Cumberland Mountains and Cumberland plateau, on the north and west, to the summit of the Smoky Mountains, or state line between North Carolina and Tennessee, on the south and east. The topographical character of this region is such that the methods of work employed in the west had to be somewhat modified. It was necessary to carry on a considerable part of the work by means of compass meander-lines; and the rapidity of this class of work, and of the triangulation, was seriously interfered with on account of the dense timber which prevails everywhere, and by the atmospheric conditions, which are rarely favorable for clear views of any great extent. The prominent topographical features are peculiar. Almost the entire main valley is occupied by parallel ridges, that have their origin in south-western Virginia, and run in a south-westerly direction through Tennessee, and into Alabama and Georgia. In this, of course, the drainage system is simple, the larger streams, with few exceptions, being confined by the ridges which enclose their head waters.

The Bays Mountain, consisting of a great number of these parallel ridges, or mountains, as they are wrongly called, constitutes the divide between the Holston River on the west, and the Nolachucky and French Broad Rivers on the east. In the vicinity of this mountain, and on either side, the drainage is almost entirely underground, the water flowing through and in the limestone strata that underlie this region. This renders the tracing of the streams a difficult matter. The minor drainage collects in numerous sink-holes, which occur on the broad divides from which the streams flow in underground channels, and come to the surface again in unexpected places, and frequently at considerable distance from the point of disappearance. A striking example of this kind of drainage is seen in Mossy Creek, which is also interesting from the luxuriant growth of confervoids and moss with which its bed is covered. This stream rises on the north slope of Bays Mountain, and, after a course of three miles, disappears, and is not seen as a surface-stream for a distance of seven miles, when it re-appears, and flows for three miles to its junction with the Holston River. Five miles from the source of the stream there is a so-called sink-hole, which is six hundred feet in length and of unknown depth. A ninety-foot pole does not touch the bottom. This is really a surface appearance of the stream. A saw-mill was located on the creek a short distance above the first point of disappearance; and the people of the country have frequently noticed that slabs and saw-dust from the mill would rise to the surface in this sink-hole, then disappear, and come to the surface again in Mossy Creek, three miles above its mouth, where it rises for the last time.

Mr. Pearson says that the topographical unity of the ridges and valleys is not recognized by the inhabitants of the country, and hence some confusion has arisen. To the same ridge or valley, often only fifteen or twenty miles in length, as many as five different names are frequently applied; the universal custom being to re-name a ridge or valley whenever it is cut in two or crossed by a stream. This confusion of names also arises partly from the fact that no thorough or connected survey of the region has ever been made, although it is one of the earliest settled portions of the United States.

The natural water-power facilities of the Appalachian region have recently been the subject of much notice, and in this respect the valley of East Tennessee is unexcelled. There are in it many streams of considerable length, affording abundant water-power, that are not indicated on even the best existing maps of the region. Other additions and corrections of considerable importance have been determined by the work of Mr. Pearson.

PUBLIC AND PRIVATE INSTITUTIONS.

Museum of comparative zoölogy.

Arrangement of exhibition-rooms. — The exhibition-rooms are comparatively small, each one devoted to a special subject, but so combined, that, when taken together, they illustrate the animal kingdom as a whole, in its general relations and in its geographical and paleontological range and distribution. They are intended not only to meet the wants of the public at large, and of beginners as well as of more advanced university students, but also to promote research by giving assistance to specialists and original investigators. Meanwhile the work of the mu-

seum proper should be in charge of assistants whose duties are so arranged as to leave a good part of their time free for original research; the museum as a whole forming an important branch of the natural-history department of the university, with which its assistants and professors are intimately connected.

An enumeration of the contents and uses to which the space is devoted will give a better idea of the aims of the museum than a lengthy description.

Exhibition-rooms.

Synoptic room: synopsis of the animal kingdom, living and fossil.

Five systematic rooms for the systematic collections of mammalia, birds, fishes, mollusca, radiates, and protozoa; and their galleries for reptiles, insects, and crustacea.

Seven faunal rooms and galleries: North American, South American, African (including Madagascar), Indian, Australian, Europeo-Siberian,[1] Atlantic,[1] Pacific.[1]

Four rooms for the paleontological collections.

Two rooms for the paleozoic, one for the mesozoic, and one for the tertiary, as follows: Silurian and Devonian,[1] carboniferous and Jura,[1] cretaceous,[1] tertiary.[1]

The work-rooms for the assistants of the museum, and the storage-rooms, which are also intended as work-rooms of their special subjects, are distributed as follows, in addition to a large receiving-room and a general workshop: —

The alcoholic collections stored in the basement occupy four rooms devoted to fishes, two rooms for fishes and reptiles, one room for birds and mammals, one room for mollusca, one room for crustacea, one room for the other invertebrates.

The entomological department is to occupy eventually four gallery-rooms of the first story.

The work rooms and storage-rooms of the fifth story are filled by collections occupying five rooms devoted to birds and mammals, three for skins and eggs and two for skeletons, one for crustacea, one for mollusca, one for fish and reptile skeletons, one for the collection of dry invertebrates (corals, echinoderms, sponges, etc.), two for fossil vertebrates (exclusive of fishes).

[1] Not yet open to the public.

The remaining paleontological collections are crowded into four work and storage rooms. There are two work-rooms for the geological and lithological department. Four rooms are devoted to the library of the museum, and one room for the office of the curator. There are also a large general lecture-room, three laboratories for students in biology, three laboratories for students in geology and paleontology, with two smaller private rooms for the instructors. With the biological laboratories will be connected also a large room for an aquarium for both fresh-water and marine animals, and another room for a vivarium, both of which are in the basement of the building.

This will give, in all, seventeen rooms devoted to the exhibition of collections for the public; ten work and storage rooms in the basement, for the alcoholic collections; thirteen work and storage rooms for the dry zoölogical collections; eight similar rooms for the paleontological and geological collections; and thirteen rooms devoted to the laboratories, lecture-rooms, and library connected with the instruction given at the museum; the arrangement being such, that, whenever any departments (as, for instance, the geological and geographical, or the anatomical, or any other) outgrow their present quarters, room can be made for them by extensions of the building, for a long time to come, without interfering with the plans which have been carried out thus far.

In adopting a small unit for the size of the rooms (30×40 feet), all attempts at exhibition-rooms, imposing from their size, were deliberately abandoned. It is aimed only to place before the public such portions of the collections as shall become instructive; and in the storage and work rooms the appliances for storage aim at economy of space, and are intended, while they do not neglect the careful preservation of the collections, to give to the assistants and students the freest and quickest possible access to them.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Cambridge entomological club.

Feb. 8. — Mr. G. Dimmock called attention to some curious habits of the common European earwig, Forficula auricularia, a specimen of which he had kept in confinement several months. These insects are omnivorous, but apparently prefer insects as food, eating their own species greedily. Although to all appearances blind, except to the presence or absence of light, the specimen above mentioned captured fleas (Pulex irritans) with ease in an enclosure about five centimetres in diameter. No notice was taken of a flea put in the enclosure until the flea actually touched the earwig, when the latter would rush after the flea, palpitating with the antennae rapidly, and thus keeping on his track. If the flea escaped from beneath the antennae of the earwig, the latter would find him again in a moment, and the amusing chase would be renewed, to end in the sure seizure of the flea in the mouth-parts of the earwig. The earwig was a glutton, and would often eat a large number of fleas or other insects in succession, at the end of his repast his abdomen being much distended. —— Mr. S. H. Scudder exhibited a specimen and drawings of an arachnid from the coal-measures of Arkansas. Two years ago Karsch figured a similar form from the coal of Prussian Silesia, under the generic name Anthracomartus, and Kušta has just described another from carbo-

niferous beds in Bohemia. This adds another to the many instances in which a new generic type of carboniferous arthropods had no sooner been announced as found on one continent than it was discovered on the other. The Arkansas species was obtained by Prof. F. S. Harvey of Fayetteville, and had not been in Mr. Scudder's hands a month before a second American species was found by Mr. R. D. Lacoe in the well-known beds of Mazon Creek, Ill.

Biological society of Washington.

Feb. 8. — Mr. W. T. Hornaday read a paper on the guacharo bird of Trinidad, describing the habits of the Steatomis caripensis as observed by him in one of the caves where it breeds. —— Mr. G. Brown Goode read a paper on the aims and limitations of modern fish-culture. Modern fish-culture he defined to be fish-culture carried on upon an immense scale, under the direction of men trained to scientific research, as distinguished from the old and insignificant method of fish-culture carried on by private enterprise. Its aims were shown to be, 1, to arrive at a complete understanding of the life-histories of useful aquatic animals, and the conditions under which they live; and, 2, to apply this knowledge so thoroughly that all fishes shall be brought as completely under control as are now the shad, the salmon, the carp, and the whitefish. The limitations of fish-culture were shown to be the same as those of scientific stock-rearing or agriculture. —— Dr. T. H. Bean made a communication upon an augmented development in the fins of a species of Siphostoma, exhibiting a specimen with a supernumerary anal fin. In the discussion of this paper, Mr. John A. Ryder remarked that this deformity was an attempt toward reversion to the condition of some remote ancestral type in which there was a continuous fin around the posterior portion of the body. —— Mr. C. D. Walcott exhibited a specimen of trilobite, Asaphus sp., in which twenty-six pairs of legs, and the mouth-parts also, were plainly to be seen; also a specimen of Maine granite containing fossil corals, probably of the Devonian age.

Philosophical society of Washington.

Jan. 19. — Mr. Israel C. Russell made a communication on the existing glaciers of the high Sierra in California. After showing the extent of the ancient glaciers of the region, and their relation to the topography, he described in detail the phenomena of the Mount Dana, Mount Lyell, and Parker Creek glaciers, closing his remarks with a reference to the literature of the subject. The Mount Dana glacier lies at the foot of a cliff on the north face of that peak, with an elevation of 11,500 feet above the sea. It is at the head of a deep cañon draining into Lee-Vining Creek, one of the tributaries of Mono Lake. It is approximately 2,500 feet long, and of somewhat greater breadth. Notwithstanding its small size, the distinction between the snow-ice of the *névé* and the solid greenish-blue ice of the glacier proper is clearly marked. Its planes of growth are indicated by a banded structure, — compact ice alternating with thin sheets of porous white ice and with dirt-bands. It is abundantly provided with crevasses, and has a terminal moraine visibly growing. The stones of the moraine show marks of attrition, and the lakelet fed by the outflowing stream is milky from suspended detritus. The Mount Lyell glacier is somewhat larger, and exhibits substantially the same characters. A portion of its surface is characterized by 'ice-pyramids.' These occur only near the foot of the glacier, where the surface is rapidly melting, and depend upon the power of superficial pebbles to rescue the ice immediately beneath them from the porosity elsewhere produced by insolation. The Parker Creek glacier, likewise at the head of a tributary of Mono Lake, resembles the others in its general features, and displays in addition a considerable number of 'glacier-tables,' — blocks of rock perched on standards of ice. A number of other glaciers were seen at a distance of a few miles, but were not visited. The various phenomena were illustrated by photographs.

Mr. Gilbert Thompson described certain glaciers on Mount Shasta believed to be new to science. Their discovery increases the number of known glaciers on the flanks of Shasta to seven. Mr. W. H. Holmes described the glaciers of the Wind River Mountains, and the glaciers of Mount Moran in the Teton Range. The former are from one-fourth of a mile to one mile in length. The latter are three in number, and lie at an altitude of 12,000 feet. Mr. Mark Kerr mentioned the occurrence of a glacier in the Salmon Mountains, a division of the Coast Range.

Prof. W. C. Kerr described the mica-mines of North Carolina, explaining their geological relations, and setting forth the economic and mineralogic results of their exploitation. He described more particularly a series of prehistoric excavations, which are large and numerous, and were evidently made for the purpose of obtaining the same mineral. One of these measures 150 by 75 feet, and, despite a partial filling with *débris*, retains a depth of 35 feet. The ancient work was performed with blunt-pointed tools, doubtless of stone; and facts connected with the arboreal vegetation show that it had been discontinued as much as five hundred years ago.

Scientific club, Manhattan, Kan.

Jan. 18. — Mr. Shartel presented some notes regarding the Suez and Panama canals and the Augsburg tunnel. Mr. Marlatt described a worm which he observed last year. Professor Kellerman made some interesting remarks respecting the occurrence of chlorophyll in animals. Superintendent Graham gave a description of some carvings on a rock in a cave in Greenwood county. These carvings were observed by Mr. Mason, and drawings which he made of them were exhibited. Mrs. Kellerman gave an interesting description of the Termites, or 'white ants.' She described their manners and customs, grades of society, architecture, political economy, and many other points. Mr. Lund read a paper on the undulations of the earth's surface. He cited numerous instances of elevations and depressions that are

taking place at the present time, as well as some of the more remarkable ones of past ages.

Cuvier club, Cincinnati.

Jan. 5. — In their annual report, the trustees stated that the club expended during the year $238.60 in the prosecution of the game-laws. The extension of the open season for quail through November was suggested as not likely to do injury; and attention was called to the continued pollution of waters, and the consequent destruction of fish. The necessity was urged of protecting the National park from the speculator, and such tracts as the Adirondacks from the wood-chopper.

Academy of natural sciences of Philadelphia.

Dec. 11, 1883. — In an account of the formicaries of the carpenter ant, the Rev. H. C. McCook related observations proving that the females of Camponotus pennsylvanicus, when fertilized, go solitary, and, after dispossessing themselves of their wings, begin the work of founding a new family. This work they carry on until enough workers are reared to attend to the active duties of the formicary; as, tending and feeding the young, enlarging the domicile, etc. After that, the queens generally limit their duty to the laying of eggs, and are continually guarded and restricted in their movements by a circle of attendant workers, or 'court.' The facts are further illustrated and enlarged by a series of observations made by Mr. Edward Potts, in accordance with the speaker's suggestions and directions. They establish or confirm the following points: 1. The manner of depositing the eggs, which, as well as the larvae, are cared for by the queen until workers are matured; 2. The stages in the development of the egg and larvae are partially noted; 3. The time required for the change from larval to pupal state is about thirty days; 4. About the same period is spent in the pupal state, the entire period of transformation being about sixty days; 5. The work of rearing the first broods begins the latter part of June, or early in July; 6. About twenty-four hours are spent by larvae in spinning the cocoon; 7. The ant-queen probably assists the callow antling to emerge from its case; 8. Not only the larvae, but occasionally the antlings, are fed by the queen; 9. The young workers, shortly after emerging, begin the duty of nurses, caring for the eggs, and tending the larvae.

Jan. 1. — Professor Joseph Leidy exhibited specimens of tin ore from the Black Hills, Dakota. They consisted of a mass of granite containing cassiterite, a fragment of quartz with the same, and a mass of pure cassiterite of about one-pound weight. He had also seen several pounds of large grains obtained from gold-washings. From among these he had picked out several characteristic crystals.

NOTES AND NEWS.

THE death, last Friday, of Professor Arnold Guyot of Princeton, removes one more of those distinguished men of broad scientific culture, who, nurtured in Europe, have given the best fruits of their lives to America. His influence on the young men under his teaching was second only to that of his devoted friend and countryman, Agassiz. We shall speak more at length of his life and characteristics in a future number.

— It will be a source of pleasure to those who are aware of the reliable and conscientious character of Dr. Joseph Leidy's contributions to science, to learn that he has been awarded by the Geological society of London the 'Lyell medal,' with its accompanying purse of twenty-five pounds, in recognition of his important services to paleontology. In a letter received from Warington W. Smith, foreign secretary of the Geological society, dated Jan. 25, Dr. Leidy is advised of the award, and requested to depute some fellow of the society to receive the same at the anniversary meeting to be held on the 15th inst., for transmission to Philadelphia.

— The fourth volume of the census reports has been issued from the press. This is upon the 'agencies of transportation,' and includes the statistics of railroads, steam-navigation, canals, telegraphs, and telephones. Naturally the first of these subjects takes up the bulk of the volume, monopolizing 651 pages out of a total of 869. The statistics and discussion of this subject, as well as of telegraphs and telephones, have been prepared by Mr. A. E. Shuman, whose thorough acquaintance with the subjects, and whose painstaking care, are amply illustrated by the reports in question.

The total railroad mileage in operation on June 1, 1880, is given as 87,781 $\frac{97}{100}$. This was under the management of 631 corporations. The total cost of construction was $4,112,367,176, and of equipment, $418,045,458. The assets of the whole system amounted to $5,536,419,788, and the liabilities, $5,425,722,560. The paid-in capital stock aggregated $2,613,606,264, over 80% of which earned a profit at an average rate of $6\frac{32}{100}$%. The total number of stockholders (estimated, in part) was not far from 300,000, giving an average of $8,700 of stock to each. The aggregate freight mileage was 32,348,846,693, and the passenger mileage, 5,740,112,502. To illustrate the amount of railroad travel, it may be said that this represents an average travel of 114 miles for each man, woman, and child in the country. The above figures, when contrasted with those representing the condition of the railroad interest in this country at the close of 1882, show an immense growth during the two years and a half. At the latter date there were in operation not fewer than 117,717 miles, an increase of 29,835 miles, while the capital had increased in approximately the same proportion. At that date the total railroad mileage of the globe is given (Spofford's Almanac) as 264,826, of which this country owned over 44%. The total of all Europe was less than that of the United States, being but 105,895. The statistical tables of the report upon railroads contain, 1°, a general financial exhibit of the several roads; 2°, a general balance-sheet; 3°, traffic operations; 4°, passenger and freight mileage; and,

5°, equipment and employees. A second portion of the report relates to the physical characteristics of the roads, with statistics regarding the history of construction, grades, curves, roadway, and tracks. This is followed by an analysis of the funded debts of railroad corporations, and by a statement regarding the amount and kind of fuel used. The report concludes with a condensed statement of the agreements existing between different railroad companies, and between these companies on the one hand, and express and sleeping car companies on the other.

The report by Mr. T. C. Purdy, upon steam-navigation, opens with a history of that subject, in which the progress of development of the species, the highest type of which is our ocean-going steamship, is briefly sketched. The tables show the number, tonnage, value, capital invested, service, and traffic of our steam-craft. The report upon canals, by the same author, opens with a history of canal construction in this country. Many persons at the present day will doubtless be surprised to learn the extent to which this class of internal improvements was pushed during the period between 1825 and 1840. The total length of canals constructed in this country was $4,468\frac{6}{10}$ miles, costing $214,041,802. Of this, $1,953\frac{6}{10}$ miles have been abandoned, and a large part of the remainder is not paying expenses. The statistics connected with this report give financial statements, date of construction, dimensions of canals, and the number and dimensions of locks.

The report upon telegraphs opens with a brief discussion of the statistics. The tables contain a general financial exhibit, a statement of volume of business, number of employees, and description of lines. The report upon telephones is of a very similar character. In regard to this, it should be borne in mind that the telephone was in its infancy during the year to which the statistics refer, and that its use has increased enormously during the years which have elapsed since. Following this report is a paper upon the postal-telegraph service in foreign countries, which cannot fail to prove of great interest at this time, when the question of a government telegraph is being actively agitated in this country. This report has been compiled by Mr. Robert B. Lines, mainly from information received from the heads of the departments of postal telegraph of foreign countries through our representatives. It details the history of the postal telegraph in each country where it exists, sketches the methods of business management, and compares the administration by the government with that by private hands, both as to cheapness and efficiency. The following countries support telegraphs which, either wholly or in part, supplant private undertakings: Great Britain, Germany, France, Austro-Hungary, Russia, Switzerland, Belgium, Netherlands, Sweden, Norway, Denmark, Portugal, Roumania, Turkey, Brazil, Japan, Canada, and New Zealand, — in short, nearly every civilized country. In most cases the telegraph has been the property of the state since its introduction, but in a few cases the property has been purchased from private owners. This was the case with Great Britain, who bought out the telegraph companies in 1870. The price paid for the property was based upon the net earnings in the year ending June 30, 1868, by capitalizing that amount at five per cent. The transfer from private to public hands has been found to be advantageous; as not only have the rates been largely reduced, but this department has been more than self-supporting, having earned in twelve years (from 1870 to 1881 inclusive) the sum of £1,996,996. This, however, need not be a matter of surprise; as the uniform rate for twenty words is one shilling (twenty-five cents), and threepence for each additional five words or part of five words. As compared with the rtaes of private corporations in this country, these rates are but little lower for equal distances, while, if we consider the greater density of population and the vastly greater volume of business done in England, it would seem that these rates are relatively quite as high. In most of the continental countries rates are less; and, in all cases where the statistics are given, the expenses of the department have been greater than the receipts.

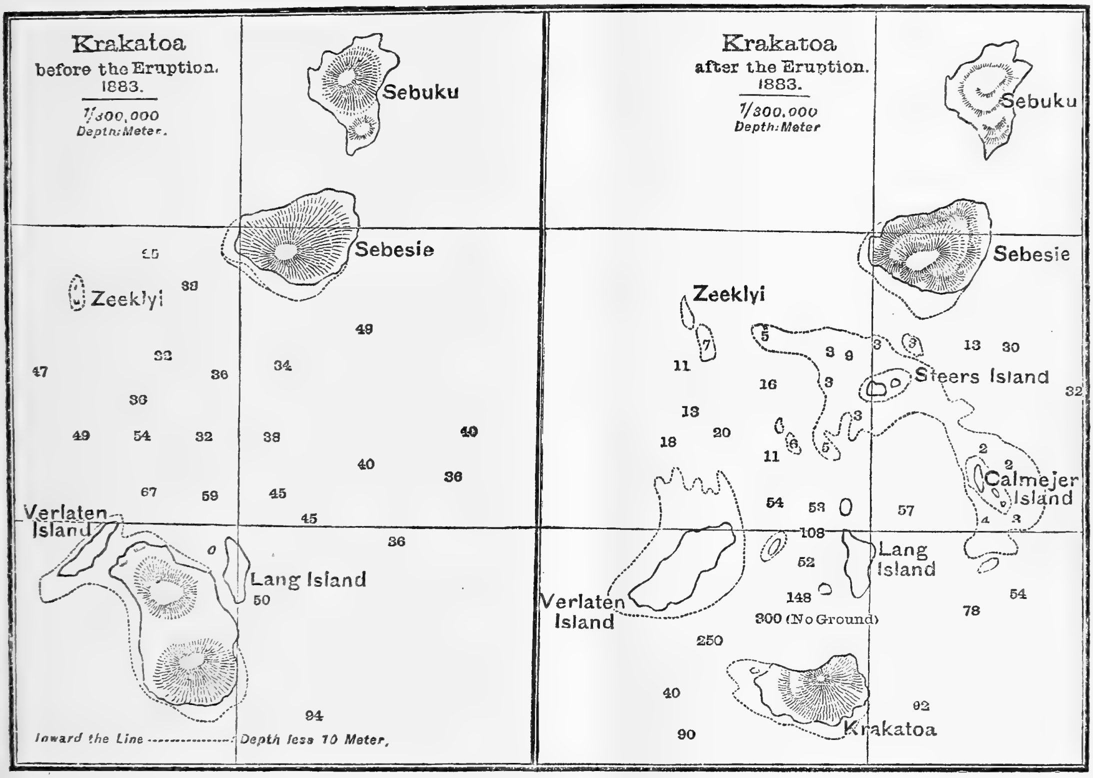
The volume has a very full general index.

— Wedenskii states (*Centralbl. med. wiss.*, 1883, 465) that he has been able to demonstrate the presence of the negative variation of the natural nerve current in a stimulated nerve by means of the telephone in a way similar to that described by Bernstein and Schönlein for the muscle. The quality of the 'nerve-tone' obtained does not differ from that of the telephonic muscle-tone. When, by tying a string around it, the physiological continuity of the nerve was destroyed, the peculiar nerve-tone caused by interruptions of the negative variation current disappeared, while that caused by unipolar action, and of a purely physical origin, could still be heard. The latter tone, however, could be distinguished from the true physiological nerve-tone both by means of its peculiar quality and by the fact that it required a greater strength of stimulus for its production than the former. Chemical and mechanical stimulation were also tried, and in each case a definite noise was heard. When the nerve was stimulated by means of a constant current, a peculiar noise was heard, in accordance with the law of contraction, either at the opening or the closing of the current.

— E. and F. N. Spon announce A pocket-book of electrical tables, for the use of electricians and engineers, by John Munro and A. Jamieson; Absolute electrical and magnetic measurements, reprinted from *Nature*, by A. Gray; Handbook of sanitary information for householders, by Roger S. Tracy.

— The deaths are announced of Mr. Hugh Powell, the first English optician to construct objectives on the water-immersion principle, and one of the founders of the Royal microscopical society, of whom only five now remain; and of the venerable Professor Sven Nilsson of Lund, known for his zoölogical work and his investigations on the prehistoric inhabitants of Scandinavia.

—A correspondent of *Nature*, who has evidently had a good opportunity to study the results of the Krakatoa eruption, and has made soundings in the neighborhood, writes, that instead of the sixteen new volcanoes which were at first reported, and the total destruction of Krakatoa, there is still a considerable portion of the island, and that the greater part of the destruction seems to have come from the wave produced by the eruption and the fall of the masses of material which were thrown from the northern portion of the island. Krakatoa at its northern end now rises in a steep wall eight hundred metres high; and,



where was once land, soundings of three hundred and sixty metres have been made without finding bottom. A large portion of this material appears to have been deposited a few miles to the north, as shown in the map, by the new islands of Steers and Calmejar, and the shoals to the north of Lang Island, which seems to have been about on the line between the upheaval and downfall, and has not been changed materially in size. All the islands are covered with ashes; the destruction of life having been nearly complete, even in Sebuku, the first patches of green showing themselves on the small islands farther north.

—Professor Richard Owen has ceased to be a commoner, having been knighted by the Queen. A banquet was given him by his colleagues on the 21st of January, as a sort of farewell celebration on the event of his resigning the superintendency of the natural-history section of the British museum. Although about eighty years of age, he is still vigorous, and reads papers before the learned societies at nearly every meeting. The establishment of a natural-history museum was long an object for which he toiled. Over twenty years ago he published an address 'on a national museum of natural history,' in which he stated his view relative to the need for, and the proper organization of, such an institution. The new museum is in a large degree the result of his labor.

—The annual course of lectures given under the auspices of the University of Pennsylvania consists this year of The development of the house, by Rev. R. E. Thompson; Why doctors exist, and how they work, by H. C. Wood, M.D.; First aid in emergencies, by J. W. White, M.D.; Order and progress, by Mr. A. S. Bolles; The romance and realities of animal locomotion, by Mr. E. Muybridge; A glance at the lowest forms of life, by J. Leidy, M.D.; Chemistry in the industrial arts, by Mr. S. P. Sadtler; The creation of an empire, or, The life and work of Count Otto von Bismarck, by Mr. E. J. James; Relation of American forests to American prosperity, by J. T. Rothrock, M.D.; How electricity is measured, by G. F. Barker, M.D. The course began Jan. 11; and a lecture will be given every Friday evening till March 21, except on Feb. 22.

— Charles Scribner's Sons announce an important book, by Professor Arnold Guyot, entitled "Creation; or, The biblical cosmogony in the light of modern science."

— The Pilot chart of the North Atlantic Ocean for February shows a smaller number of wrecks than were given on that of last month. The thick scattering of wrecks along our coast from Cape Hatteras to New York, and on the January chart farther north, as compared with those charted on the European coast, attracts immediate attention, but may be due to the more complete information received by the hydrographic office from vessels entering American ports, rather than to greater carelessness or recklessness on the part of American navigators.

— Dr. H. Laspeyres has been appointed professor of mineralogy in the university at Kiel, and Dr. F. Kurtz of Berlin, professor of botany at the university at Cordoba in the Argentine Republic.

— Over a million visitors passed the turnstile of the South Kensington museum during 1883; and since the opening of the museum in June, 1857, the number of visitors is stated to have been 22,675,912.

— The course of 'practical lessons' in anthropology, of the Parker memorial science class, began Jan. 6, and will continue to March 30. Among the subjects of the essays to be discussed we find 'Infant education,' 'Language and its evolution,' 'Heredity,' and 'Allopathy *vs.* homoeopathy.'

— The annual watch-trials undertaken at the Yale college observatory for the encouragement of horology are now in progress, and watches or marine chronometers whose record is to appear in this year's observatory report will be received not later than April 15. The report is published the latter part of June. Full particulars of the conditions of the watch-trials will be furnished upon application to the secretary of the observatory.

— Dr. Benjamin Sharp has been appointed professor of lower invertebrata by the council of the Academy of natural sciences of Philadelphia. Dr. Sharp is a graduate of the University of Pennsylvania, from which he received the degrees of Doctor of medicine and Doctor of philosophy in 1881. He afterwards studied under Leuckart in Leipzig, and under Semper in the University of Wurzburg. He took his degree from the latter after presenting a thesis in German on the anatomy of Ancylus. A translation of this memoir has been published in the proceedings of the academy, and is considered an important addition to our knowledge of the group of animals described. Dr. Sharp was granted the privilege of studying at the Bavarian table in the Zoölogical station at Naples, an honor rarely granted a foreigner. Dr. Sharp proposes delivering lectures, during the coming spring, on the lower forms of life. The course will, in some degree, supply the lack of biological instruction in Philadelphia, which has recently been the subject of public comment.

— Barnum's 'white elephant' arrived at the Zoölogical gardens on Jan. 17, since which time it has attracted much attention. To call the elephant 'white' is certainly to use that term in a very broad sense. The general color of the animal, which is a male about seven feet high, is a light gray, perhaps a shade lighter than is usual. The only parts which approach white are the tips of the ears, the breast, a space in front of and behind the eyes, the middle of the forehead, and a space under the ears. The color in these regions is a sort of dull fleshy tint, although the blotch on the forehead has a brownish tinge. The blotches are very irregularly margined, and plentifully sprinkled with small spots of the normal gray of the body. A much more remarkable feature than these slight irregularities of color is the length of the tail: the tuft at its extremity all but touches the ground. The elephant appears to be in excellent condition, and has fine pointed tusks.

— Upon the resignation of Professor (now Sir) Richard Owen from the superintendency of the British museum, the trustees of that institution have unanimously chosen Professor William H. Flower, LL.D., F.R.S., F.Z.S., etc., to be his successor. In accepting this position, Professor Flower will probably sever his connection with the Museum of the Royal college of surgeons, of which he has been for a number of years the conservator. In the latter position he also succeeded Professor Owen.

The election of Professor Flower to the prominent and responsible post of superintendent must be regarded as a very happy occurrence. His numerous contributions to mammalogy (especially to the knowledge of the cetacea) and to other branches of zoölogy entitle him to the high rank which he holds in England and throughout the scientific world. His administrative ability is amply displayed in the perfection to which he has brought the arrangement of the collections of the Royal college of surgeons.

The keepers of the several departments of the Natural-history museum who are next in rank to the superintendent are as follows: keeper of zoölogy, Dr. Albert Günther; assistant, Arthur G. Butler; keeper of geology, Dr. H. Woodward; assistant, R. Etheridge; keeper of mineralogy, L. Fletcher; keeper of botany, W. Carruthers.

Professor Flower is at present engaged in the preparation of a series of lectures on anthropology, to be delivered in the coming spring; in the publication of a complete catalogue of the collection of the College of surgeons; and of numerous scientific papers of importance, notably, one upon the Delphinidae.

— The sixth fasciculus of Dr. Fisher's *Manuel de conchyliologie* has appeared, carrying the work from Siphonaria, through the opisthobranchs, nucleobranchs, and to the beginning of the prosobranchs, including the Toxoglossa and Rhachiglossa as far as the Volutidae. The character of the work is fully maintained, or, if any thing, becomes more satisfactory as the better-studied groups are taken up. About three-fifths of the work has now appeared.

— *Papilio*, a journal devoted solely to Lepidoptera, and published for three years as the organ of the New-York entomological club, under the superintendence of Mr. Henry Edwards, is to be transferred to Philadelphia, and edited by Eugene M. Aaron.

SCIENCE.

FRIDAY, FEBRUARY 22, 1884.

COMMENT AND CRITICISM.

It was an old theory, taught in text-books of philosophy, that the conclusions of mathematics were absolutely certain, — quite exempt, in fact, from that liability to error which so troubles our conclusions on other subjects. Yet disagreements among mathematicians upon the demonstrable results of their science, even if rare, are not wholly unknown. A remarkable case of this sort is now seen in a discussion which has been going on since last summer in the Royal astronomical society of London. Mr. E. J. Stone, president of the society, and director of the Radcliffe observatory at Oxford, informed the society that he had detected a serious error in the astronomical measurement of time, arising from the substitution of Le Verrier's tables of the sun in the *British nautical almanac* in 1864 in place of the old ones. To this cause, he claimed, were due certain extraordinary errors in the tables of the moon, which had perplexed astronomers for the past ten years. At the same time he communicated to the Royal society an extended memoir, in which he gave several elaborate demonstrations of his views.

These papers no sooner appeared than the new theory became the object of attack on all sides. Such astronomers as Airy, Adams, Cayley, and Christie, in England, as well as their French neighbors, published elaborate refutations, showing that Mr. Stone was wholly mistaken. His carefully prepared memoir was refused admission to the Philosophical transactions. If mere numbers or authority could have settled the question, Mr. Stone would have been crushed; but he has so far maintained his ground against his numerous opponents with a perseverance which we cannot but admire, how little soever we may share his views. After going on for eight months, the discussion seems to be as lively as ever. Its most curious feature is, that the questions involved are purely mathematical. The new tables of the sun make the year shorter than the old ones by about one and a half seconds. Mr. Stone claims that the unit of time is changed by this same amount; that is, that we are using a new measure of time, which is gaining on the old one at the rate of three seconds every two years, so that it has gone ahead thirty seconds since 1864. His opponents claim that this is absurd, since it is not the year, but the day, which is taken as the fundamental unit; and the change in the length of the day is totally inappreciable. As yet, the dispute shows no signs of approaching its end.

It is stated that the outlines of the plan for the Greely relief expedition, approved by the Navy department, are practically as follows: the relief party to go north in two vessels, reaching Upernavik not later than May 15; thence to Littleton Island, endeavoring to open communication with the Eskimos at Cape York. A depot with one year's supplies, coal, clothing, boats, and a steam-launch, should be established at Littleton Island by the first ship, and left in charge of an officer and two men. This vessel would then approach the borders of the pack, and push northward at the first favorable opportunity; the second vessel to cruise about the edge of the ice, and hold herself in readiness to establish another depot on shore in case the first vessel be lost, and the second required to proceed northward in her place. Should Smith Sound be comparatively open, the first vessel will proceed to form secondary depots at or near Washington Irving Island, Cape Collinson, and Carl Ritter Bay; the second, after making a depot at Cape Sabine, to proceed north not farther than Dobbin Bay, unless required by disaster to the first vessel.

In the latter case, before proceeding farther, the second vessel is to land her house, two boats, and a year's supplies for the whole party, in the vicinity of Dobbin Bay. Should both vessels avoid disaster, yet not succeed in communicating with Greely, one is to winter in Franklin Pierce Bay, and the other near Littleton Island. The coast is to be examined on the way north, and cairns enclosing notices of the relief party's plans established at prominent points on both coasts. The naval vessel or tender is to go as far as Littleton Island or Cape Sabine. Whalers and sealers are to be asked to keep watch of the ice-floes for any drifting party. It is also suggested that an advance ship be sent up still earlier, if possible, to relieve the Greely party, if by any chance they should have reached the Danish settlements or the entrance of Smith Sound. It is stated that Commander W. S. Schley, U.S. N., has been selected to take charge of the expedition.

In many respects this plan seems well considered, and, in proper hands, likely to succeed in the desired object. It may be doubted, however, if the projectors fully realize the inadvisability of too great haste in attempting to proceed northward of Littleton Island, or the strong probability that no satisfactory opportunity for northward progress will occur in the natural course of things much before the end of July. Nothing would be easier than to grind up two or twenty of the strongest ships by pushing them into the pack too early. On the other hand, a proper method of early relief preceding the time of navigation — namely, by small coastwise boat and sledge parties combined — does not seem to have received any consideration in the report. Such parties would be much more likely to get early information than any number of vessels entangled in the floes off shore. It is certain, from all previous experience, that the chances are greatly in favor of finding the party on the western shore rather than on the Greenland coast. The probability of their having been able to reach Littleton Island is infinitesimal. We hope, that, in addition to the government expedition, a large reward will at once be offered to any one who may succeed in rescuing the party. This would enable private parties to make their preparations for such an attempt before all the whalers and sealers have left port, would greatly increase the chances of a rescue, and would put all parties on their mettle. To neglect this precaution would be almost criminal.

The destruction of the forests is frequently assigned as an efficient cause of freshets. But all the primeval forests which covered the head waters of the Ohio did not prevent freshets, nor could they under certain combinations of circumstances. A wide-spread storm, with heavy rain on frozen ground and snow, such as to raise all its tributaries at once, must inevitably cause a flood. The floods of early days were of longer duration than those of to-day, by reason of the forests standing upon the river-bottoms and adjacent banks, which became filled with matted drift-wood, forming a tangled mass which obstructed rapid flow, and through which the water found its way but slowly. The most serious effect of the denudation of the land is the increased erosion to which it is exposed, by which the fertile soil, unprotected by vegetation, is swept by the rains into the rivers, and lost. The magnitude of this loss, and the great erosive effect of water on the clay soil of the west, can only be realized by those who have observed the tawny floods, thick with mud, which flow through the deep and wide valleys which the western rivers have cut in the soft earth.

In bright lands like Australia, where sunshine is sometimes so prevalent as to give rise to complaint, it would seem that the advent of the rain-doctor should cause no alarm. Mr. Russell, the government astronomer of New South Wales, has, however, gone a long way toward discouraging the endeavors of this well-minded individual, notwithstanding his offer to work reasonably, as it will appear to some, with nitroglycerine, with cannon, with elec-

trical machines, with kites, etc. But Mr. Russell predicts his speedy loss of position in the modern social scale, if, having no correct understanding of cause and effect, he pretends to pull down the clouds with a wire, or frighten them with a few crackers. In this habit of belief, apparently so thoroughly ingrained in human nature, that a comparatively slight artificial commotion in the atmosphere is enough either to bring rain out of a clear sky, or to superinduce a calm in violent storms, there is, it must be confessed, something akin to the popular conception of homoeopathy. But in countries other than Australia it may be possible that the necessary condition of unstable equilibrium is more frequently attained, when artificial rain might be a matter of easy production. For Australia, however, there can be little doubt that Mr. Russell is in the right; and when, as he remarks, so many proposals are put forward, some even going so far as to propose that his government should take to cannonading the sky, it is time that some one took the matter up.

THE Philadelphia papers are vigorously discussing Dr. Harrison's plan for a biological institute in that city, and the outlook for it appears favorable. The only exception that has been taken to the plan has been doubt as to the desirability of creating an independent institution, when the work might better be intrusted to the already existing academy or university. This is comparatively unimportant: what is essential is a separate and ample endowment in safe hands. Yet it must be said, that neither of those establishments carries on its work primarily for the training of *investigators*, which is the special aim of the proposed institute; and such an institute Philadelphia absolutely requires, if it would not lose the position it has long held in American science. The academy certainly has neither room nor funds for the purpose; and being at this moment before the public, asking for a large sum of money for building-purposes, only to carry out more fully work in which it has long been engaged, it would be hampered rather than aided by the partial endowment which would probably result for either purpose.

THE legislatures of Virginia and Maryland, stirred by the approaching failure of the oyster-crop, are moving for protection for the beds in apparent good faith. Something will doubtless be done; but the devastation has gone so far, that no immediate improvement can reasonably be expected.

RETURNING to the question of the use of copper as a prophylactic in cholera cases, so much discussed during the recent Egyptian epidemic, Mr. Vulpian presented a note to the French academy, at a recent meeting, written by Mr. Axel Lamm of Stockholm. Mr. Lamm states, that it is a fact that the workers in the copper-mines of Fahlun, in Dalecarlia, did escape during the epidemic of 1834. Judging by this, plaques of copper were tried as a remedy, placed on the stomachs of the patients in the cholera hospitals. The only result was the formation of verdigris if the plaques were not properly cleaned, and consequent ulceration from its caustic action. Fahlun has escaped five or six times, however, when Stockholm has not; and Mr. Axel Lamm suggests the possibility of the great amount of sulphuric-acid gas in the air being the reason, but he has not as yet made any further investigations.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Macrospores in the rocks about Chicago.

SINCE submitting the committee's report on this subject (see p. 237) to the Chicago academy of science, I have continued the investigation of drift material in this vicinity, and from other parts of the northwest. So far as examined, all of the clays on the west shore of Lake Michigan, from Kenosha, Wis., on the north, to the Indiana state line on the south, contain an abundance of the disks, or macrospores, referred to in that paper, both free in the clay and *in situ* in fragments of shale. These clays range from some seventy feet above the level of Lake Michigan to (I am advised) over two hundred feet below its surface.

In the examination of clays from other localities, I get some very unexpected results. In several specimens of 'blue bowlder clay' kindly sent to me by Prof. N. H. Winchell, state geologist of Minnesota, and "taken from fourteen to twenty-one feet below the surface, when digging a well at Litchfield, Meeker

county, Minn.," I find an abundance of macrospores, besides several species of fossil rhizopods, fragments of Diatomaceae, and other organic remains, and several species of well-preserved and characteristic Foraminifera, — among others, Textularia globosa and Rotalia globosa as identified by Professor Joseph Leidy, who advises me that these forms are yet living and common in the Atlantic Ocean. A disk form with crenate margin, much resembling the lorica of an infusorian, is quite abundant, and large quantities of forms and fragments not yet identified. I presume that these fossils are mostly derived from the cretaceous formations, of which the Minnesota clays contain large amounts.

From careful observation and comparison, and the great similarity of much of the contents of the Minnesota clays with what I find associated with the macrospores found here, I am confident that I shall yet find in the Minnesota clays, mingled with the Foraminifera, etc., of the cretaceous formation, the shale and macrospores of the Devonian.

All of the fossils yet identified in the Chicago or Minnesota clays are undoubtedly of marine origin.

B. W. THOMAS.

Chicago, Feb. 11.

Rare Vermont birds.

The work of collecting material for a list of Vermont birds has revealed some notes of particular interest to ornithological students. Quite a number of rare or hitherto unobserved species have been found to be regular summer visitors in certain localities.

The orange-crowned warbler (Helminthophaga celata Say, Bd.), a rare straggler to New England, has been detected breeding in small numbers at Island Lake, Mount Killington, and at Lake Bomoseen in Castleton. In the latter locality, also, the blackpoll warbler (Dendroeca striata Fonst.) is a common summer resident. A specimen of the rare Connecticut warbler (Oporornis agilis Wils., Bd.) was taken at Rutland, April 24, 1879. This is probably the first published record north of Massachusetts. At Burlington I noted several flocks of the Bohemian waxwing (Ampelis garrulus L.), Nov. 25, 1882, and Jan. 21, 1883.

The loggerhead shrike (Lanius Ludovicianus L.) is a regular resident in certain districts in summer. Several nests have been found at Brandon, Rutland, and elsewhere.

White-winged crossbills (Loxia leucoptera Gm.) come frequently in winter, and some are known to breed. The discovery of two nests with young, at Lunenburg, March 22, 1878, by Mr. W. E. Balch, is notable.

The pine linnet or American siskin (Chrysomitris pinus Wils., Bp.) was found nesting at Rutland, May 15, 1879; and Mr. D. C. Worcester discovered two of their nests at Hartland. One was built in a pine in his yard, and commenced in March: the other was in a spruce, and contained young birds by the first week in April.

The black-backed three-toed woodpecker (Picoides arcticus Sw., Gr.), known generally as a casual winter visitor to New England, was found in the capacity of a resident at Lunenburg, where the nests were taken June 1, 1880, and May 29, 1882.

A nest of the American avocet (Recurvirostra americana Gm.) was recorded at Rutland in the spring of 1882; and the Florida gallinule (Gallinula galeata Licht, Bp.), of southern extraction, breeds at Castleton, where several of the birds have been secured. A specimen of the common cormorant (Phalacrocorax carbo L., Leach) was shot on Lake Champlain, and is now in possession of Mr. Jenness Richardson of Rutland, upon whose valuable observations many of these notes are based.

Of the sooty tern (Sterna fuliginosa Gm.), another rare straggler from the south, two specimens have been recently taken in Vermont, — at Rutland and Larrabee's Point, Lake Champlain. Of the still rarer short-tailed tern (Hydrochelidon lariformis L., Coues), Mr. Richardson saw three individuals on Lake Bomoseen, Castleton, one of which he secured.

The sea-dove or dovekie (Alle nigricans Sink), a winter waif from the arctic regions, has been known to occur but once in the state. This was at Sharon, where it was found one morning in the autumn in a gentleman's porch.

Several other birds might be mentioned whose presence here, or in the New-England States, is casual and infrequent. About two hundred species have thus far been noticed within the borders of the state, and it is likely that future observations will largely increase the number.

FRANCIS H. HERRICK.

The red skies in the Pacific.

Only last week I learned from Hon. H. M. Whitney, postmaster-general, that on Sept. 5, Mrs. Whitney and himself distinctly observed the sun's disk, before setting, to be green. His residence is an exception to most of ours in Honolulu, from which trees cut off the view of the horizon. My wife spoke much that night of a strange green cumulus, seen by her ten minutes before calling me to observe the portentous masses of color pouring out all over the sky.

I beg special attention to my remark in the *Hawaiian annual* upon the 'earth's shadow sharply cutting off' the upper rim of the first-glow: —

> "One marvellous effect is often a sudden appearance of thick luminous haze where a minute before all was pellucid, unsullied blue. Meantime the glow especially gathers and deepens above the western horizon along a line of 60 degrees until the whole occident is a uniform sheet of flaming crimson, shading up into lilac and orange. Down upon that creeps the dark earth-shadow, sharply cutting off the edge of the blazing sheet, often serrated with the shadows of remote cumuli. As the shadow descends, the glow deepens, until night has closed down upon it. At once on the darkened sky arises a secondary or 'after'-glow, repeating the same phenomena as the stars come out with almost equal brilliancy of effect. In this after-glow the defined shadow-line is lacking, and the deep fiery red above the horizon bears a singular resemblance to the peculiar reflection on the sky of some immense but remote conflagration. These appearances occur before sunrise with equal brilliancy, but in reversed order."

This effect was very manifest in the strong, heavy glows of September, showing clearly that the first glow reflected the sun's direct rays, while in the after-glow, which had no defined upper rim, but continued much longer, the haze reflects only the light of the first-glow. This bears upon estimates of the height of the haze.

Observers here are well agreed that during November there was a very great abatement of the glows, amounting almost to a cessation, although the whitish corona was always well developed through the day. Early in December the glows were renewed, and for six weeks continued with much uniformity, and quite as brilliant as in October. They are now somewhat abated, although quite uniform nightly. In September and October they were extremely unequal, as well as varying in position of greatest color north or south of west.

The bark C. Southard Hurlburt observed the glow on Sept. 3. She was dismasted in a cyclone, Aug. 18, and came to Honolulu for repairs. On the former

date she was in about latitude 17° north, longitude 125° west. The captain's wife, Mrs. Davis, described the phenomena to me as extremely brilliant.

S. E. BISHOP.

Honolulu, Jan. 30.

The Philadelphia biological institute.

The proposition of Professor Allen of the University of Pennsylvania for the establishment of an institution for the education of both sexes in biological science, is one that he, and many others like minded, have long hoped to see established in Philadelphia. Indeed, it was somewhat expected, when the large building-fund that enabled the Academy of natural sciences to put up its present elegant quarters was asked for, and generously subscribed to principally by the manufacturers of Philadelphia, that something of the kind Professor Allen asks for would be the result. The writer was principal of the school of design for women at the time the successful effort was being made for a new building for the academy; and well does he remember the promises that were then made as temptations to contributors. It may be that 'the representative members of the academy' think that the quite limited extent of the 'educational' plans that they have been pursuing is a fulfilment of the promises then made; and perhaps they are, as they understood it at the time. Yet do I feel quite certain, that if the gentlemen who so generously helped the academy then, and before that time, also were told that the controlling parties of the academy were to refuse to put the building and what there is therein to the use of extended scientific education, it would be to most of them, if not to all, a surprise. I do not mean to say that the academy people have refused to do so; but it looks, from your 'Comment and criticism,' as if something of that kind had been done. My long and intimate experience with 'representative members' of public educational institutions has impressed my mind strongly with the idea that those gentlemen fail to draw distinction enough between themselves and the schools they represent; and, being placed there to manage and direct, they too often seek to carry out *their own ways*, rather than consider broadly the full purpose, scope, and public usefulness, of the institutions under their care, which should ever be rule, amongst evolutionists at least.

The Academy of natural sciences in Philadelphia would be a grand central body, magnificently prepared as a starting-point for biological education; and it would be a pity indeed, if the generous citizens of my old city should be put to the expense of another distinct building, and its professors to the trouble and expense of getting together another collection, perhaps to be placed within a few hundred yards or feet of the present academy. Would it not be more than a mere pity?

T. W. BRAIDWOOD.

Cassiterite from King's Mountain, North Carolina.

Mr. Robert Claywell, a student at the high school at King's Mountain station, on the line between Cleveland and Gaston counties, found in the street of the village a piece of mineral, which he sent me for determination. The mineral turned out to be massive cassiterite, the first found in this state. Ascertaining that there was a considerable amount of it scattered through the surface-soil there, I visited the locality, and instituted some explorations.

My expectations were more than verified when I found pieces of cassiterite from the size of an egg to the finest sand, loose and sticking in quartz, scattered over the surface in a belt beginning about the centre of the village, and extending southward a mile or more. Several shafts were sunk, and trenches dug, which finally exposed a main vein and several smaller veins of quartz and quartzite, bearing the tinstone. The veins are nearly vertical; direction of outcrop, north-east with the rocks of the country. The wall-rock is a mica schist, which is broken down from both sides of the vein at places farther than has been dug. The chief accompanying minerals are tourmaline, titanic iron, mica, and, less abundant, zirkon and rutile. At points the tinstone is disseminated abundantly through the vein-rock: at other points little is found. It is mostly in small grains mingled with the other minerals, tourmaline chiefly. Changes of temperature have broken it out of the surface-rock; and washing the soil yields a black sand, which is composed of the dark-colored minerals mentioned.

The cassiterite is mostly massive or semi-crystallized. I have noticed the forms P, $P\infty$, ∞P, and $\infty P\infty$ in only a few specimens. Hardness, 6.5 to 7; specific gravity, 6.6 to 6.9; color, generally dark brown, but varying from black to almost colorless; composition, mostly an impure cassiterite, with 50 % to 60 % of tin, some specimens running as low as 46 %, others, light-colored ones, as high as 74.4 %. The other ingredients are silica and oxide of iron. So far, I have not detected any sulphur or arsenic.

According to Dr. Emmons, the village of King's Mountain is near the dividing-line between the Laurentian granite and the Huronian slates. To the east of the village the rocks are micaceous and slaty quartzites, talcose slates, and bluish crystalline limestone. A few miles west are the hornblende slates, gneiss, etc.

The only remark on tin which I find in writings on North Carolina mineralogy is the following from Dr. Genth ('Mineralogy of North Carolina'): "No tin ore has been found in North Carolina as yet; traces of this metal have been found in the tungstates of Cabarrus county, *and in a micaceous slate* (Huronian) *in Gaston county*, associated with garnet and columnar topaz" (the Italics and parenthesis are mine). The observation is very interesting in the light of the recent discoveries. Have we not here at King's Mountain, at or near the juncture of these slates and the older gneiss and granite, a concentration of this diffused tin?

CHARLES W. DABNEY, jun.

N.C. experiment-station, Feb 14, 1884.

Behavior of Dolomedes tenebrosus.

Last August I obtained a large female specimen of Dolomedes tenebrosus. It measured over four inches from the tips of the first pair of legs to the fourth pair. It was taken in a swamp, and confined in a tin can, where it remained a day or two before it came into my possession. Upon opening the can, I found it apparently half dead with fright. It had deposited its eggs without attempting to make a cocoon. The appearance of the eggs indicated that it had extruded them prematurely. They were mixed with an abundance of mucilaginous substance, which soon hardened, and held the eggs firmly together and fast to the can. I now put it in a cage, where it soon recovered from its fright. The cage was two by three feet, the top covered with glass, and the bottom uncovered, so that it might have the fresh earth and plants to run among.

I also put the can in the cage; but a colony of small ants (Crematogaster lineolatus) soon found the eggs, and carried them all to their own dominions. It was amusing to see them work and struggle

to separate them from the hardened mucilage. The spider seemed to be looking at the ants, but probably did not comprehend what was going on; for it soon went to work and made a cocoon, which it carried in its mandibles. Several times I tried to take it away, but could not get it without injuring the spider. At last, after it had carried it over three weeks, I saw the cocoon lying on the ground, and supposed it had been abandoned. On pulling it to pieces, I found it composed of a cocoon and chrysalis shell of some moth, together with bits of stick, and parts of the dried flowers of the common everlasting (Gnaphalium polycephalum). While I was examining the cocoon, the spider came back to where it had left the cocoon, and appeared to be looking for it. I now put the fragments (which were partly held together by the web wound around them) near the spider, which immediately seized them with a quick, almost frantic eagerness.

The next morning it had again made quite a respectable-looking cocoon, — an irregular sort of ball, which it persevered in carrying some two months, and I do not know how much longer; as toward the latter part of October it succeeded in making its escape, and carried its precious charge away.

During all this time it took no food. I captured a number of different insects, and put them in the cage, to all of which it paid no attention. Grasshoppers recognized the spider as a foe, and at first seemed paralyzed with fear, but gradually overcame their fright, and became lively in its company.

Mary Treat.

ARNOLD GUYOT.

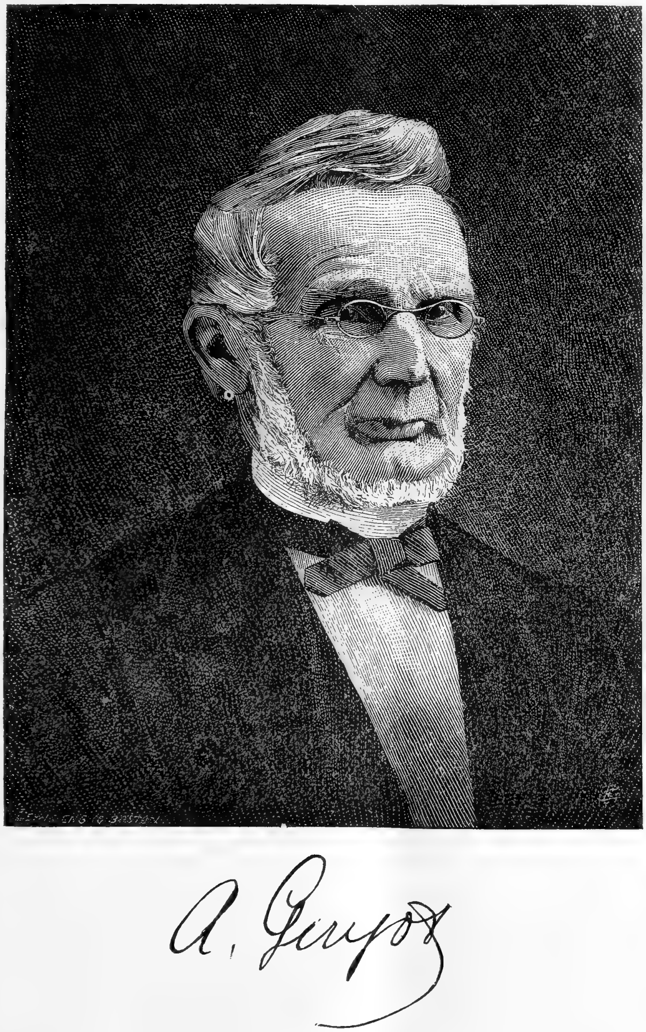
Professor Guyot, whose death occurred at Princeton on the 8th of February, at the age of seventy-seven, is everywhere honored for what he was, as well as for what he did. There is hardly an epithet appropriate to a good scholar, which may not be applied to him, — true, wise, helpful, considerate, devout; accurate, learned, skilful in research, apt to teach, inspiring. His life was devoted to the principle laid down by Smithson for the great institution in Washington, — "the advancement and diffusion of knowledge among men." He was equally ready to engage in a long and tedious investigation, — such as the measurement of a group of mountain peaks, the tracing of lines of bowlders to their sources, the preparation of elaborate tables for the use of meteorologists, and the like, — or to make known in a popular lecture, or before a teachers' institute, or in the conversation of a parlor, or in a series of school-books, the results of his study. He never seemed to be thinking of himself, but always of his subject and his hearers. He cared very little for fame, very much for the study of nature and the education of man.

Like Beck, Follen, Lieber, Agassiz, and several who are still alive, he came to America after his academic training had been completed in foreign schools, and devoted himself to the service of his adopted land with an enthusiasm rarely equalled and never surpassed by the native citizen. He avoided the snare of routine which entraps so many of the college professors of this country; but, by always proposing to himself new lines of inquiry and new subjects of investigation, he kept his mind perpetually fresh, so that, until the infirmities of old age attacked him, he was younger than many of his juniors. He required no 'endowment' in order to lead him to investigation, no instructions, no commission, no salary: all he wanted was freedom. So, when vacation released him from his professor's chair, he took to the field, and, with such comrades as were ready to join him, pursued his geographical researches.

His most original out-of-door work was performed in his own land before he came to this country, where, by a study which lasted for several summers, he succeeded in tracing to their primeval origin some thousands of erratic rocks strewn through the valleys of Switzerland. He thus rendered essential help in elucidating the problem of glacial action which his colleagues, Agassiz and Desor, were engaged in solving. Almost as remarkable was the study which he began, soon after coming to this country, of the great range of Appalachian mountains which borders the Atlantic seaboard, from Maine to Georgia. He determined barometrically the height of the principal summits in the White Mountains, then made a prolonged series of similar measurements in the Black Mountains of the south, then produced a memoir (accompanied by a map) of the entire chain, — a memoir which remains to this day the best existing description. More recently he turned his attention to the Catskills, and revealed the fact, that in this group of mountains, so near to the summer-resorts of wealth and intelligence, the highest peaks were not recorded upon the maps, and inferior peaks were regarded by the scientific visitor and the resident forester alike, as the actual summits. He knew that the problems of nature were always at hand; that careful observation and reflection would reveal some truths of interest and importance, whether the observer were placed in a new country or an old. He was one of those rare men who can ask a hard question, and proceed to answer it.

When he came to this country, in 1849, meteorology was hardly worthy to be called a science. He foresaw what light could be thrown on the law of storms and on the variations of climate by accurate observations extended over vast areas. But he saw, also, the need of good barometrical and thermometrical

instruments, and of accurate tables for the reduction of observations. Under the Smithsonian auspices, he superintended the production of both, applying himself with assiduous labor, for several years, to the preparation and publication of the volume which bears his name, and of which a new edition was in preparation before his final illness. It is easy to see that this work of a pioneer, in a department comparatively new, was of fundamental importance. It helped on the meteorological work which was long superintended by Professor Henry and the Smithsonian observers, and was subsequently developed on a grand scale by the government signal-service.



As we are not endeavoring to review in detail the scientific work of Mr. Guyot, but simply to point out some of the elements of his character, we pass on to his influence as a teacher. For a long while after he came to this country he was a professor without a desk, — a peripatetic teacher, engaged by the Massachusetts board of education to unfold the right principles of geographical instruction. His remarkable insight into the relations of the 'Earth and man' had been developed in the atmosphere of Berlin, when Humboldt, Ritter, and Steffens were in their prime. He learned their methods of thought: he worked out his own. His earliest utterances upon this subject were given at the Lowell institute in 1849, when, with the eloquence of an original thinker, he showed how the earth was fitted to be the dwelling-place of the human race. His task was performed with such profound perception of the truth, and with such suggestive and stimulating reflections, that the unpretentious volume of lectures (notwithstanding the fact that science has revealed so much which was then unknown) remains to this day one of the best introductions to physical geography which the general reader can find in any language. The acquaintance which he formed with American schools and teachers showed him how poor and dry and immethodical were the geographies then in use, how flat and unsuggestive the maps. He endeavored to remedy the evil, and for years was occupied, with skilled co-operators, in the production of a series of wall-maps and text-books, which have since been used in every part of the land. It is not too much to say that they revolutionized the methods of teaching geography. Every series of geographies which has since appeared shows the influence of Guyot.

During a period of nearly thirty years he has been a professor in Princeton college, and his name is cherished by hundreds of loving pupils, who have found in him a friend as well as a teacher; but until a recent period he was easily induced to lecture in other places, and his voice has often been heard in distant cities, expounding his favorite ideas.

The intimacy of Agassiz and Guyot, and the parallel courses of their lives, may be beautifully traced in the memoir of Agassiz which Guyot wrote for the National academy in 1877–78, but did not print until April of last year. It is a biographical gem. The two friends were born in Switzerland, were companions in study, were colleague professors in a post-graduate academy at Neufchâtel, were co-workers in glacial researches, were disturbed by political changes in their native canton, were emigrants to America, were neighbors in Cambridge, were comrades in sensible efforts to make science intelligible to the people, were investigators of American problems. In this memoir of his friend, Guyot has revealed himself by many a characteristic touch. After a fresh perusal of its pages, we are led to wonder how much scientific progress would have been delayed in this country, if it had not been for the inspiring and co-operating influence of these noble immigrants.

Like Faraday, Clerk Maxwell, Agassiz, Joseph Henry, and Benjamin Peirce, Guyot was a man who was devoted to research, who believed in carrying it to the utmost, and yet who was never troubled by the idea of a possible 'conflict' between science and religion. To him nature was a manifestation of God. Natural laws were divine laws. There could be no antagonism between them. On the contrary, he believed that the more we learn of the human soul, of the course of history, and of the structure of the world, the more harmonious will they appear as parts of one great plan. His faith, both in science and in religion, was so strong that his influence kept many clergymen from bigotry, many students from atheism. In him they saw a man to whom the study of science and the worship of God were alike obligatory.

THE ALASKA MILITARY RECONNOISSANCE OF 1883.[1]

THIS expedition arose from a desire of the department commander in the military department in which Alaska territory is situated[2] to gain some military knowledge of the Indian tribes in that district, and especially in those parts recently opened by mining discoveries, fishing industries, and other causes. Besides gaining this information, it has also done something in the interest of science, especially for geography. The part of the route here treated was almost unexplored, excepting the Chilcoot and Dayay inlets, and the portion from the Kotusk Mountains to Lake Lindeman, which had been traversed by the Krause brothers, sent out by the Bremen geographical society. If such an expression may be considered correct, it was really worse than wholly unexplored, in that the maps and books purporting to be authority over this section of the country were erroneous beyond the limits of sensible guessing. The party consisted of seven white persons, — two officers and five others, — and a number of Indians that varied from two to sixty or more.

There are said to be three or four passes through the glacier-clad mountains that separate the salt-water estuaries of the Pacific from the head waters of the Yukon, two of which are known as the Chilcat and Chilcoot trails; and over these two it has been known for about a century that Alaskan Indians of certain tribes had passed, in order to trade with the Indians on the sources of this great stream. The last (the Chilcoot) is the best of all the trails, and was the one undertaken by the party. Why this or the Chilcat route had not been picked out long ago by some explorer, especially those of comparatively recent dates, who could thereby have traversed the entire river in a single summer, instead of combating its swift current from its mouth, seems singular in the light of the above facts, and can only be explained by supposing that those who would place sufficient reliance in Indian reports to put in their maps the gross inaccuracies cited would also be likely to place reliance in the other reports of the same Indians; and these from time immemorial have pronounced this part of the river as unnavigable even for canoes, being filled with rapids, cañons, whirlpools, and cascades.

Formerly this Chilcoot pass had been monopolized by the Chilcoot Indians, who did not even allow the Chilcats — almost of the same blood — to use it: these were thus forced over the Chilcat route, which has an irksome portage of twelve or thirteen days to the head of the Tahk River (*Tahk-heen-a* of the Chilcats), a branch of the Yukon about half the size of the parent stream where it empties into the latter. Both of the bands on the upper Lynn Channel have united in keeping back the migration of the interior Indians to their waters in order to monopolize this trans-montane commerce. However, of late years, not only have the Chilcats used the mountain-pass of the Chilcoots, but both have allowed the *Tahk-heesh* or 'Stick' Indians of the interior to visit their own domain. I employed some of

[1] Explorations and surveys from Chilcoot mission, Alaska, to old Fort Selkirk, British America.

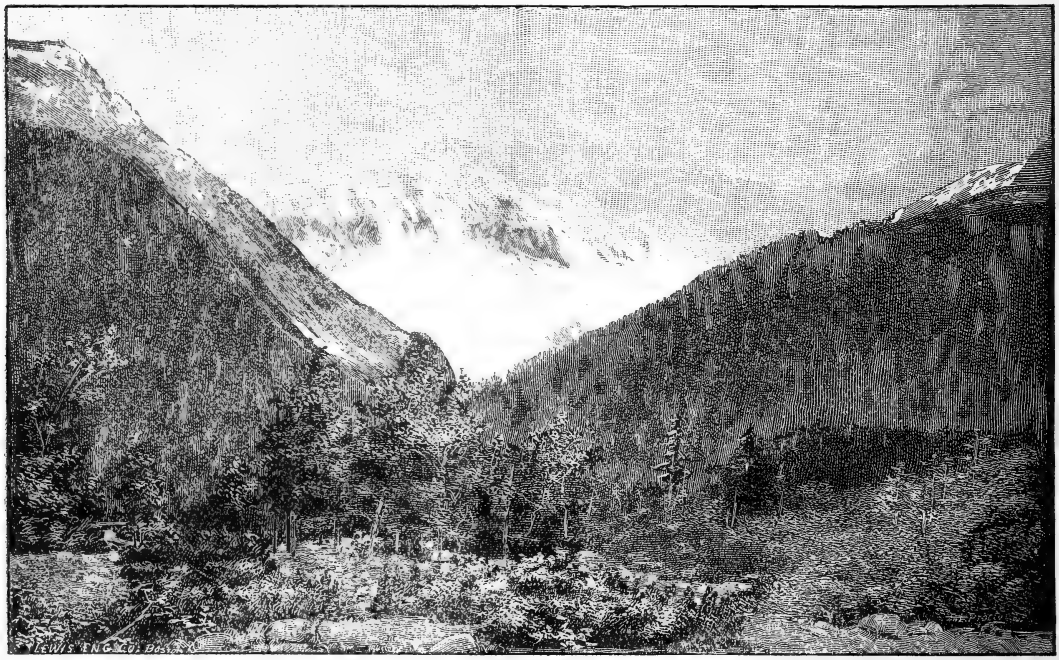
all these three Indian tribes in my passage through their country.

Reaching Chilcat on the 2d of June, I found, as I had surmised from reports, that miners had pioneered the way some distance down the river in search of gold; but no one seemed to be much the wiser regarding the route, except that, as near as could be gleaned, they confirmed to a great extent the old Indian stories. My suggestion of a raft as my means of conveyance was ridiculed by whites and natives; and they could hardly conceal their contempt when the programme was known to be the passage, that summer, of the whole length of the river. Two or three hundred miles of tortuous lakes and a number of rapids, aggregating eight or ten miles in length, which the Indians never essayed, and around which the miners dragged their whip-sawed boats, were reported to exist, and supposed by all to be sufficient to wreck the raft theory of transportation; and, by the time I started, I felt very anxious myself regarding my plan.

We left on the 7th of June from Chilcat, with thirteen canoes, towed by a steam-launch kindly placed at my disposal by Mr. Spuhn, manager of the North-west trading company. At Chilcoot mission, four or five canoes were added to the already long chain, and the course resumed. Leaving Chilcoot Inlet, we entered another, that the Indians call the Dayay, an exact image of the fiord-like inlets characteristic of this part of the Alaskan coast; that is, having more the appearance of a large river than a salt-water estuary, its sides being immense precipitous mountains, covered three-fourths of the way to the top with a dense growth of spruce, fir, and pine, the latter holding to the lower levels, and capped with blue and white glacier ice that feeds innumerable and picturesque waterfalls coursing down the mountain sides. The mouth of the Dayay was reached that evening, our load of three or four tons lightered to the shore, the canoes and the bundles assorted and given to the different Indian packers, numbering over sixty. The packs varied from thirty-six to a hundred and thirty-seven pounds in weight, the adults generally carrying a hundred pounds, and the boys according to their age and strength. Here was found a small camp of

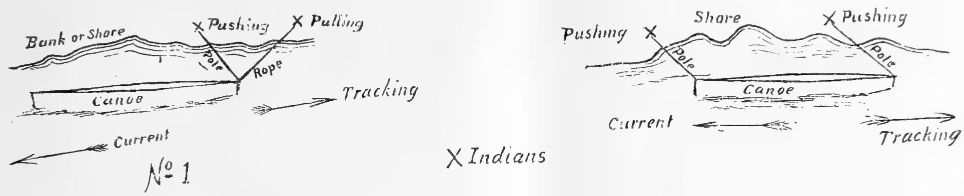


DAYAY VALLEY, LOOKING UP THE NOURSE RIVER VALLEY.

A glimpse of Baird Glacier covered with fog is given. The mountains holding the glacier being twice as high as the one shown on the left, their crests, if they had been visible, would not have shown in the photograph from which this illustration is made, being above the line where it is cut off. The lower edge of the fog-bank is just below the upper edge of the glacier. It is only at night that the fog-banks lift, when it is too late to take photographs.

Tahk-heesh Indians who were hunting black bear, said to be very numerous in this vicinity. During the evening we could hear many hooting-grouse (Bonasa Sabinii) in the spruce woods of the hillsides, this part of the day seeming to be their favorite time for this strain. I could but notice the very peculiar expressions of surprise given by the Chilcat Indians. Whenever one sets up a 'Ya-a-a!' at any thing that attracts his notice, especially the ludicrous mishap of a companion, every one in hearing, from two to two hundred, joins instantly; and a prolonged shout goes up that would astonish one not used to it. This may be repeated a number of times in a minute; and the suddenness with which it commences and stops is astonishing, and strongly reminds one of a gang of coyotes howling, or the baying of Indian dogs, from which I think they have borrowed it.

The head of canoe navigation on the Dayay is ten miles from the mouth of the river, although fully fifteen are travelled by the canoemen in ascending its tortuous course. They 'track' against the current in two ways, two persons being necessary for each method for a single canoe. The diagrams above will show these methods without further explanations.

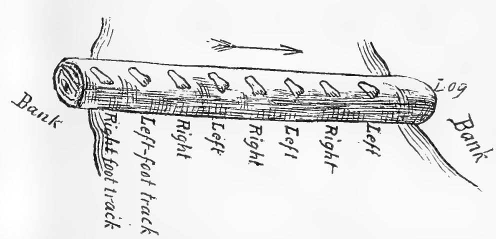


METHODS OF TRACKING A CANOE UP A RAPID.

The current of the Dayay is very swift, and it often takes two days' 'tracking' over the navigable part. Every few hundred yards or so the river has to be crossed, and oftentimes a hundred yards is lost in this undertaking. From the head of canoe navigation on the Dayay to the point where the Indian packers left the party is twenty-six miles, or the true length of the portage. Two miles and a half beyond the head of canoe navigation the Cut-lah-cook-ah of the Chilcats comes in from the west. This is really larger in volume and width than the Dayay, the two averaging respectively fifty and forty yards in width by estimation. I shortened its lengthy name, and called it after Professor Nourse of the U. S. naval observatory. Large glaciers feed its sources by numerous waterfalls, and its cañon-like bed is very picturesque. Both the Nourse and Dayay, like most streams fed by glaciers, have their waters noticeably white and chalky. Not a 'bite,' nor a 'rise,' could be had in either with bait or flies, although the Indians catch trout in them in their fish-wears.

At the head of the Nourse River the Indians say there is a very large lake. Its westward-bounding mountains are capped with an immense glacier, that could be traced along their summits for probably ten or twelve miles, and was then lost in the lowering clouds that these icy crowns form from the moisture-loaded atmosphere of the warm Pacific.[1] These light fogs are frequent in the warm days, when the difference of temperatures at the upper and lower levels is more marked, clearing up at night as they approach each other.

The march of the 10th of June was a very rough, fatiguing one of about ten miles, consuming from 7.30 A.M. till 7.15 P.M. It brought us to the foot of the mountain pass on the other side of which we should find the sources of the Yukon. I noticed that day that all my Indians, in crossing logs over streams, always turned the toes of both feet in the same direction (to the right), although they kept the body square to the front, or nearly so, and each foot passed the other at every step, as in natural walking. The advantage to be gained was not obvious to the author; as the novice, in attempting it, feels much more unsafe than in ordinary walking. Every evening was spent by the Indians in their gambling games, their orgies

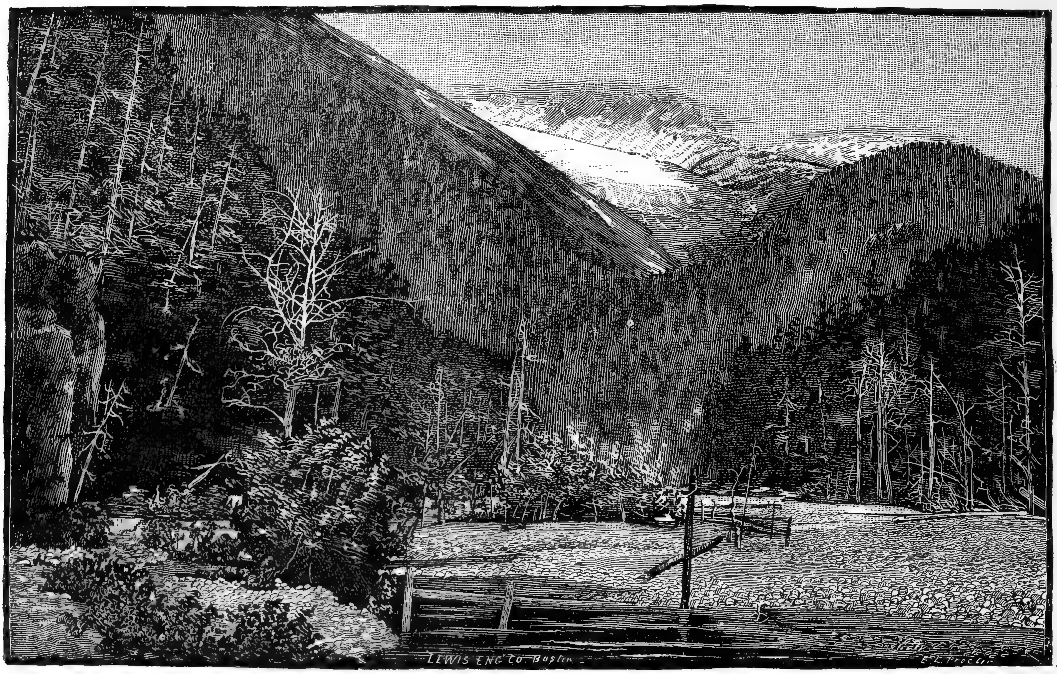


POSITION OF THE FEET IN WALKING A LOG, AS PRACTISED BY THE ALASKAN INDIANS.

[1] This glacier (see illustration, p. 222) was named after Prof. S. F. Baird of Washington, D.C.

often continuing until midnight or past. This, added to their rapidly improvised birchbark hats with pictures upon them that would prohibit their being sent through the mails, does not speak well for missionary efforts among them.

On the 11th we crossed the pass (Perrier Pass), ascending to forty-one hundred feet above the sea-level, being among the clouds formed by the glaciers in the upper third of the ascent. It was the usual severe alpine climbing; the agility and endurance of the Indian packers, with their immense loads, almost surpassing belief. The entire distance of six or seven miles was on the deep snow, the depth of which could only be inferred. Once through the Perrier Pass, the descent is rapid for a few hundred feet to a lake of about a hundred acres in extent, which was yet frozen over and the ice covered with snow. It very much resembled some old extinct crater, and I doubt not but that it was active in ancient times. Here there was no timber, nor even brush, to be seen; and the gullies of the granite hills, and the valleys deeply covered with snow, gave the whole scene a decidedly arctic appearance. My Indians, in following a trail on snow, whether it were up hill, on a level, or even with a slight descent, always stepped in each other's tracks, so that my large party made a trail that looked as if only five or six had passed over; but, when going down a steep descent, each one made his own trail, and they scattered out over many yards. I could not but be impressed with the idea that this was worth considering in estimating their numbers under such circumstances. From the little crater-like lake at the very head of the Yukon, the trail leads northward through a valley that converges to a gorge; and while on the snow in this we could hear the water gurgling under the snow bridge on which we were evidently walking. Farther on, where these snow arches were too wide, they had tumbled in, showing in many places deep perpendicular snow-banks, oftentwenty to twenty-five feet in height. Passing by a few small lakes on our left, some yet containing floating ice, we caught sight of the main lake late in the afternoon, and in a few hours were upon its banks. It is a beautiful sheet of water, ten or eleven miles in length,[1] and looked not unlike a limited area of one of the broad inland



A VIEW IN THE DAYAY VALLEY.

A finger of the Saussure Glacier is seen peeping round the mountain, the rest being covered with fog.

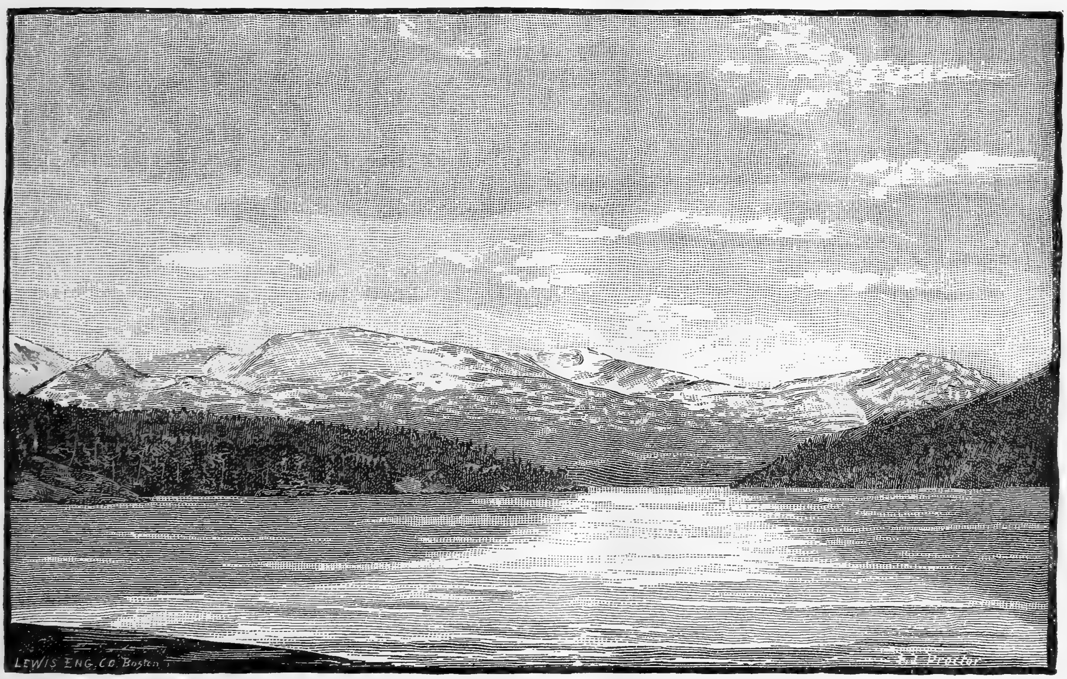
[1] Named in honor of Dr. Lindeman of the Bremen geographical society.

passages traversed by the steamers plying to Alaskan ports farther south. Fish were absent in these glacier-fed streams and lakes, but we managed to kill a few dusky grouse (Tetrao obscurus) and green-winged teal (Nettion carolinensis) to vary the usual government ration; but all were tough beyond measure, it being their breeding-season. Over Lake Lindeman were seen sea-gulls and the graceful little arctic tern that I recognized as an old and garrulous companion. Of large game, a small black bear cub was the only thing seen; although mountain goats were abundant a short distance back in the hills, one having been seen by us in the Perrier Pass.

The next day we commenced building our raft on Lake Lindeman; although the logs were very small, consisting of dwarfed spruce and contorted pine. Fifteen by thirty feet was considered large enough until we commenced to load it, when we were forced, during a heavy gale on the 15th, to send it ahead with but half a load and three men, the remainder of the material being stowed in two dilapidated wooden canoes, — fair samples of the very few that exist from here until old Fort Selkirk is reached, where birchbark canoes commence. The remainder of the party took a whole day in struggling overland through the tangled brush and marshes of the gullies, and climbing the steep, smooth granite banks that separate them from the ridges covered with a labyrinth of fallen timber.

At its northern end Lake Lindeman is drained by a small river fifty to sixty yards in width, full of rapids and cascades, and about a mile in length, where it empties into a large lake that I named after Mr. James Gordon Bennett, a well-known patron of American geographical research.

The raft was shot through the connecting river, June 16, and the dimensions enlarged to fifteen by forty; although, counting all projections, it really came nearer sixteen by forty-two. Around this series of rapids the Indians portage their effects on their backs; and I named it Payer Portage, after Lieut. Payer of the Austro-Hungarian expedition of 1872–74. By the 17th of June, at midnight it was light enough to read print like that of *Science*, and continued so through the month, except on very cloudy nights. Har-



LAKE LINDEMAN.

The view is taken from the upper (southern) end of Payer Portage, looking (south) toward Kotusk Mountains. Perrier Pass is on the extreme right wrapped in fog. There are higher ice-capped mountains in the distance, not shown here.

lequin ducks were noticed on the southern end of Lake Bennett, and black and brown bear and caribou tracks in the valley of a small stream emptying into the lake near by. A couple of Tahk-heesh Indians were here encountered, one of whom stammered considerably. Among my Chilcat packers I also noticed one that was deaf and dumb, and two or three afflicted with cataract in the eye. On the 19th of June we commenced traversing Lake Bennett. Through the ice-fields capping the timbered mountains to the east of the lake protruded a great many dull red rocks and ridges, specimens of which, found in the terminal moraines of the little glaciers putting down the gulches, showed iron; and I named this bold range the Iron-capped Mountains. By three P.M. it was blowing a gale; and by five the waves were washing over our raft, and threatening to tear it to pieces, for there was not a single log that extended the whole length of the raft proper. We accordingly put into a cove, where we obtained four large spruce to strengthen the raft, and on the 21st resumed the journey, reaching the northern end of Lake Bennett that evening. The lake is thirty miles long, and flanked by precipitous hills three thousand to thirty-five hundred feet high, capped with glaciers. At its north-western face there come in a couple of streams, forming a wide, flat, and conspicuous valley that we all felt sure was going to be our outlet as we approached it. Several well-marked buttes spring from this valley, giving it a very picturesque appearance; its largest river being sixty to seventy-five yards wide, but quite shallow. I called it Watson valley, after Professor Sereno Watson of Harvard.

The draining river of Lake Bennett is about two hundred yards wide, and is called by the Tahk-heesh, 'the place where the caribou cross;' these animals, in their migrations, fording its wide, shallow current, and passing out and in through Watson valley. It is hardly two miles long before it expands into another lake, whose general course now turns to the east; and our old friend, the steady, summer south wind, was of no avail for sailing our huge craft. Although this lake (Lake Nares, after Sir George Nares) was but three or four miles long, its eastern trend kept us three days before we got a favorable wind, the banks not being good for tracking. Although small, Lake Nares was one of the prettiest in the lacustrine chain. The country was perceptibly opening; and trap, granite, gneiss, and metamorphic and eruptive rocks generally, were giving way to the sedimentary and fragmental. Many level places were appearing, the hills were less steep, and the snow disappearing from their crests. Roses of varying hues were in bloom, and also wild pansies; while wild onions lined the lake-shore in profusion, and everywhere there was a general change of verdure, and variation for the better. Grand terraces in beautiful symmetry on the two sides of the lake plainly showed its ancient and subsiding levels. These, too, — in a less conspicuous manner, however, — had been noticed on the northern shores of Lake Bennett. Lake Nares drains through a short river of a hundred yards into another lake[1] about eight miles long, and on whose limited shore-line I was compelled to make two camps and a half-dozen extra landings, so baffling was the wind on which we had to depend. Two bungling side-oars on the huge raft allowed us to make about a half a mile an hour with laborious effort, a wall-tent for a sail driving us along as fast as two miles and a half under the most favorable wind. An oar on the bow and stern gave us steering apparatus, and a dozen strong wooden poles served us as pries over many a lake and river bar of sand, gravel, and mud.

During one of these temporary landings on the shores of Lake Bove, some of my Indians set fire to the green spruce-trees by a large blaze kindled under them, and a dense volume of smoke ascended high in the heavens. Late that day a smoke was seen north of us some ten or fifteen miles away, and our Indians told us it was an answer to the one they had accidentally made that morning. These signal-smokes between the two bands were formerly quite common; the Chilcats thus heralding to the Tahk-heesh that they had crossed the Kotusk Mountains, and were in their country for trading purposes. Not many years ago, as I was told by an old Hudson-bay trader in these parts, this Chilcat-Tahk-heesh trade has been known to be so great that not less than seventy-five or eighty of the Chilcats and Chilcoots crossed the mountains twice annually, each carrying a hundred pounds of trading-material, or a grand total of eight tons, to be exchanged for furs that were collected from a wide circuit by intertribal commerce. Fort Selkirk, established by the Hudson-bay company near the junction of the Pelly and Yukon, interfered with their trade for a brief period, until 1851, when a war party of Chilcats extended their trading-tour nearly five hundred miles in order to destroy it; and its blackened chimneys still attest their success.

Lake Bove has a deep bay in its southern

[1] Lake Bove, after Lieut. Bove of the Royal Italian navy.

face; and into this, our Indians reported, empties a large river. Rounding Point Perthes (after Justus Perthes of Gotha), nearly white with its covering of limestones, some of them almost true marble in their brilliancy, we enter Tahko Lake, eighteen miles in length by our measurement (forty-five, according to one guess on record). A well-deserved remark regarding conjectural geography in order to 'fill out' maps, charts, or books, I hope will not be found amiss at this point. In one of these we were given to understand that from here the Indians make Fort Selkirk in a day and a half in their birchbark canoes. There are no birchbark canoes used on the lakes, nor as far as Selkirk. The very few Indians living on the four hundred and thirty-three miles between Tahko and Selkirk never stay in their cramped wooden canoes over six hours during a day, and would therefore have to paddle over each mile at the rate of one minute and thirty-five seconds.

Tahko Lake receives a small stream on the south, which, followed up, leads to one of the mountain passes that debouch upon the waters of the Pacific, so said our Indians. The same authorities gave us to understand that it drains smaller lakes, and has a smaller bed than the rivers and lakes through which we had passed; and its appearance, as we sailed by, seemed to confirm their opinions, thus showing that we had been on the main stream, or the Yukon proper.

(*To be continued.*)

FLOODS IN THE OHIO.

No river of the same magnitude fluctuates in depth so much as the Ohio. Twice, or oftener, during most years, the river rises at Cincinnati to a stage of forty-five feet six inches by the gauge at the water-works, when the occupants are compelled to vacate the premises at the foot of Commercial Row. A greater depth than this is a flood, and occasions more or less loss and suffering. Extreme low water is two feet, and extreme high water of February, 1883, was sixty-six feet four inches, — a difference of sixty-four feet four inches.

The gauge at the water-works was fixed in 1858, and all observations since then are referred to that standard. This gauge is intended to show the depth of water on two principal bars near Cincinnati, — Four-Mile bar above, and Rising-Sun bar below, the city. All observations of the stage of water of which we shall speak have been reduced to this gauge.

We may mention the noted floods preceding the establishment of the gauge in 1858.

1774. — It is traditional that at about this year there was a great flood in the Ohio. Vol. i. p. 343, of the *American pioneer*, states that two white hunters were detained some time in March of this year at the mouth of the Big Kanawha by a remarkably high freshet, which, from fixed marks on Wheeling Creek, is supposed to have been equal to that of 1832.

1789. — Various records show that there was a remarkable flood this year observed by the first white settlers, which must have been of much longer duration than any of later date.

1792. — It is within the recollection of some now living, that four years after the settlement of Losantiville (Cincinnati) there was a flood that covered the land on which Columbia now stands. The stage of water must have been sixty feet or more.

1815. — Another great flood occurred this year, but it was of less magnitude than that of 1792.

1832. — There are several points in Cincinnati where permanent high-water marks were made on Feb. 18, 1832; and they almost exactly agree in showing that the stage of water was then sixty-four feet three inches. The population of Cincinnati was then twenty-eight thousand; and, as the city was situated upon the river-bank, nearly the whole of it was inundated by a flood, which increased continually for ten days.

1847. — Cincinnati contained about ninety-six thousand people at this date. The river began to rise on Dec. 10, and on the 17th reached sixty-three feet seven inches.

The following table records the highest stage of water at Cincinnati each year since 1858, as well as those just given for 1832 and 1847: —

Year.	Date.	Feet.	Inch.	Year.	Date.	Feet.	Inch.
1832	Feb. 18,	64	3	1871	May 13,	40	6
1847	Dec. 17,	63	7	1872	April 13,	41	9
1858	June 16,	43	10	1873	Dec. 18,	44	5
1859	Feb. 22,	55	5	1874	Jan. 11,	47	11
1860	April 16,	49	2	1875	Aug. 6,	55	5
1861	April 19,	49	5	1876	Jan. 29,	51	9
1862	Jan. 24,	57	4	1877	Jan. 20,	53	9
1863	March 12,	42	9	1878	Dec. 15,	41	5
1864	Dec. 23,	45	1	1879	Dec. 27,	42	9
1865	March 7,	56	3	1880	Feb. 17,	53	2
1866	Sept. 26,	42	6	1881	Feb. 16,	50	7
1867	March 14,	55	8	1882	Feb. 21,	58	7
1868	March 30,	48	3	1883	Feb. 15,	66	4
1869	April 2,	48	9	1884	Feb. 14,	71	$\frac{3}{4}$
1870	Jan. 19,	55	3				

The flood-stage of 1875 was remarkable as occurring in summer, when the river is in most years low.

The great flood of 1883 was of unprecedented magnitude, and so great a rise was entirely unexpected. The stage of water had not exceeded sixty feet for thirty-seven years. By it the whole of those parts of Cincinnati and the towns on the opposite side of the river — Covington, Newport, and Dayton, Ky. — located nearest the water were inundated. In Covington, in all, perhaps 350 houses were submerged. In Newport not less than 2,100 houses were flooded. In Dayton and Bellview, Ky., over 400 houses were under water.

In Cincinnati, travel on many of the street-car lines was suspended; nearly all the freight and passenger depots were submerged; all but two of the railroads stopped running; fifteen of the largest coal-yards were under water; and the gas-works suspended, leaving the city in darkness. More than 1,500 business-houses, and nearly 3,700 dwelling-houses, were inundated, causing more than 2,400 people in Cincinnati alone to become objects of charity, for whom shelter, covering, clothing, and food must be provided.

It is within bounds to say that one-tenth of the population in and around Cincinnati needed assistance of this kind. The Associated charities superintended the distribution of aid to those suffering. From Feb. 12 to March 5 this organization relieved 5,260 families, or 24,111 persons. It issued 105,141 rations, and supplied 2,046 families with clothing, 1,916 families with bedding, and 647 families with coal. It also distributed 3,991 pairs of boots and shoes.

The pecuniary losses that resulted from this flood can never be precisely known, but it has been estimated that along the two thousand miles of shores inundated it aggregated sixty millions of dollars.

The town suffering most in proportion to its size was Lawrenceburg, Ind., which was completely inundated. It is so situated that at this stage of water the Miami River runs directly through the town, pushing houses from their foundations, and sweeping away every thing movable.

The flood was due to two storms, — the first from Feb. 3 to 6, in which about 3.5 inches of rain fell at Cincinnati; and the second on Feb. 10 and 11, in which the rainfall was about 2 inches. These storms extended to the head waters of the Ohio, and fell upon frozen ground; so that the water could not soak into the earth, but was carried at once into the water-courses.

The flood of 1884 arose from a single storm on Feb. 4 to 6, in which the precipitation was unusual in amount and rapidity, being as much as 4.46 inches in eight hours less than three days. This storm, combined with the warm weather, caused a general thaw over all the region from which the feeders of the Ohio come, and sent large volumes of water into the rivers, besides the immediate rainfall.

When we consider what an unusual combination of circumstances is necessary to cause a stage of water exceeding sixty feet, and that such an occurrence cannot be ordinarily expected more than about once in a quarter of a century, it appears most remarkable that two such floods should happen in successive years.

A WOMAN'S JOURNEY TO THE KARAKORUM VALLEY.

MADAME UJFALVY, who recently accompanied her husband to Kashmir and Baltistan, has published an interesting and lively account of the glacial region of the Himalayas, which she was the first European woman to penetrate. In the village of Shamba, in the Kulu country, on the occasion of a ceremonial visit to the temple by the rajah, it is customary for the priests to sacrifice a she-goat. Once undertaken, the priests may not eat until the sacrifice is complete; and the assent of the animal to its own death, without which it may not be killed, is supposed to be indicated by a trembling of the body. The unconscious creature is not always in a trembling mood; and to induce the same the priests squirt cold water into its ear, which usually has the desired effect. On one occasion, the authoress relates that even this failed, and the goat, outraged by such treatment, escaped to the rugged mountain side, and, even after recapture, refused to gratify its captors. Put to their wits, the priests finally plunged it bodily into the icy mountain stream which dashes through the village. Taken out again, it naturally trembled with its whole body; and the sacrifice was finally completed to the satisfaction of all, especially of the priests, who had already imagined themselves perishing of famine.

Srinagar, capital of Kashmir, sometimes known as the oriental Venice, seemed less attractive than report had made it. The streets were narrow canals of stagnant and offensive water, in which swarms of ragged people disported themselves. Dirt was too evident to be ignored. Only when evening set in, and all contrast disappeared under the moonlight, did this singular and sombre town seem to harmonize with the magnificent mountains which surround it. There are some hundred thousand inhabitants; and, besides the finest quality of shawls, they produce the finest and most artistic work in silver and copper. The passage to Baltistan from Srinagar traverses a singular plateau fourteen thousand feet above the sea. The earth is bare, and undulated as if in waves. It is the bed of an extinct glacier, and surrounded by mountains, between which the wind rages, rendering it passable only in the three summer months. Even in

September, snow-hurricanes may destroy rash travellers. Though English authorities had informed them that rain was impossible on this plateau, the party were drenched. Marmots and bears alone inhabit this solitude. Grass is rare, and, at one place where abundant, is said to be poisonous for animals. These regions offer a desolate grandeur, unsoftened by vegetation.

The descent to Baltistan and the sources of the Indus was through scenery equally wild and melancholy, so that the first signs of cultivation met the eye as grateful relief.

The Baltis are Mussulmans, and chiefly remarkable for their devotion to the game of polo; which, in fact, originated here, and for which their well-trained, tough little mountain ponies are admirably adapted.

Their capital is Skardo; but the purest type of the race is found in the Shigar valley, which contains the largest glaciers in the world after those of Greenland, and the highest mountains in the world after Mount Everest. The glaciers form an unbroken line for nearly a hundred miles. Mount Dapsang of the Karakorum range is only some two hundred feet lower than Mount Everest. But even here the Shigar River waters an attractive oasis of some six miles in extent, with fields of millet and beans, and orchards weighed down with fruit, among which nestle tombs, mosques, and picturesque though uncomfortable habitations. The apricots and melons of this region are delicious.

The party returned by another and very difficult route, which followed all the windings of the Indus; yet here and there little villages were set, like verdant nests, among the rocks. In spite of the incessant conflict with nature, which a residence here entails, the people are devoted to their country, and prefer it to any other.

The journey to Shigar was due to the munificence of the Maharajah Rambir Singh of Kashmir; and its scientific results, which remain to be published, are believed to be important.

THE ARTIFICIAL PRODUCTION OF RAIN.

In his anniversary address delivered to the Royal society of New South Wales, Mr. H. C. Russell, the president and government astronomer, deals at some length with the subject of producing rain artificially. He begins with a few points in its history, telling first how Arago, finding the practice of firing guns common in some of the departments of France, had tried to trace the origin of the custom, which probably began in 1769. A retired naval officer, who at sea had seen water-spouts destroyed by cannon shots, made his home in a district that suffered from violent rain and hail storms, and determined to try the power of shot and shell upon these new foes; and, setting up his battery, his success was such that the district was protected from the violent storms. The practice became popular in France; and up to the year 1806, and even later, many communes kept a battery of small guns for this purpose, the commune of Fleury even going so far as to get a cannon which used a pound of powder at each discharge. Arago could not trace what the effect had been, but he at least was not convinced that it had had any good effect; and after a time the practice became obsolete. Volta's biographer says that "it is well known that Volta thought a possible advantage might be found in having large fires during thunder-storms;" his reason probably being, that the smoke would serve as a conductor for the electricity, and so prevent dangerous discharges.

To test the effect of the discharge of artillery on the weather, Arago examined the weather-record of the Paris observatory for many years, especially for the days adjacent to those on which the regular gun-practice took place in the fort, situate somewhat less than two miles from the observatory. The firing took place at this fort on certain days in the week, from seven to ten A.M., about one hundred and fifty shots being fired. Arago found, that, out of 662 days preceding the practice, 128 were cloudy; out of 662 days of practice, 158 were cloudy; out of 662 days following practice, 146 were cloudy; which he regarded as proof that the discharge of heavy artillery does not seem to have the effect of dissipating the clouds.

Struck at one time by the amount of destruction caused by hail-storms, Arago proposed drawing off the electricity by means of wires carried up to great elevations by captive balloons; but, when he came to the practical consideration of the scheme, it was soon seen that each balloon would not protect more than, perhaps, a thousand square yards, — a mere speck of France. In later years he was led to doubt the value of such a means of protection.

Arago relates, that, in tracing the history of the use of cannons, he found that bells, and especially church-bells, had preceded them; and it was at one time firmly believed that the vigorous ringing of church-bells was sufficient to dissipate dangerous storms. Mr. Russell finds that up to 1810, or later, the idea was popularly prevalent that storms might be destroyed or prevented by fire or guns; and he thinks that a complete change to the opposite opinion has taken place since then. He says, —

> "Australia, like Africa, wants the rain-doctor to make rain, not drive it away. It is not only in Australia, however, that the belief in the artificial production of rain exists. In America, during the civil war, it was a matter of common observation that rain followed the great battles; and the belief in this became so general, that farmers began the practice of making large heaps of brushwood on each farm, and, when they wanted rain, lighting them all together. I cannot find any reference to the results of this system in the Smithsonian publications, in which almost every subject of this kind is dwelt upon; but the practice seems to have been given up."

Mr. Russell then alludes to the well-known little volume by Mr. Edward Powers, published in 1870, and entitled 'War and the weather, or the artificial production of rain;' and to the review of this book in *Silliman's journal*, inclining to the opinion that great battles do exert some influence in the production of rain, but failing to accept Mr. Powers's incom-

plete discussion of the facts as proof. He turns next to Espy's conviction, that rain might be produced economically whenever it was wanted, and cites Professor Henry's opinion in the matter: —

"I have great respect for Mr. Espy's scientific character, notwithstanding his aberration, in a practical point of view, as to the economical production of rain. The fact has been abundantly proved by observation, that a large fire sometimes produces an overturn in the unstable equilibrium of the atmosphere, and gives rise to the beginning of a violent storm."

The opinion of Professor Everett, president of the Meteorological society, is also cited. He believed that great battles and great fires tend to produce rain, but that rain does not, of necessity, follow battles or fires.

The climate of Australia being peculiar, Mr. Russell has endeavored to collect the records bearing upon the question there; and, there having been no battles (except a mimic one, which produced no rain), he passes to an examination of the meteorological conditions of the times of the great fires which have occurred in Sydney since 1860, and assumes, that, if a fire produced rain, it would fall within forty-eight hours. His record embraces forty-two large fires (including two serious explosions), extending over a period of twenty-one years; and he concludes that there is not one instance in which rain has followed within the forty-eight hours as an evident consequence of the fire.

In cases where it is asserted or believed that rain has been produced artificially, it would be interesting to examine whether the rain was due to the fires or to ordinary meteorological changes. While it is evident that some of the most competent authorities in England and America think that under certain circumstances rain may be produced artificially, Mr. Russell thinks they all carefully avoided saying what the circumstances were; and he proceeds to develop some idea of what they are, from a consideration of the natural conditions under which rain is deposited, and adducing certain instances as illustrations, from nature, of the conditions under which the leading scientific meteorologists of the day tell us that rain is formed. He says, —

"If we can get a measure of these [observed] effects, it will serve as a guide in estimating what would be required to make rain. At Sydney the average relative humidity is 73, and at Windsor it is rather less; and we have just learned that such atmosphere lifted from Windsor to Currajong, 1,800 feet, deposits 60 per cent more rain. If we could make it rise up over Sydney 1,800 feet, we might fairly expect to get 60 per cent more rain. Now, a wall built 1,800 feet high, and of considerable length, so that a wind would not divide and go round it, but go over, would have the desired effect; i.e., to lift the air and cause rain: but any thing that would do this would serve the purpose, and it may be done by fire; but of course the fire must have the effect of lifting the atmosphere up. It will not do for the products of the fire to rise up slowly, mixing with the air, and making it drier as they rise. If it is to have the effect of a wall, — that is, making the whole of the air passing over rise up 1,800 feet, — it must act as an explosion would do, suddenly, or by a constant uprush of such violence that it would rise up 1,800 feet. The force necessary to do this is easily computed, and we can in this way get a money value for the work to be done. At Sydney the average velocity of the wind is 11 miles per hour; and all the air passing over is to be lifted, and the weight of it on the surface is, say, $14\frac{1}{2}$ pounds on the square inch, and $13\frac{1}{2}$ pounds at 1,800 feet high. At least, for our present purpose, these figures are sufficiently exact. The average weight to be lifted, therefore, is 14 pounds on the square inch. The fire must have the same length as the proposed wall, for the same reason, and a breadth equal to the forward motion of the air in a given time. We have therefore to lift a weight of 14 pounds on the square inch over a surface of 1,000 feet by 10 miles (52,800 feet), and raise it up 1,800 feet every minute. To do this we will assume that coal is employed, and that, as it is burnt in the air, the whole of its heat will be effective. The mechanical equivalent of good coal is 14,000,000 foot-pounds for each pound of coal used. We have, therefore, —

$$\frac{14 \times 12 \times 12 \times 1{,}000 \times 1{,}800 \times 52{,}800}{14{,}000{,}000 \times 112 \times 20} = 6{,}110 \text{ tons per minute} =$$

8,800,000 tons in a day, or nearly 9,000,000 tons of coal per day, to increase the rainfall 60 per cent, at a cost, at 10s. per ton, of £4,500,000.

"Of course this is only a theoretical experiment, and ignores all the heat lost by radiation and imperfect combustion; but it serves to give some idea of what is necessary to disturb the course of nature, and, I think, shows how utterly futile any such attempt would be, even near the sea, where the air is moist."

It would seem unreasonable, Mr. Russell concludes, to hope for the economical production of rain under ordinary circumstances; and our only chance would be to take advantage of a time when the atmosphere is in the condition called unstable equilibrium, or when a cold current overlies a warm one. If under these conditions we could set the warm current moving upwards, and once flowing into the cold one, a considerable quantity of rain might fall; but this favorable condition seldom exists in nature.

ROTATION OF JUPITER.

MR. W. F. DENNING has recently published an investigation of the rotation of certain spots on Jupiter which confirms in a remarkable degree a theory already propounded that this planet resembles the sun in not only rotating in different times in different latitudes, but in having the period of rotation of its equatorial region shorter than that of regions in middle latitude. From the red spot which has formed so conspicuous an object on the planet for nearly five years, the following rotation periods are obtained at different times: —

Interval.	Number of rotations.	Period of rotation.
		h. m. s.
1880, Sept. 27–1881, March 17	413	9 55 35.6
1881, July 8–1882, March 30	640	9 55 38.2
1882, July 29–1883, May 4	674	9 55 39.1
1883, Aug. 23–1883, Dec. 5	251	9 55 38.8

A gradual lengthening of the period is thus indicated. On the other hand, from a white spot near the equator the following times are obtained: —

Interval.	Number of rotations.	Period of rotation.
		h. m. s.
1880, Oct. 20–1881, Sept. 30	842	9 50 5.8
1881, Sept. 30–1882, Dec. 23	1,095	9 50 8.8
1882, Dec. 23–1883, Nov. 25	823	9 50 11.4

We thus have the paradoxical result that the rotation period is more than five minutes less at the equator than in the latitude of the red spot. The effect of the motion of matter from one part of the planet to the other would be to make the actual time of rotation longer as we approach the equator. The opposite effect noticed in the times of rotation of spots suggests the possibility that the latter may be endowed with a motion of their own; partaking, perhaps, of the nature of cyclones on the earth's surface.

RED SKIES A CENTURY AGO.

I VENTURE to suggest that recent phenomena are a re-appearance of those of 1783. It will therefore be interesting to give a sketch of the phenomena of 1783, in order to ascertain their similarities and differences.

In the spring of 1783 one of the greatest eruptions of Shaptar Jokul in Iceland resulted in the largest lava-streams ever observed, ten miles long, five miles wide, and a hundred feet deep. Obviously, great quantities of ash must also have been thrown up.

Towards the end of May, *höhenrauch* (dust-haze) was remarked first on the western coast of Europe. It was so thick as to render the sun invisible on the horizon, and even at mid-day it was only a red indistinct disk. It was first noticed, May 29, at Copenhagen, then in England, on July 6 and 7 in France, and rapidly spread over Europe, northern Africa, and eastern Asia. Neither rain, heat, nor cold dispelled it; and, having reached a maximum at the end of July, it remained visible till Sept. 26, 1783, at Copenhagen, thus lasting four months.

There are numerous instances of volcanic ash being carried very great distances. The dust from Coseguina in Central America was carried a hundred and seventy miles, towards Jamaica, and was so dense there as to darken the sky. Hence meteorologists concluded that the *höhenrauch* of 1783 was due to dust from Shaptar Jokul.

The similarity of the 1783 phenomenon with the present seems to me extraordinary. The frightful volcanic explosion of Krakatoa in the Sunda Straits, which began on Aug. 26, 1883, supplies, as did Shaptar Jokul, the material. The splendid redness at sunrise and sunset was first reported from India; and it will be an interesting inquiry to study the spreading of the phenomenon, as was done in 1783.

It was first seen in Japan at the end of August, but only reached Germany in November; and, from the dates of the various records, it seems evident that the ash was thrown into the upper regions of the atmosphere in the tropics. The extraordinary duration corresponds with that of 1783, and is to be explained by the fineness of the dust.

The differences are, that in our country the obscuration of the sun is less than in 1783, which would accord with the greater proximity of Iceland than Java.

It seems probable that rain and snow may bring some of the dust to the earth. I have therefore examined the residue of the rain-gauges from the 1st of December, but thus far without any positive results. Hence I infer that the dust is at present too high for it to be brought down: it is therefore most necessary that such observations be made in many places.

These views have been advocated by Lockyer, who, through spectroscopic research, has been led to the same conclusion.

Before, however, a final decision upon one or another hypothesis can be given, it will be necessary to collect observations, researches, and investigations, from as many points of the earth's surface as possible, which will doubtless be done in meteorological journals.

G. KARSTEN.

Kiel.

BROWNE AND BEHNKE'S VOICE, SONG AND SPEECH.

A practical guide for singers and speakers; from the combined view of vocal surgeon and voice-trainer. By Dr. LENNOX BROWNE and EMIL BEHNKE. New York, *G. P. Putnam's Sons*, 1884. 322 p., illustr. 8°.

A CAREFUL perusal of this work must establish the conviction in the mind of the reader, that the authors thoroughly understand their subject. In reference to voice-formation, many hitherto obscure points are made clear, and many hitherto doubtful points are settled, on physiological, and therefore indisputable, grounds. Thus, the distinctions between the various 'registers' of voice are proved to be due to demonstrable differences in the adjustments of the 'voice-box' and the vocal ligaments. A great deal of information is communicated on the subject of voice-cultivation, and the prevention and treatment of the ailments of 'voice-users.' The precepts in regard to hygienic habits for singers and speakers, their diet, and their clothing, so as to secure unrestricted freedom for the chest and the abdomen, are both judicious and important. About one-half of the book is taken up with the single subject of respiration. The proper management of the breath is shown to be a matter of the highest possible value to singers and speakers. The conclusions arrived at, in reference to the healthful and efficient use of the lungs, commend themselves as thoroughly sound and practical; but condensation in the treatment of the subject would have been a great improvement, as the same principles are again and again repeated under different heads.

The use of the laryngoscope is recommended more than will be thought generally advisable, so far as practical results are concerned; but the authors have handled this instrument to

good purpose in illustrating their descriptions of the larynx by photographs taken from the reflected images in the laryngoscopic mirror. Thus, the chink of the glottis is shown in the act of forming sound. Photographs are also given of the interior of the mouth, showing the positions of the soft palate during the singing of certain notes. These and other illustrations greatly add to the interest of the elaborate descriptions of the processes of phonation.

The book commences with a plea for the study of vocal physiology. The importance of a knowledge of the *principles* of vocal physiology to singers and speakers, no one will dispute; but it may be doubted whether any practical benefit can be derived by voice-users from the anatomical detail of the structure of the vocalizing-apparatus, which is here so copiously exhibited. This part of the treatise might have been much condensed with advantage, so far as its practical applications to speaking and singing are concerned. This portion of the book may, perhaps, have its utility to voice-*trainers*, who ought fully to understand the mechanism which they undertake to direct; but voice-users could not 'govern the ventages' in speech or song with any better effect from knowing the shape and name of the individual cartilages which they set in motion.

In the chapter on defects and impediments of speech, both stammering and stuttering — very indefinitely distinguished — are traced to one common source: "A fault in respiration is at the root of all the mischief." No system is presented or advocated for the relief of stammerers, for the specified reason that "there is none that is honestly applicable to all cases." Something more definite might have been expected under this head. For facts relating to the vocal registers, and to the anatomy of the larynx and the chest, this book will be useful as a work of reference in the libraries of scientific teachers of speech or song; but it will not add much to their knowledge of practical vocal physiology.

M'ALPINE'S BOTANICAL ATLAS.

The botanical atlas: a guide to the practical study of plants, containing representatives of the leading forms of plant-life, with explanatory letterpress. By D. M'ALPINE, F.C.S. 2 v. New York, *Century Company.* 1883. 52 pl. 4°.

IT is difficult to see why this work should be entitled '*The* botanical atlas' (except to distinguish it from the other atlases compiled by the author), since many of its best plates are from an entirely different treatise, which may as fairly lay claim to being called '*The* atlas;' namely, that of Dodel. Judging by its size, it is apparently designed to be used in class demonstrations; but its sumptuous binding somewhat unfits it for the laboratory table, while, on the other hand, the figures are not large enough to be used in place of lecture diagrams. The work is in two volumes, one of which is devoted to phanerogams, the other to cryptogams.

The drawings in the volume on flowering-plants are, for the most part, very good, some of them possessing remarkable clearness of outline; and the coloring is above the average in delicacy of effect. The impression made by this volume as a whole is, that it has received an amount of care which could have been more usefully expended in a slightly different direction. With the exception of the words 'magnified' and 'highly magnified,' there is nothing to serve as a guide to the relative size of the figures of corresponding parts. Every practical teacher of botany would have suggested to the compiler the desirability of furnishing what is never out of place in an atlas of any kind, to wit, a scale of parts. This is always serviceable in the treatment of microscopic or of any minute figures: in fact, without it they are often misleading to the beginner. It may be said, that it is impracticable to state in every case the approximate amount of enlargement or reduction; but certainly in most cases it is not impossible to give a hint as to the relative sizes of the figures.

Drawings of the size given in this atlas are chiefly useful for individual and not class study. With a greater enlargement, the plates would have proved useful in classes of ordinary size. A few attempts have been made to provide plates of suitable size for class use; but the subjects have not always been so well chosen, nor so successfully treated, as those in this volume. The well-known series made by Professor Henslow is so crowded that the effect of the exquisite drawing is obscured. In the lack of good wall-plates, we have a want which ought to be supplied. If the plates in the present volume were larger, so that they could be employed for demonstration before classes of moderate size, they would go far to meet this need. Their size now restricts their employment to the individual student, and this necessarily lessens their utility; but this is a matter for publishers to consider.

The volume relating to cryptogams contains twenty-six plates, some of which include a large number of figures copied from standard

authorities, a small number of the figures being original. The object seems to be quite as much to attract the eye by brilliant coloring as to furnish the student with accurately drawn microscopic details. The quality of the plates varies considerably: for, while those of Volvox and Mucor are effective, the same cannot be said of those of some of the lower forms, — as Nostoc, Oscillaria, Gloeocapsa, etc., — where a mass of color takes the place of clearness of outline, and important details are not well brought out. This may, however, be the fault of the lithographer, rather than of the original drawings. Considering their biological importance, better and more numerous figures of Myxomycetes might have been given. The plates of Fucus and Cetraria are unnecessarily bad, considering that there are several works from which excellent figures could have been copied; and the same may be said of the plate of Florideae, where no good figure of the procarp or cystocarp is given, and that of mosses, where the peristome is badly drawn. The antherozoid of a fern is represented not only without the usual bladder-like appendage, but also without cilia.

The text consists of brief descriptions of the figures, with directions for studying the objects themselves in the laboratory; the whole forming a skeleton to be filled out by the instructor. It seems to us that the use of the term 'gonidium' in the sense of non-sexual spore is hardly warranted. The word has a technical meaning in lichens, and its use in other orders has been superseded by better terms; and it is certainly undesirable to speak of the gonidia of Penicillium, for instance.

The work is likely to have a large sale among amateurs who wish a hasty glance at the subject; but it would be better for students to purchase some of the text-books, like Sachs or Luerssen, where they will find the same figures, and a full text as well.

ECONOMIC ENTOMOLOGY.

Injurious insects of the orchard, vineyard, etc. Illustrated with over seven hundred and fifty woodcuts and twenty-five pages of classified illustrations. By MATTHEW COOKE. Sacramento, *Crocker*, 1883. 472 p., illustr. 8°.

DURING the last few years, there has been a great growth in the popular appreciation of the importance of economic entomology. As a result of this growth, the demand for popular works on this subject has increased. To supply this demand, numerous publications have appeared in rapid succession. Of especial interest among these publications are the manuals of Miss Ormerod, Mrs. Treat, Mr. Saunders, and Mr. Cooke.

The work of the last-named author resembles in many respects the works of the others. Like them, it is largely a compilation; its chief merit being that it gives, in an easily accessible form, descriptions and figures which were scattered through many works. There is, however, some original matter. This consists of notes respecting various Californian species, which were studied by the author while serving in the capacity of chief executive horticultural officer of that state. The insects are discussed under the head of the plants they infest. The descriptions are written in a clear and popular style; but in some cases they are too brief, and in others they bear the marks of hasty compilation. A peculiar and excellent feature of the work is the bringing-together into one part descriptions of all the remedies suggested. These are referred to throughout the work by numbers. In this way unnecessary repetition is avoided. In the introduction a history of the legislation to prevent the spread of injurious insects in California is given. The work is profusely illustrated; but the good figures are not new, the new ones are not good, and all are poorly, printed. Still the book will be found to be a very useful one, especially to the fruit-growers of California.

Twelfth report of the state entomologist on the noxious and beneficial insects of the state of Illinois. First annual report of S. A. Forbes, for the year 1882. Springfield, Ill., 1883. 10+154 p., illustr. 8°.

IN this work we have the results of the first half-year of Professor Forbes's administration as state entomologist. In studying the report we are deeply impressed, both by the amount that has been accomplished and by the thoroughness with which the work is being done. Several of the articles in the report have been published separately during the past year, and have been noticed already in these columns. Of the other articles, the notes of experiments in the destruction of the European cabbage-worm, the account of a new plant-louse infesting cucurbitaceous plants, and studies on the chinch-bug, are the most important. The observations on Micrococcus insectorum Burrill, a bacterium parasite of the chinch-bug, are especially interesting.

We are glad to see that Professor Forbes has adopted the plan of intrusting some of the more special investigations to his assistants, and publishing the results they have

obtained in their own words, over their own signatures. One can hardly over-estimate the value of the added enthusiasm which assistants will bring to their work under this method. Not only will they do more work, but it will be of a much higher quality; and the office in which they are engaged will be able at an early day to command the services of a corps of specialists instead of mere day-laborers. At the same time a large part of the work of each individual in an office of this kind must be merged into what shall go out as the work of the office. And it is not the assistants alone who suffer from this; for the chief must devote much attention to executive duties, which shorten greatly his time for study.

In this report there are two papers by Professor Forbes's assistants. The first is an important article on the gall-mites, by Mr. H. Garman. It deals with the general characteristics of structure and habits of the Phytopti, and includes descriptions of seven new species, and the cecidii of several species for which names are not proposed. Previous to this, but three species have been indicated by name in the United States. The second paper is by Mr. F. M. Webster, and is an excellent account of the angoumois grain-moth and its parasites. There is also an account by Prof. T. J. Burrill, of the habits of Agrilus granulatus, which he has found to be a destructive borer of the Lombardy poplar.

First annual report on the injurious and other insects of the state of New York. By J. A. LINTNER, state entomologist. Albany, 1882. Senate doc. No. 93. (Issued October, 1883.) 381 p., 84 cuts. 8°.

AFTER an interval of eleven years, we are again favored with a report of a state entomologist of New York. This first report by Mr. Lintner is a large one, and evidently represents a great amount of work. The first eighty pages are devoted to a history of American economic entomology, and a discussion of the more important insecticides now in use. Then follow accounts of thirty species of insects. Of especial interest among these are those of Polype laricis, Crambus vulgivagellus, and some species of Anthomyiidae. In an appendix there is a very complete account of the writings of Dr. Fitch.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Paleontology. — During the field-season of 1883, Prof. W. W. Fontaine was detailed to collect and study fossil plants in Virginia. Late in July he began an examination of the tertiary strata in the vicinity of Richmond. Throughout the remainder of the season his field-work was continued on the mesozoic and tertiary of eastern Virginia, after which he was occupied in the preparation of drawings of the specimens collected.

Prof. L. C. Johnson, who has been working in the South Atlantic district, principally in Alabama, has returned to Washington after a most successful season. He is now engaged in unpacking and arranging the large collections that he secured during the summer and autumn. Several barrelfuls of material from the Claiborne group in Alabama were obtained; and the sorting of the extremely interesting collection included in them has kept him busy since his return from the field.

Mr. J. B. Marcou (assistant to Dr. C. A. White, in charge of the department of mesozoic paleontology) reports that a collection of very interesting fossils has been sent to the National museum from Skonum Point, British Columbia, by Mr. James G. Swan of Port Townsend, W. T. These fossils are being examined by Mr. Marcou, who says some of them are new, and that others are evidently identical with specimens from the coal-bearing rocks of Queen Charlotte Island, described for the Canada geological survey by Dr. J. F. Whiteaves in his 'Mesozoic fossils of Queen Charlotte Island.' Mr. Marcou says that the collection presents quite an oolitic facies.

Miscellaneous. — Mr. F. M. Pearson, topographer, who has been working in eastern Tennessee, says that the waste of valuable timber in that region, which has only recently ceased, is almost inconceivable. The finest specimens of walnut and cherry timber are found, and are used by the inhabitants for fence-rails, fire-wood, and other wasteful purposes. Since the survey has been working in the country, it has been instrumental in working a change in this respect, and the people are beginning to appreciate the value of their timber resources. Another result is, that the mineral resources are becoming known, and investments both in timber and in mineral properties are now being made where but a short time ago they would have been considered unprofitable.

Dr. Thomas M. Chatard of Baltimore has been appointed assistant chemist on the survey, and will be in the laboratory at Washington with Prof. F. W. Clarke.

Educational rock suites. — The survey proposes to collect suites of about one hundred representative rocks, to be used in teaching the elements of lithology. Two hundred specimens of each kind of rock will be

gathered; and they will be obtained as nearly identical as practicable, according to a scale adopted by the survey. Eventually, therefore, two hundred suites, of about a hundred specimens each, will be made up. They are to be accompanied by descriptive text, and issued to colleges and other educational institutions. The work of collection will be divided among the members of the survey, and will be distributed through about two years' time.

Additions to collections. — During the season of 1883 two hundred boxes of specimens were sent in to the main office of the survey by the various field-parties. They included rocks, minerals, fossils, and mineral waters. This number by no means comprises all the collections made, as a large number have not as yet been forwarded to Washington.

In the Rocky Mountain district, in charge of Mr. S. F. Emmons, with headquarters at Denver, Col., twelve hundred specimens of rocks from the Silver Creek mining-district were collected, and series of the type-specimens of hypersthene-andesite of Buffalo Peaks were secured.

After the close of field-work in the Yellowstone National Park, Mr. Joseph P. Iddings was sent to the Eureka district in Nevada to make collections of rocks for the educational rock series. He obtained sufficient material for two hundred cabinet specimens of five characteristic rocks. Three of them illustrate types of igneous rocks from the Great Basin, and two belong to the sedimentary series. They will all be fully described in the 'Geology of the Eureka district.'

Harvard college herbarium.

Additions. — Of the 8,755 sheets incorporated during the year, over 5,000 (holding probably 7,000 specimens) were derived from the rich herbarium of the late George Curling Joad of Wimbledon, near London, from which at least 3,000 more are still to be selected. For this most valuable collection of the plants of Europe and adjacent parts of Africa and Asia, or rather for such portion of it as will be retained, the herbarium is indebted to Sir Joseph Hooker, director of the Royal gardens at Kew, to which establishment it was bequeathed, and by whom, after certain selections had been made from it for the Kew herbarium, it was generously made over to this herbarium for the supply of its needs, the residue to be passed on to the National museum at Washington. So rich and abundant this collection proves to be, — containing, as it does, the principal published *exsiccata*, and most of the critical or local species of Europe, in authentic and attractive specimens, — that, notwithstanding the ample appropriation on our part, the materials which pass from our hands will still well represent the principal part of the European flora. This collection is supplemented by the presentation (in continuation of former gifts) of several hundred plants of Algeria and Tunisia, on the part of Dr. Cosson of Paris, who is engaged upon a Flora of Algeria.

The demand which such foreign collections make upon the time of the curator, Mr. Sereno Watson, and the director, Dr. Asa Gray, although very considerable, is small in comparison with that which has to be devoted to the critical examination and naming of the multifarious collections, large or small, which are incessantly poured in from all parts of our own country. A response to these demands cannot be avoided, generally cannot be deferred, in justice to the collectors and donors, and without risk of diverting the streams, which, flowing in ever since its establishment, have enriched this herbarium, and rendered it adequate to its leading purpose. But they press so heavily and unceasingly upon the officers, that they greatly retard progress in the preparation of works undertaken, and which ought to be proceeded with.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Ottawa field-naturalists' club, Canada.

Feb. 14. — Mr. W. Hague Harrington presented a list of Coleoptera captured in the neighborhood of the city during the past six years, and read a brief paper introductory to it. The list was stated to contain 926 species; but, as a large number remain yet undetermined, the list, when published, will include about 1,050 species. Many species are recorded which were formerly unknown in Canada, and there are three or four beetles which are probably new species. Mention was made of a few of the rarer forms which had been captured, such as Chrysobothris pusilla, Phymatodes thoracicus, Fornax badius, F. Hornii, and Sarpedon scabrosus. Of the latter, two females had been taken, which were now in the respective collections of Drs. Horn and LeConte. The collection was stated to be poor in Carabidae, Dytiscidae, etc., and comparatively rich in Buprestidae, Elateridae, Cerambycidae, and other families which had been specially investigated as containing species destructive to vegetation. The Ottawa fauna was briefly compared with that of several other districts, and was shown to resemble most closely that of Lake Superior. —— Mr. J. B. Tyrrell read a paper on the 'Revision of the Suctoria,' giving an outline of the different opinions held by entomologists in regard to the fleas, and the results of his own microscopical researches. A brief mention was made of some of the species which occur upon Canadian animals, and of the fact that other species had been found, both on mammals and birds, which it had been as yet impossible to determine. ——After an interesting discussion, the report of the conchological branch was read by Mr. F. R. Latchford. One species, Patula asteriscus Morse, had been added to the list of shells, and additional specimens of several very rare species had been obtained. Of the new shells, several specimens

had been obtained by Mr. Harrington while sifting moss for small Coleoptera; and with it occurred a number of other species, including Hyalina milium Morse, Pseudohyalina exigua Stimpson, Vertigo milium Gould, and V. Gouldii Binney. Among many other interesting and valuable facts was reported the rapid increase, in and around the city, of Limax agrestis Linn. In 1882 a single individual of this species was found in a garden. During the past summer it was found in hundreds in this garden, and other gardeners complained of its destructive attacks. The advent in Ottawa of this voracious species of foreign origin (long known in cities along the Atlantic coast) is a fact of much economic as well as scientific interest. After the reading and discussion of this report, the members spent some time in examining the specimens exhibited by Messrs. Harrington, Tyrrell, and Latchford, in connection with the papers and report.

Torrey botanical club, New York.

Feb. 12. — Dr. Newberry gave an account, continued from a previous meeting, of the vegetation bordering the line of the Northern Pacific railroad. Many of the trees are undoubtedly specifically the same as eastern ones, although considered and described as distinct. They should probably be referred to varieties of the same species. All are, no doubt, descended from the same ancestors, although now altered by the difference in surrounding circumstances. Many of the smaller plants are identical, but generally the aspect of the vegetation is very distinct and striking. The Douglass spruce (Abies Douglassii, Lindl.) and Pinus Lambertiana, Doug., are scarcely less in size than the famous 'big trees' of California. Some of the former are three hundred feet high and six feet in diameter. The annual rings are sometimes half an inch wide, showing very rapid growth. One specimen, about five feet in diameter, showed five hundred annual rings. Mountain mahogany (Cercocarpus ledifolius, Nutt.) has a very hard, dense wood, considered superior to coal for making a bright, hot fire. Several species of the genus Berberis are conspicuous features, owing to the showy racemes of berries. They are called indiscriminately 'Oregon grape.' Several species have apparently not been described. The 'Manzanita,' a name given to several species of Arctostaphylos, produces a fruit resembling a small apple, which is used as a food by the Indians. No hickory-trees are found, and only one hazel (Corylus rostrata, Ait.). The berries of Gaultheria Shallon, Pursh., are much used by the natives, as are also the fruit of the 'service-berry' (Amelanchier alnifolia, Nutt.) and several species of Vaccinium. Spirea millefolium, Torr., is very abundant and conspicuous: it would make a very ornamental garden-shrub. Artemisia tridentata, Pursh., is the common sage-brush of the region. Kalmia glauca grows the same as with us; and Rhododendron Californicum, Hook., is hardly different from our R. maximum, L.

Amongst the herbaceous plants are to be seen, particularly, three species of Mimulus, — cardinalis, Lewisii, and luteus. Antennaria dioica is very conspicuous with its red flowers. Many species of the genus Phlox are abundant and conspicuous. The showy genus Castilleia is also well represented. One of the most extensively represented genera is Eriogonum, — more than twenty species in this region. Many species of Ribes are to be seen, some of which have apparently not been described. Fire has devastated immense tracts of forest, and completely altered the appearance of the landscape in many places. Where the ground has been burnt over, there generally springs up a thick growth of Pteris and Vaccinium.

Peucedanum ambiguum, Nutt., is an important food-staple, the root being dried and powdered.

Cincinnati society of natural history.

Feb. 5. — Mr. W. H. Knight read a paper on the motions of fixed stars and on non-luminous bodies of space. —— Dr. W. A. Dun exhibited a series of relics from the Swiss lake dwellings, and read a short paper describing them. —— Prof. Joseph F. James gave a brief account of some observations on the common Caladium. After cutting off a growing, healthy leaf, a jet of water shot out from the apex of the unfolding leaf, and continued flowing with a rhythmical movement at the rate of a hundred and eighty pulsations per minute for several hours.

Academy of natural sciences, Philadelphia.

Jan. 10. — Miss S. G. Foulke stated that the modes of reproduction of Clathrulina elegans are four in number, — by self-division, by the instantaneous throwing-off of a small mass of sarcode, by the formation and liberation of minute germs, and by the transformation of the body into flagellate monads. The fourth mode is significant in bringing to light a new phase in the life-history of the Heliozoa. The Clathrulina, in which the phenomena were observed, withdrew its rays, and divided into four parts, as in the ordinary method; but the sarcode instantly became granular and of a rough surface. Then followed a period of quiescence, in this case of five or six hours' duration, although in other instances lasting three days and nights; after which one of the four parts began slowly to emerge from the capsule, a second following a few moments later. While passing through the capsule, these masses of sarcode seemed to be of a thicker consistence than the similar bodies, which, in the ordinary method, instantly assume the Actinophrys form. After both had passed completely through, for nearly a minute they lay quiet, gradually elongating meanwhile. Then a tremor became visible at one end, and a short prolongation of the sarcode appeared waving to and fro. This elongated at the same time into a flagellum, the vibrations becoming more rapid, until, at the same moment, both the liberated monads started away through the water. They were followed for about ten minutes, when both were lost to sight among a mass of sediment, and the fear of mistaking one of the common monads for them led the observer to abandon the search. Another monad was followed through various movements, and finally seen to attach the tip of its flagellum to the glass, and revolve swiftly for a few moments, when

instantly the whole body became spherical, rays were shot out, and the transformed monad was in no point, except that of size, to be distinguished from its Actinophrys-like relative. The whole development, from the time when the monad began its free life, occupied two hours and some seconds.

Prof. H. C. Lewis called attention to a mass of cast-iron from the Emaus iron-works, near Allentown. The iron contained crystals of graphite, which, again, held portions of cast-iron in their interior. The composition of cast-iron, which permits the formation of graphitic carbon, was considered, and compared with that of steel. Although the mass of iron must have been at one time in a molten state, it yet contained pieces of unaltered anthracite coal, which undoubtedly remained unconsumed in consequence of the entire absence of the oxygen necessary for its combustion. The presence of such unconsumed pieces of coal in a mass of molten iron might be held as illustrating the way in which carbon may exist in meteorites, or chalcopyrite in trap rocks.

Dr. Benjamin Sharp, referring to his recent communication on the visual organs of Solen ensis, stated that he had since determined the presence of similar organs in the mantles of the clam, the oyster, and the sand-clam. Their presence was made evident by the retraction of the mantles when shadows are passed over them. The structure of the peculiar cells, supposed to be primitive eyes, was the same as that of the cells before described in the siphon of Solen, including the presence of the transparent portion at the end of each.

Chicago academy of sciences.

Jan. 14. — The committee, consisting of Dr. H. A. Johnson and B. W. Thomas, appointed to investigate the bowlder-clays underlying the city, made its report upon a disk-shaped organism found both in the clays, and also in the filtrate from the water-supply, of Chicago. They were yellow, apparently flat or concavo-convex, and varied in size from $\frac{1}{85}$ to $\frac{1}{250}$ of an inch. Similar organisms have been found by several naturalists in the Devonian rocks of North and South America; and they were described by Dr. Dawson under the name of 'Sporangites,' and considered by him as macrospores of some acrogenous plant. Professor Orton of Ohio believes there are several species of varying sizes. We have, however, say the committee, none so large as discovered by Professor Orton. Our largest forms are not more than $\frac{1}{85}$ of an inch in diameter, and our smallest about $\frac{1}{250}$ of an inch. We have two, and possibly more, varieties. One has a well-marked ledge or zone around it, and extending, perhaps, an eighth of the way across it. Within this are the spines noted below. Others have no such markings, and do not, as a rule, have spines; and while some are a very light yellow, and almost transparent, others are of a dark reddish brown, and almost opaque. Whether these differences are sufficient to justify a separation of them into different species seems to be at present doubtful. So far, no forms have been met with by either of us, having any thing like a stem or point of attachment. Nor have we found any of the spherical or oval sacs which were contained in the collections of Mr. Derby, in Brazil.

There are found here, however, what we believe have not been found elsewhere; namely, on many of the disks, well-marked spines. These are, as a rule, clustered together, occupying a central portion, the diameter of which is three-fourths of the entire breadth of the disk, but in some instances the spines cover the entire surface. Along with these disks are, in quite large quantities, broken pieces of what seem to have been leaves, perhaps pinnate in form. Besides these, dark globular masses, which seem to be possibly spores or microspores, are frequently seen on the disks, and also scattered among them. These are — at least, in some cases — also contained within the substance of the disk. They are regular in form, and vary in size from $\frac{1}{600}$ to $\frac{1}{3000}$ of an inch in diameter. They are evidently organized; for in some cases there is seen a reticulum, or net-work, within the dark substance of the body. With these microspores, if such they are, are also masses of dark matter that, at least in some cases, are made up either of these globular forms alone, or of these and other organic material, such as the stems described by both Professor Dawson and Professor Orton. The clay beneath the city of Chicago and in the vicinity is full of bowlders of various sizes, from that of a walnut up to several cubic yards; and on many of these bowlders are well-defined ice-markings. Some of the smaller bowlders are shale which has never been ground down, and in these unchanged pieces we also frequently find large numbers of disks. These masses of shale, so far as we can ascertain, are identical with the shales of the upper Devonian formation. It will be seen that the disks are evidently not the product of their present location. They have been in some far-off age embedded in the shales; and subsequently these shales have been ground to clay, and, with other material constituting the bowlder-clays, have been redeposited beneath the lake and the adjacent shores. They are now undergoing another dispersion; for they are washed from their present position in the Chicago clays, and are mixed with the sands and alluvium, to be carried by the currents and winds to some new resting-place. Consequently our water-supply is now full of these products of probably some millions of years ago. They were perhaps water-cresses, and might have been of excellent flavor when fresh. They were fragant with gums or spices, as we know from their present composition. They are not now probably injurious to health, but they are especially valuable as a reminder, that in some widely different time, and amid very different surroundings, an abundant marine vegetation was being produced which has been preserved to our own day.

Vassar brothers' institute, Poughkeepsie, N.Y.

Jan. 2. — C. B. Warring, Ph.D., exhibited the gyroscope, and gave the explanation of its action the following form.

Dr. Warring, in giving his explanation of these phenomena, said it was important to clearly grasp these two principles: 1. A body set in motion will con

tinue in motion until something stops it; 2. A body moving in any direction is not retarded by a force exerted at right angles to its direction.

We will suppose the ring to be laid aside, since it serves only for holding the disk, and that the disk or wheel is cut away until only a narrow strip is left, like two arms extending in opposite directions from the axle: its form will then resemble a T-square, which will now be used to illustrate the actions of the gyroscope.

Hold the stem of the square in the left hand, close to the end, and make the cross-piece vertical; hold the left hand still, and let the cross-piece move up or down: evidently it will describe part of a circle. If it is held so that the cross is just in front of a plumb-line, so that both can be viewed at once, it will be seen that the upper end of the cross moves away from the plumb to the right, while the lower moves away from it also, but to the left. If, while the left hand remained stationary, the cross had been allowed to drop freely, the top and bottom would evidently acquire a certain horizontal motion, one to the right, the other to the left. If, now, the T-square be quickly turned over, so that the top and bottom change places, this will not interfere with motion previously acquired: the bottom (which has now become the top) will continue to move to the left, while that which was the top will move to the right; and, as the motion continues (as in case of a pendulum), the ends of the cross are pushed back to where they were, and the instrument rises to its first position.

This explains why the gyroscope, in apparent defiance of the law of gravity, remains, when supported only at one end, in a horizontal position.

To understand why the instrument rotates around the central point, in a direction always the opposite of that of the top of the disk, the T-square is again brought into service. Hold it as before, and let it fall a few inches: as in the first experiment, the top, when the T goes down, gets a motion towards the right; but, before the instrument can be reversed, it must go half way, and point horizontally, instead of up and down. Evidently the motion which sends the upper end to the right will push the instrument (if the top was revolved towards the south) towards the north: hence the horizontal motion.

The horizontal motion is slow in proportion as that of the disk is rapid, because of the movement of the arms of the T. If the T turns slowly, it has more time to give motion to the ends of the arms, and consequently they push it around faster. If the T turns very quickly, it falls a very short distance (has so little time): hence the ends of the arms get very little motion, and, of course, can impart but little. A quick motion of the disk, therefore, makes a slow horizontal movement, and a slow motion of the disk makes a quick horizontal movement.

A careful consideration of the above will make it easy to see why the gyroscope ceases to maintain itself if the lateral (or horizontal) motion is stopped; for, in order to maintain itself, the motion imparted to the ends of the T-square, when vertical, must be expended in lifting: if spent in any other way, nothing is left to overcome gravity. Now if, as the square falls, and the T has become horizontal, some obstacle prevent its moving still farther to the right, its motion in this direction would cease; and, of course, when it arrived at the lowest point, nothing would be left to lift the instrument.

Another paradox is, that the instrument must fall somewhat, in order to produce any of its peculiar phenomena; but this, too, is easily explained. Every thing depends upon the two extremities of the T getting a motion, one to the right and the other to the left, when the T is vertical. If the T does not fall, or if it is not lifted up (for either movement will do equally well), there will be no such motion: only, if the first sends the instrument north, the other will send it south.

This directly or impliedly explains all the phenomena of the gyroscope.

NOTES AND NEWS.

THE death of Guyot has been soon followed by that of another of the notable scientific men, who, educated in Europe, took up their lot with us, and became, so to say, wholly our own. Dr. George Engelmann of St. Louis — our oldest botanist (excepting the venerable Lesquereux), as well as an eminent physician, for a time a fellow-student with Agassiz in Germany — died on the 11th inst., at the age of seventy-five. A biographical notice may be expected in an ensuing number.

— The *Journal of agricultural science* proposed from the North Carolina agricultural station recently, and to which we referred Dec. 28, has met with universal approval and most unexpected support.

Nearly one hundred shares of stock have been taken upon the plan proposed; and the Houghton farm proposes to assume all of the mechanical work of a monthly journal, and guarantee this part of its expense for one year. Without any special effort to secure them, about three hundred subscribers are reported.

In response to a cordial invitation of the commissioner of agriculture, a meeting will be held to organize this enterprise, at the Department of agriculture at Washington, at ten A.M., Wednesday, Feb. 27. All the friends of the scheme are urged to be present at this meeting, and participate in the inauguration of the journal. It is hoped that each agricultural college, experiment-station, etc., will send a representative.

— Commodore Samuel R. Franklin, U.S.N., has been detached from duty on the naval examining board, and ordered as superintendent of the naval observatory, to succeed Rear-Admiral R. W. Shufeldt, who was placed upon the retired list on Feb. 21.

— At a concert given by the Choral club of the University of Wisconsin on the evening of Feb. 8, two songs by Sir William Herschel were sung, — the first, a glee, 'Go, gentle breezes;' the second, a catch,

'They say there is an echo here.' The manuscript copies of this music were loaned by the college library.

— The American ornithologists' union, with the enthusiasm of new institutions, has taken up the English sparrow question in an energetic and scientific way. A committee of the association has issued a circular asking answers to a series of twenty-eight questions. The value of the replies, especially to the later questions, will vary exceedingly; and we should judge it exceedingly difficult to assign them their proper relative value. Nevertheless, the general conclusion the committee will reach as to whether the bird is, on the whole, injurious or beneficial to agriculture, will not be likely to be disputed. The committee has divided the field among its members, Mr. Montague Chamberlain of St. John taking the British provinces; Mr. N. C. Brown of Portland, the three northern New-England states; Mr. H. A. Purdie, the other New-England states; Mr. E. P. Bicknell of New York, New York and the Western states; and the chairman, Dr. J. B. Holder of New York, the Southern and Middle states. The committee intends to construct a map of the present geographical distribution of the sparrow; and any volunteer information by those not reached by the circular will be gladly received by the chairman, who may be addressed at the American museum of natural history, New York. The authorities in Bermuda already offer bounties for the destruction of the sparrow, although heavy penalties are laid on the destruction of other birds on that lonely island.

— The sixth Saturday lecture of the Washington course was delivered on Feb. 9, in the lecture-room of the National museum, by Capt. C. E. Dutton, U. S. A., on 'The Hawaiian Islands and people.' Capt. Dutton visited the islands two years ago, in the interest of the Geological survey, to study the volcanic phenomena there for purposes of comparison with the region of extinct volcanoes in the western part of our own continent. His lecture was devoted in large part to a discussion of the geology of the Hawaiian group. An audience of about eight hundred was present. Mr. H. C. Burchard, director of the Mint, occupied the chair; and at the close a vote of thanks was moved by Major J. W. Powell.

— The Fish-commission steamer Albatross, now cruising in the Caribbean in behalf of the Hydrographic office, arrived at St. Thomas, Jan. 17, after a seven-days' voyage from Norfolk, and, after coaling, started on the 24th for Curaçoa, where she was due on the 14th of February. While at St. Thomas, the naturalists of the ship made considerable collections of birds and shallow-water invertebrates.

— Mr. F. W. True, curator of mammals in the National museum, is now at the British museum, studying the types of cetaceans, and especially of the Delphinidae, with the view of settling some important questions in the nomenclature and relations of the North-American forms. It is probable that his studies will demonstrate the identity of many of our Atlantic species, described as distinct by Agassiz, Cope, and others, with long-known European forms.

— At the November meeting of the Society of biblical archaeology, London, Mr. Budge of the British museum read a paper on the fourth tablet of the series of cuneiform texts relating to creation. Mr. Rassam has recently found a large Babylonian fragment of this fourth tablet. The language of the tablet is vigorous, and, like that of many of the cuneiform hymns, approaches in dignity the majestic roll of the Hebrew psalms. The deepest interest in connection with the tablet is the apparent acquaintance with rhyme and rhythm. Mr. Budge does not give enough of the original to aid us in testing this subject, but what he does give is favorable to the supposition. A peculiar kind of alliteration in the Babylonian cuneiform writing is already familiar. The fragment of a hymn on pp. 15 and 16 of Mr. T. G. Pinches' 'Texts in the Babylonian wedge-writing' is divided into stanzas of five lines each, and the same syllable begins each line of the stanza. There are five lines beginning with *ar*, five with *ba*, five with *su*, etc.

— The London papers are now discussing the desirability of opening the various museums of that city in the evening, for the benefit of that large class who have no command of their time during the day. The *Globe* is filled with letters on the subject. This discussion is called forth by the rumor that a bill will be presented in Parliament at the next term, for the opening of several of the more important art-galleries, museums, etc., after business-hours. South Kensington museum, and the Museum of practical geology, are now open from ten A.M. to ten P.M. on Saturdays, Mondays, and Tuesdays. There is no doubt but that these evening sessions are very useful, especially to that great and intelligent class of persons who do not belong to the group of 'workingmen' as that word is generally understood, but who, nevertheless, earn their living by work during the day, and have only the evening in which to gain information and widen their mental horizon. Many of our own cities would be greatly benefited if the museums and art-gallery could be opened in the evening.

— It has been the feeling for some time past in Germany, that that country should have a meteorological society. The want of this has been met by the publications of the Austrian society; but now that meteorology is making such rapid strides, and so many are becoming interested in it, there is much reason for the recent move made by the German meteorologists.

On Nov. 18, 1883, the following well-known contributors to our knowledge of this science met at Hamburg to ground a 'Deutsche meteorologische gesellschaft:' Assman, van Bebber, vo nBezold, Börgen, Börnstein, von Danckelman, Dinklage, Ebermayer, Hellmann, Honsell, Karsten, Klein, Koch, Köppen, Krebs, Müttrich, Neumayer, von Schroder, Schreiber, Sprung, Thilenius, Zöppritz. Many others sent letters expressing their intention to give aid to the project. The first general meeting of the society

will take place in September, 1884, at Magdeburg. Dr. Neumayer is president.

The aim of the society is to pay attention to the science of meteorology, as well as its relations to practical life. As a means of accomplishing this, 1°, meetings of the society and its branches will be established; 2°, a journal of meteorology will be issued; 3°, meteorological investigations will be aided, partly directly, and partly through its branches; 4°, lectures and other measures will be introduced for the distribution of meteorological knowledge in wider circles. The members are to be honorary, foundation, ordinary, and corresponding. The yearly assessment for ordinary members is ten marks ($2.50).

From private letters we are informed that the first number of the journal will be issued in a couple of months. It might seem at first as though this new journal would interfere with the work of that excellent journal, the *Oesterreichische zeitschrift für meteorologie*; but we believe that the editors of the journals will enter into such relations with each other that the two journals shall be supplementary the one to the other. It may be expected that this new journal will occupy as important a place as the Austrian, and therefore it ought to find its way into the hands of all those who wish to keep informed of the progress of this science. The *Deutsche seewarte* at Hamburg will naturally be the chief seat of work in connection with the issue of this journal. The treasurer of the society is Mr. Ernst Bopp, Königstrasse, No. 6 II, Hamburg.

— The M. P. club, a club of mathematicians and physicists living in Boston and vicinity, which meets once a month for the discussion of vexed questions in their departments, has issued the following list of subjects for discussion: —

1. Given a solid body in which the moments of inertia about four axes passing through one point are equal, does it follow that the moments of inertia about all axes, through the same point, are the same? 2. Are there any general methods for determining the form of a function when certain special values are known, or when certain conditions are given? For example: (*a*) To find $F(x, y, z)$, given $F(x, x, z) = 0$, and $F(x, y, z) = 1$. One solution is $F(x, y, z) = \frac{x-y}{z-y}$: what others are there? (*b*) $p = F\left(\frac{u}{v}, \frac{du}{dv}\right)$, $t = \dot{F}\left(\frac{u}{v}, \frac{du}{dv}\right)$: given $\frac{dp}{dv} + \frac{p-t}{v} = 0$, also given, that, when $\frac{u}{v}$ and $\frac{du}{dv}$ are interchanged, then p and t are interchanged, to find F and $\dot{F}$. 3. "Is it, therefore, an essential condition of equilibrium that $p\,(X\,dx + Y\,dy + Z\,dz)$ should be a perfect differential of some function?" (W. H. Besant's 'Hydromechanics,' p. 13.) "In this case of compressibility, $u\,dy - v\,dx$ is not the differential of any function; so that the function F does not exist, although, of course, stream lines exist" (Minchin's 'Kinematics,' p. 152). Such passages as these suggest the inquiry, "How are we to interpret physically the fact that a given differential is not an exact differential?" (see Clausius' 'Mechanische wärmetheorie,' p. 4.) 4. The graphical treatment of algebraic problems (see Vose's little book on the subject, published by Van Nostrand). 5. Graphical statics. 6. Anharmonic ratios; suggestions of new nomenclature. 7. Koenig's researches on beats and beat tones. 8. Euclid's doctrine of proportion. 9. Multiple algebra. 10. The comparison of Grassmann's theory of extension and Hamilton's quaternions. 11. Imaginaries in quaternions. 12. Weierstrasse's investigations in analytics and geometry. 13. The precise nature of the ancient problem of the quadrature of the circle. 14. The twelfth axiom of Euclid. 15. The bearing of the modern conception of non-Euclidean space on our theory of the foundation and certainty of geometric truth. 16. The true relation of hyper-space analytics to questions of actual existence. 17. Riemann's surfaces. 18. The meaning of an infinitely distant point on a straight line. 19. $\frac{1}{\infty}$ does not equal $a - a$. 20. Cayley's exposition of the logical structure of plane geometry ('Encycl. Brit.,' 9th ed.). 21. The synthetical (as opposed to analytical) character of all judgment and proof that is strictly mathematical. 22. The development of algebra from first principles as the science of pure time. 23. The calculus of logic. 24. The writings of François Viète. 25. Comparative merits of the method of limits and method of infinitesimals in elementary methods. 26. The same in the exposition of the higher calculus (with especial reference to Johnson and Rice's new 'Method of rates'). 27. Is gravitation a truth empirical, or *a priori?* and the limits of Newton's law of rate in gravity. 28. The principle of least resistance. 29. What exactly is meant by the correlation of forces, and what is its bearing on the conservation of energy? 30. The dissipation of energy. Its meaning and bearing on the stability of the universe. 31. Recent researches upon the atomic theory and upon the resolvability of the elements. 32. What constitutes the chief resistance in the case of a body moving through the water? 33. What is the form of least resistance for a row-boat? What for a sail-boat? What for a steamer? 34. Cause of capillary ascensions and depressions. 35. The means whereby water is able to penetrate capillary tubes against a superior pressure of a gas (see Daubrée's 'Études synthétiques de géologie expérimental,' Paris, 1879). 36. Microscopic action. 37. The diathermancy of ice from the point of view of James Croll's theory of glacial motion. 38. Direction of electric currents in diamagnetic bodies, e.g., bismuth. 39. Underground telephone circuits. 40. Elasticity and permanent set. 41. Diffraction gratings, plane and curved. 42. A short discussion (not too technical) on some of the instruments of research, such as the bolometer and the inductive balance. 43. Recent researches on the distance of the sun. 44. The origin of meteorites: are they volcanic ejections? 45. The aurora borealis, zodiacal light, etc. 46. If steam be enclosed in a cylinder open on the outside to the air, and compressed, is it possible to get a compression curve concave downwards (abscissae representing volumes, and ordinates pressures), and, if so, when?

SCIENCE.

FRIDAY, FEBRUARY 29, 1884.

COMMENT AND CRITICISM.

SOMETHING was said in these columns recently about the shortcomings of geography-teaching in the lower schools. The same complaints hold in regard to elementary science teaching in general. The wave of enthusiasm for teaching science in primary and middle schools, which swept the country a few years ago, has not brought us as much nearer the millennium as was at first fondly anticipated; but it has left many of us wiser, if not sadder. There was at first a general but strange misconception of what ought to be taught, and how the teaching was to be done. A poor workman with bad tools, which he does not know how to use, is hardly likely to turn out a finished product. One distinguishes genuine metal by its ring, only after he has heard it many times; and a teacher who knows little or nothing of any department of science is easily caught by the tone of a text-book which is often little better than a base alloy. 'Science made easy' finds its way into the schoolroom to the temporary delight of both teacher and pupil, but to the lasting benefit of neither.

Have the scientific men of this country done their full duty in this matter? It is a pertinent question, and it cannot be answered in the affirmative. Two forces are here to be dealt with, — the teachers and the text-books. Concerning the latter, it will be remembered by many that something akin to a sensation was produced, at the Minneapolis meeting of the American association for the advancement of science, by Professor Rowland's vigorous denunciation of American science text-books. His resolution was doubtless too sweeping in its character, — more so, in fact, than was really intended by its author; but it cannot be denied that it contained a large measure of wholesome truth, however unpalatable it might have been. But can Professor Rowland and others, whose names will occur to the reader, hold themselves wholly free from responsibility in the premises? It is not unreasonable to assert that the preparation of text-books, including those that are elementary in their character, ought to be undertaken by specialists; and it is gratifying to know that many eminent American scholars have not shrunk from their duty in this respect. A few years ago, in a review of an elementary treatise on physics, Clerk Maxwell remarked that there seems to be "some opposition between accurate statements and school-teaching, which, if not a fundamental necessity, is at least a universally existing phenomenon in the present order of things." Nowhere is the hand of a master more needed than in the making of an elementary text-book. Science can be 'made easy' by being made clear and accurate; and such elementary treatises as those prepared by Maxwell and Balfour Stewart show how well the real scholar can do this. It can hardly be done by any one else.

THE recent deliberations of the committees of the American ornithologists' union, upon the rules of zoölogical nomenclature, will, when published, be of great interest to zoölogists working in other classes. The day is not far distant when the nomenclature of American zoölogy, particularly in its vertebrate division, will be reduced to a uniformity based upon consistent interpretation of the law of priority. American zoölogists are now waiting with much curiosity to see what their fellow-workers in Europe are going to do in the matter, and whether it be possible that they will cling to the illogical and inconsistent usages now prevalent among them. At present the names sanctioned by the great authorities, like Cuvier, appear to be regarded as sacred and immutable. In a recent official report upon the

Berlin fishery exhibition, Professor Giglioli, the leading authority in Italian vertebrate zoölogy, commenting upon the collections sent from the U. S. national museum, remarks, "I feel obliged to make reference to the singular nomenclature current among the zoölogists of the United States, which is in most instances entirely arbitrary, and at variance with that generally adopted in Europe. Only the working zoölogist can form an idea of the confusion which is sure to result from such practices. If the present courses are continued, they will end in the destruction of the wise, convenient, and simple *sistema zoologico* conceived by the great Linnaeus."

Most English zoölogists follow, though not very consistently, the rulings of the Stricklandian code; but on the continent, except in Norway, there appears to be no general appreciation of the importance of conforming to any consistent policy in nomenclature. The authority of Cuvier, or one of his contemporaries, is allowed to outweigh any consideration of justice or uniformity. In the United States, however, the number of indigenous species to be systematically catalogued is so great, that systematic zoölogists have been forced to follow the rule of priority, without fear of contemporaries, or favor to the workers of the past. It is somewhat unfortunate that the common sea-bream of Europe should be known to transatlantic ichthyologists as Sargus vulgaris, while here it is called Diplodus sargus; equally so, that our black bass, Micropterus salmoides, should there be known as Huro nigricans. The American zoölogist has, however, the advantage of standing on a foundation of priority, upon which his European brethren must sooner or later take refuge, or be overwhelmed in an ocean of synonymes.

IN closing a review of the different means employed by man to rid himself of destructive insects, Mr. de Fontvielle expresses a regret that the attempts made to popularize the use of insects as food have made so little progress. We are, in fact, behind the Chinese, and even behind the monkeys, who, if we may believe Millet, eat their own lice. It is not necessary, he adds, to go to this length; but we ought not to forget the remark of the Roman emperor, who said that the body of an enemy never tasted bad, and the banquet of the Society of insectology, before which he spoke, would always lack something so long as there was not placed before them at least some grasshopper farina and fried white worms.

'CHARACTERIZED by high, unbroken mediocrity' is the description which the *Pall-mall gazette* gives of the literature of the past year. This only brings up again the question whether the age of literature and of good talkers, as well as writers, may not be passing away. The energies of a large portion of the able men of the present are occupied by the work of their special avocations, — avocations in which they have few associates, or possibly none, in their particular branch. What has the foremost position in these men's thoughts they find no opportunity of mentioning to those with whom they may be thrown. Where Franklin found time to be a printer, a statesman, and a physicist, is now so much ground to be covered, that a physicist may soon be a thing of the past; the electrician possibly being quite ignorant of the laws of heat, and each student only striving to cover faithfully the subject of sound, or light, or heat, as may seem most attractive. Shall the active man of the future limit himself in his department that he may gain a polish that will make him the more agreeable companion? or, that he may serve the world's purpose the better, shall he, by his education, largely separate himself from all others? What this differentiation has come to, is shown by the fact that a learned academy not long ago honored with a gold medal a memoir which no member had read. A meeting of this society has often been compared to a funeral, — a funeral only to be enlivened by the queries of some garrulous layman; and how can it be otherwise when the words of our wiseacre fall upon the ears of others, incapable of vibrating in sympathy?

LETTERS TO THE EDITOR.

A clock for sending out electric signals once an hour or oftener.

It is necessary that the central clock of a system of controlled clocks should send out an electric signal once an hour, by means of which signal the controlled clocks have their hands set to time.

It is often convenient to have such a clock send out signals oftener than once an hour: for example, at the University of Wisconsin a central clock automatically rings an electric bell in each recitation-room at the end of each hour, and also at ten minutes before the end of the hour, i.e., at fifty minutes and sixty minutes.

There are many ways of accomplishing this end. One of the simplest of these is described below from a clock which is now in use at the Washburn observatory to control by hourly signals a system of secondary clocks in the city of Madison.

The apparatus was made in the University machine-shops by me, and cost, perhaps, five dollars; and it is perfectly satisfactory in its operation. Figs. 1 and 2 represent the projection and section of an ordinary clock-dial, with a ring of black walnut or ebony, *B*, screwed on it.

Around the outer circumference of *B*, and about a quarter of an inch from it, runs the brass wire *C*. This wire is threaded from end to end, and, passing through the four screw-eyes *k*, *k*, is held to, and supported by, the wood ring *B*. The two ends of the wire are joined by means of a long nut, or thimble, *b*. Strung loosely on the threaded ring *C*, and at various points of its circumference, are the small brass nuts *a*, *e*. Some of these are employed as jam-nuts, *a*, *a*, to prevent any tangential motion in the threaded ring. The walnut ring can be made of convenient thickness, so that the minute-hand will pass over it; and for final adjustment the minute-hand may be bent in or out to get the required contact pressure. A thin strip of platinum (*P′*, fig. 3) is soldered to the under side of the minute-hand along the portion which traverses the walnut ring *B*. Around this *point* is fitted the small block, *I*, of bone or vulcanite, with its under face sloping upward to form a sort of inclined plane to precede the platinum point *P′*. A short piece of platinum wire of suitable size is flattened at one end (*P*, fig. 3); and the flattened part, secured to the small piece of vulcanite, *s*, is laid upon the walnut ring *B*. The other end is bent round the threaded wire *C*, and secured in place by means of the nuts *e* strung on the ring for that purpose.

FIG. 1.

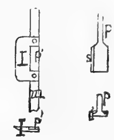


FIG. 3.

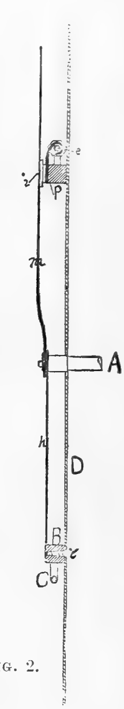

FIG. 2.

The points at which the circuit is made and broken are the platinum points *P*, *P′*. The minute-hand, being carried around with its point *P′* in light contact with the ring *B*, is sprung out when the inclined block *I* comes in contact with the projection of *s*; and, being carried along, the points *P*, *P′*, are brought together by the springing-back of the hand. The length of contact depends on the width of the point *P*, and may be varied at pleasure. The circuit-wires are led from the works of the clock and the threaded ring respectively, and may be provided with suitable binding-posts outside the clock. As the ring *C* runs clear around the dial, a platinum point may be inserted anywhere in its circumference; so that any number of signals may be made during the hour, or those already set may be easily changed. The nuts *e* on the threaded wire not only insure a good metallic contact with the platinum point, but aid materially in its adjustment for a given time of contact. The device is simple, in that it requires no great delicacy of workmanship in its construction, and is of such a form that almost any clock will receive it without change.

H. W. PENNOCK.

Deafness in white cats, and statistics of deafness and epilepsy in America.

In my letter of the 4th inst. (*Science*, iii. 171) I drew attention to the remarkable fact, that white cats, if they have blue eyes, are almost always deaf.

Darwin, in his book on 'Animals and plants under domestication,' attributes the peculiarity to a slight arrest of development in the nervous system in connection with the sense-organs. He thinks there is nothing unusual in the relation of blue eyes and white fur; but in regard to the deafness, he says (ii. 323), —

"Kittens, during the first nine days, whilst their eyes are closed, *appear to be completely deaf.* I have made a great clanging noise with a poker and shovel close to their heads, both when asleep and awake, without producing any effect. The trial must not be made by shouting close to their ears; for they are, even when asleep, extremely sensitive to a breath of air. Now, as long as the eyes continue closed, the iris is no doubt blue; for, in all kittens which I have seen, this color remains for some time after the eyelids open. Hence, if we suppose the development of the organs of sight and hearing to be arrested at the stage of the closed eyelids, the eyes would remain permanently blue, and the ears would be incapable of perceiving sound; and we should thus understand this curious case. As, however, the color of the fur is determined long before birth, and as the blueness of the eyes and the whiteness of the fur are obviously connected, we must believe that some primary cause acts at a much earlier period."

Darwin's conclusion is supported by a remarkable case recorded in France by Dr. Sichel (*Annales sc. nat., Zool.* 3d series, 1847, viii. 239), in which the iris, at the end of four months, began to grow dark-colored, and *then the cat first began to hear!*

In the human race, also, while it is exceedingly problematical how far congenital deafness is associated with a deficiency of coloring-matter in the skin and hair, it appears, according to Darwin ('Animals and plants under domestication,' ii. 322), that some relation exists between various affections of the eyes and ears.

He states that Liebrich found, upon examining the eyes of 241 deaf-mutes in Berlin, that no less than fourteen suffered from the rare disease called pigmentary retinitis. He also states, upon the authority of Mr. White Cooper and Dr. Earle, that color-blindness is often associated with a corresponding inability to distinguish musical sounds.[1]

I have already shown that the census returns for 1880 indicate that the proportion of deaf-mutes among our colored population is much less than among the whites; but private inquiry at the census bureau seems to show that the proportion of *congenitally* deaf among the colored deaf-mutes, instead of being less, is very much greater, than among the white deaf-mutes.

Of 19,475 white deaf-mutes, 10,738 (or 55 per cent) were stated to have been born deaf, and 8,737 (or 45 per cent) were returned as deaf from disease or accident: on the other hand, of 1,751 colored deaf-mutes, 1,301 (or no less than 74 per cent) were reported as congenitally deaf, and only 450 (or 26 per cent) as deaf from disease or from accidental causes.

By the kindness of Gen. Seaton, I am enabled to give the following unpublished figures from the census returns bearing upon the point: —

Number of deaf-mutes in the United States, living June 1, 1880, *arranged according to race and sex.*

Causes of deafness.	Colored.		Foreign white.		Native white.		Total.	
	Male.	Female.	Male.	Female.	Male.	Female.	Male.	Female.
Congenital . . .	714	587	545	444	5,229	4,520	6,488	5,551
Injury to ear . .	7	2	8	2	34	17	49	21
Disease of ear . .	7	8	10	7	204	166	221	181

[1] These statements are taken from Mr. Sedgwick, in the *Medico-chirurg. review*, July, 1861, p. 198; April, 1863, pp. 455 and 458. Liebrich is quoted by Professor Devay in his 'Mariages consanguins,' 1862, p. 116.

In my former communication I quoted from Dr. Lawson Tait's paper on 'Deafness in white cats' (*Nature*, xxix. 164) the following remarkable statement: "Every kind of white animal I have kept as a pet has proved to be the subject of epilepsy; and the association is suggestive, when we are told, as I have been frequently, that the disease is unknown among negroes."

I presume that Dr. Tait must have referred to the negro in his native habitat; for I find, upon inquiry at the census bureau, that epilepsy appears to be more common among the colored people of America than among the whites. I am indebted to the courtesy of Gen. Seaton for the following unpublished figures from the tenth census: —

Percentage of epileptics in the United States, 1880, *by race and sex.*

White male	.004749
White female	.003751
Black male	.005011
Black female	.004267
Indian male	.002942
Indian female	.003084
Chinese male	—
Chinese female	.020925

These results will doubtless be of interest to your readers. Alexander Graham Bell.

Washington, D.C., Feb. 29, 1884.

In a letter to *Science* of Feb. 15, Prof. A. G. Bell quotes from Dr. Lawson Tait, that "every kind of white animal I have kept as a pet has been the subject of epilepsy; and the association is suggestive when we are told, as I have been frequently, that the disease is unknown among *negroes.*" This remark in regard to the negroes, I know, cannot be entirely true. I am a southern-born man; and I have seen a great deal of negroes all my life, and have always considered that epilepsy prevailed among them, even to a greater extent than among white people. I can easily give a number of instances of its occurrence, coming under my own observation and that of my friends to whom I have mentioned the subject.

Georgetown, D.C., Feb. 21, 1884. Benj. Miller.

The Krakatoa eruption.

The council of the Royal society has appointed a committee for the purpose of collecting the various accounts of the volcanic eruption at Krakatoa, and attendant phenomena, in such form as shall best provide for their preservation, and promote their usefulness.

The committee invite the communication of authenticated facts respecting the fall of pumice and of dust, the position and extent of floating pumice, the date of exceptional quantities of pumice reaching various shores, observations of unusual disturbances of barometric pressure and of sea-level, the presence of sulphurous vapors, the distances at which the explosions were heard, and exceptional effects of light and color in the atmosphere. The committee will be glad to receive, also, copies of published papers, articles and letters, bearing upon the subject.

Correspondents are requested to be very particular in giving the date, exact time (stating whether Greenwich or local), and position whence all recorded facts were observed. The greatest practicable precision in all these respects is essential.

All communications are to be addressed to

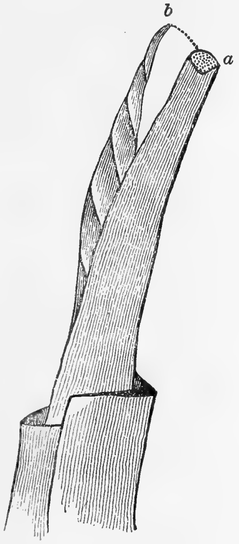
G. J. Symons,
Chairman Krakatoa committee.

Royal society, Burlington House,
London, Feb. 12, 1884.

Expulsion of water from a growing leaf.

My attention was some time ago called to an interesting and remarkable fact in connection with the expulsion of water from the tip of a growing leaf. It is well known that drops of water are often found on the margins and apices of growing leaves. It is readily observable in corn and other grasses (see Sachs's text-book, p. 676); but the phenomenon to which I wish now to call attention is of another character. The circumstances were as follows: —

A lady had growing in her house a strong and thrifty Caladium with three or four large leaves. A new leaf being ready to expand alongside of an old one, this last was cut off at *a* in the figure. It was noticed soon afterward, at about half-past ten A.M., that from the apex of the new leaf (*b*) there was being shot out, for a distance of about an inch, a jet of water, falling in the shape of very fine spray on the cut surface of the other leaf. The jets were counted, and it was found that there was a regular *pulsation of about a hundred and eighty per minute;* that is to say, three jets of water were forced from the apex of the leaf every second. It was observed from time to time until five P.M., and but little cessation of the rate of motion was seen. At eight the next morning the pulsations were about a hundred and twenty per minute; and they gradually decreased, until, on the third day, drops of water would accumulate at the apex, and be expelled with some force at a rate of about ninety per minute.



It is to this regular pulsating movement of the water that I wish to call attention. I cannot find, in any of the books accessible to me, any account of any such motion in the water of plants. Sachs does not mention it; and, if any of your readers know of the mention of any such motion, I should like to know where it is to be found. We know that the exudation of water from cut surfaces, or newly-expanding leaves, is often caused by the taking-away of an evaporating surface (say, a large leaf) while the root is still absorbing a large amount of moisture from the soil (see Sachs's text-book, p. 689); but why this pulsating movement? There can be no doubt as to the accuracy of the observation, as it was seen by several persons besides the owner of the plant. Prof. J. W. Lloyd of this city has informed me that some years ago he made the same observation, but he has not been able to give me an exact statement as to what took place.

JOSEPH F. JAMES.

Cinc. soc. nat. hist., Cincinnati, O.

[This interesting phenomenon has been described by Musset, who states that water was forced from the leaf-tips of Colocasia antiquorum, another plant of the Aroid family, with such force that the jet was three inches and three-quarters high (*Comptes rendus*, 1865, 683). Professor Pfeffer, to whom we are indebted for this reference, calls attention to a singular communication by Munting (1672), who describes the emission of a fine stream of water from the leaves of certain Aroideae, *resembling a fountain.*]

A scientific swindler.

A few weeks ago a man calling himself N. R. Taggart, and claiming to be a member of the Ohio geological survey, visited Philadelphia. He called on the principal scientific men of this city, and attended one of the regular meetings of the Academy of natural sciences. He seemed to have an extended acquaintance with scientific men all over the country, talked very glibly about fossils, and claimed to be preparing a report on the Productidae for the Ohio survey. He is about five feet eight inches in height, a hundred and sixty pounds in weight, heavy set, heavy featured, with light hair, and rather deep-set eyes, shabbily dressed, and wore an old gray overcoat. He had an adroit way of ingratiating himself into the confidence of his intended victims; and then, if he could not steal, he would, under some plausible pretext, borrow valuable books or specimens to take to his hotel, and forget to return them. His victims are to be found scattered all over the country. In New York he was E. D. Strong of Fort Scott, Kan., and claimed to be employed by the Kansas Pacific railway to collect statistics of coal production. In West Philadelphia he gave his address as E. Douglas, Columbus, O., member of the State survey. In Auburn, N.Y., he was a deaf-mute, under the name of E. D. Whitney, U. S. geologist, Denver, Col. There he obtained a large quantity of valuable books and fossils from the family of Professor Starr, in the absence of the owner. In Harrisburg, Chambersburg, Columbus, and Indianapolis he was a deaf-mute. He swindled the state geologist of Indiana out of over a hundred dollars' worth of scientific books. From the Cleveland historical society's rooms he obtained Indian relics of great value, and in Cincinnati, minerals and fossils which he converted into cash. He has been permitted access to several museums, public and private, from which he has succeeded in abstracting valuable specimens, and sold them. Any information in regard to the real name and residence of this man is much to be desired.

F. V. HAYDEN.

AN INTERNATIONAL SCIENTIFIC ASSOCIATION.

THE coming of the British association in August next to this continent to hold its meeting will result, it is hoped, in bringing the scientific representatives of two great nations twice together, — once at Montreal; and later, again, at Philadelphia. The interest felt in these two gatherings is very great, and rapidly increasing as the time approaches for their occurrence. It is realized that they will be very important and delightful. Both meetings will be international in character; and the pleasant anticipations formed in regard to them suggest the advisability of establishing some permanent organization which may insure

the recurrence of similar opportunities in the future.

There are many persons who have long wished that an international scientific association should be formed, where those of similar pursuits could meet one another, and, as it were, exchange thought between the nations. All acknowledge that the chief value of the large general associations lies in the stimulus of personal intercourse and discussion; and this would doubtless apply still more decidedly to an international society. The principal purpose of its meetings would be, we doubt not, to secure that stimulus.

An international scientific association would necessarily be largely European, and Americans would have to cross the ocean to attend its sessions. But with our habits of active travel, this necessity cannot be thought likely to prove a serious obstacle to our active participation in the association; which might, too, at some time, be induced to follow the example of the British association, and meet upon our side. Perhaps no opportunity will soon recur so favorable for the formation of the suggested association as the meeting at Philadelphia, and it seems very possible that the initiative may be there taken. The two English-speaking races can then act in concert, and, by a double appeal, more easily achieve the result than either could alone. America takes no share in the international complications which agitate Europe, and is therefore a friend with all, and might, on that account, the more readily inaugurate such a general movement.

Some limitation would necessarily be made upon the membership of the body suggested, confining it, perhaps, to original investigators. It is a question how far the indiscriminate presentation of scientific communications could be made feasible; for, if the whole of the annual additions to science were to be presented, the association would sit the entire year. Obviously some restrictions are requisite: their character must be decided by discussion and experience. Thus, formal addresses upon special subjects, or discussions limited to specified topics, might serve the purpose; or it might be considered wise to follow the example of the new Society of naturalists, which devotes its attention to the ways and means, the practical technique, rather than the results, of science. We hope that the plan we have briefly indicated will meet at least with consideration, and awaken discussion, so that it can be ascertained whether it ought to be pursued farther. It is too early yet to venture upon any definite proposals.

THE ALASKA MILITARY RECONNOISSANCE FOR 1883.[1]

LEAVING Tahk-o, the Yukon, for the first time, assumed something of a riparian air, the draining river being nine miles long. It is from three hundred to four hundred yards in width, very swift, and the first part of its course full of rocks and great bowlders, that make its navigation hazardous for even a stanch raft. On its right-hand bank stood a roughly built Tahk-heesh house, the only one on this part of the Yukon River for hundreds of miles on either side; and even it was deserted. The next lake was nearly thirty miles long, and appreciably wider than those through which we had sailed. I called it Lake Marsh, after Professor Marsh of Yale college.

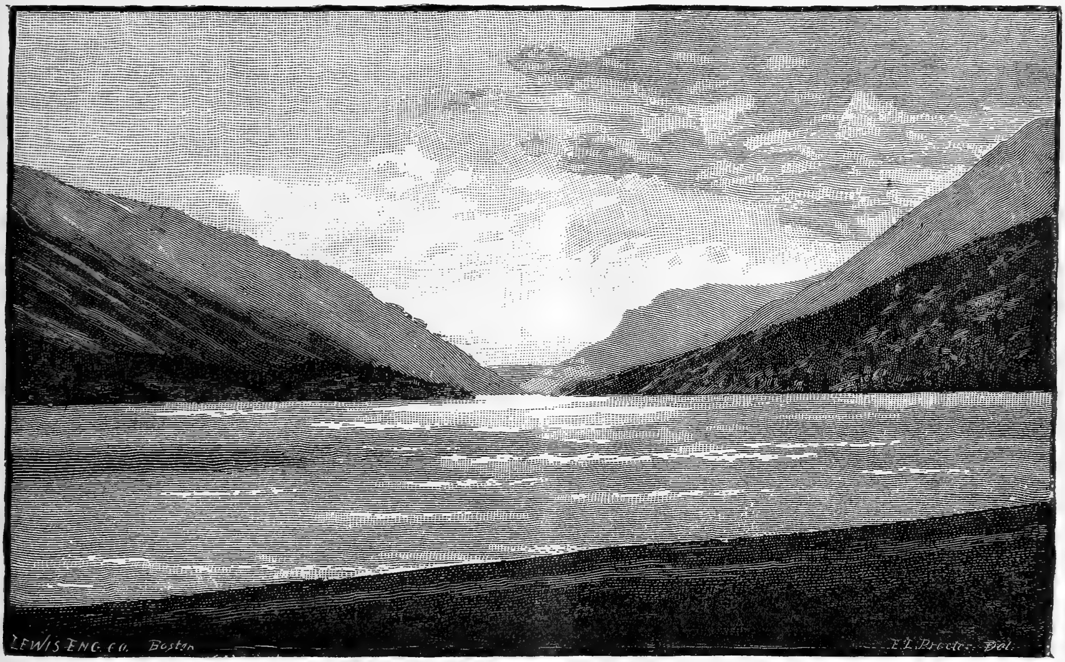
I have spoken of a great number of glaciers that were constantly encountered, and the white condition of the water emanating from them. In Lake Marsh the water near the shores was very shallow, owing to large deposits of this fine glacier mud; and we often found it impossible to get much nearer the beach than sixty to eighty yards, although our craft drew less than two feet of water. When a high wind lashed the lake into waves, these mud deposits gave a clear-cut outline between the whitened water within their exterior edges and the deep blue water beyond, that showed in many places an extension of the deposits of four hundred to five hundred yards from the beach. It is possible that the stages of water may vary in Lake Marsh at different seasons sufficient to lay bare these mud-banks, or cover them so as to be navigable for small boats; but there seemed to be a wonderful uniformity in the depth of the water over these banks in every part of the lake, being about eighteen inches. Through this tenacious mass, that even threatened to pull off our rubber boots, we would have to carry our camping-material each evening as we went into camp, and each morning as we broke it for our departure. The trees on the hills overlooking the lake, as had been often noticed before on the upper waters of the Yukon, all leaned more or less conspicuously towards the north, or down stream, thus plainly showing the prevailing direction of the stronger winds. Faint signs of terraces were still to be seen on the hillsides; but they were lower, nearer together, and not so well marked as on Lake Nares. The level ridges on the eastern hills were still covered with the luxuriant yellow grass of last year's growth, and, as we viewed

[1] Continued from No. 55.

them from the lake, turned one's thoughts to the stubble fields of grain in temperate climes.

On the 28th, on Lake Marsh, a spirited rain and thunder shower lasted from 12.45 P.M. to 2.15 P.M., and is, I believe, the first thunder-storm recorded on the Yukon, it being unknown on the lower river, according to all accounts. It brought us a head wind; and, after dying out, a favorable breeze sprang up, and kept us going until 12.30 next morning, so essential was it for us to take advantage of all favorable wind. At midnight it was so light, however, that but one star could be seen in the unclouded sky, — the planet Venus. For the first time bathing was possible in the lakes, although not pleasant, except on very warm, still days.

The northern shores of Lake Marsh are especially flat and boggy, making our camps very disagreeable. Our rough mode of navigation also suffered from the ceaseless banks of 'glacier-mud' as we approached its outlet, most of which was probably deposited by a large river (the McClintock[1]) that here comes in from the east, — a river so large that we were in some doubt as to its being the outlet, until its current settled the matter by carrying us into the proper channel. This channel much more closely resembled some of the streams in temperate climes than any we had met. Its flanking hillsides of rolling ground were covered with spruce and pine, here and there breaking into pleasant-looking, grassy prairies, while its own valley was densely wooded with poplar and willows of several varieties. These latter, in fact, encroached so closely upon the very water's edge in such impenetrable confusion that camping-places were hard to find, unless a spur from the hills, covered with evergreens, wedged its way in on the river's face to break the continuity of this barrier to a night's camping-place. The raft's corduroy deck of pine poles often served us for a rough night's lodging.



LAKE BENNETT FROM PAYER PORTAGE.

Iron-capped mountains on the right, covered with fog.

Muskrats were plentiful in this part of the river, and in the quiet evenings a number could be traced at once by their wedge-shaped ripples as they were swimming about. Small broods of ducks were also occasionally noticed, and numbers of the great American diver were seen on almost all the lakes.

On the 1st of July, with a Tahk-heesh Indian as a guide, we approached the great rapids of which we had heard so much. An inspec-

[1] In honor of Vice-Admiral Sir Leopold McClintock, Royal navy.

tion of them showed that they were really quite formidable and dangerous for any sort of craft whatever. Nearly five miles in length, the first half or three-quarters of a mile is through a cañon from fifty to sixty feet deep, where the original stream is contracted to one-eighth or one-tenth its former width, and through which the river fairly boils. This cañon, the only true one on the Yukon River,[1] is composed of basaltic columns, so regular that they are not unlike representations of the Giant's Causeway on the Irish coast. In the centre of its length it expands into a large, circular, basaltic basin seventy or eighty yards wide, or double the width of the cañon proper; and here the water's edge could be reached on the west shore. After leaving the cañon, the channel expands into a sheet of rushing rapids, often three hundred to four hundred yards wide, broken by rocky bars into frothy chutes full of bowlders and foaming and bristling dams of lodged and water-logged timber, ten times more dangerous than the cañon itself, although not so in appearance. About four miles of this brings us to the end, where the river, again contracting into a few yards, shoots down a cascade so narrow and swift that the ascending banks of rock are covered with the rushing current that falls over their sides in sheets, and makes it a veritable funnel of foaming water.

Through this cañon, rapids, and cascade we shot our raft July 2, losing the two side-logs in a collision in the cañon with its basaltic columns, and, just below the cascade, hauled in for repairs, and to redeck the raft with the fine straight spruce and pine poles that we here found in large quantities, thoroughly seasoned by some fire that had destroyed them two or three years before. Like all the Coniferae growing in dense masses, these timber districts have their periodical devastations of fire; and years after, the fallen timber, coupled with the new growth, makes pedestrianism border on the impossible.

A few Tahk-heesh Indians had been employed by us in our labors around the Miles' cañon and rapids;[2] and I was forced to contrast their great kindness to each other, and especially to their women, with the conduct, the very reverse, in the Chilcats. These Chilcats, in tracking canoes up the Dayay, refused to convey the loads of their fellows not provided with these craft, although to have done so would have necessitated no extra labor, thus compelling the latter to carry their packs as they did over the Perrier Portage. They would not even ferry them over the swift Dayay, forcing them into long détours or perilous crossings up to their middle in the rapids. Even in cases of sickness they would do nothing for their comrades, unless compensated by a part of the payment.

Grayling were caught in large numbers in and around these rapids, some four hundred to five hundred being secured by the party. They were also caught in straggling numbers from Lake Bove, until White River, below old Fort Selkirk, was reached. Moose and caribou (woodland reindeer) tracks were abundant, but no animals seen; and the dense swarms of mosquitoes were amply sufficient to convince any one that the tracks of an animal were the only part that could remain in the country during this part of the year. These pests, coupled with the gnats, were the greatest discomfort that the party was called on to bear; and there was no cessation from them the whole length of the river, although the upper part was much the worst. The dense smoke of the camp-fire was always crowded with the party whenever the wind was not blowing, and meals were eaten under mosquito-bars for protection. From the time the snow is half off the ground until the first severe frost comes, no one disputes the valley with them. Dogs have been known to be killed by them; and, after two or three months of the closest intercourse with them, I was willing to believe the Indian stories that they even slay the brown and grizzly bear of these regions.[1]

I noticed that a Tahk-heesh Indian, in arranging his head and breast-band for a load, pulled the former forward until taut, and the latter just far enough beyond to allow the width of his hand between them, when they were considered adjusted. I had also noticed this among the Chilcats.

One evening, about eight, while encamped some four hundred or five hundred yards below the cascades in the Miles' rapids, we could hear dull, heavy concussions in single blows, at intervals of every two or three minutes. It was noticed by more than one, and thought by some to be possibly distant thunder, although it sounded strangely unlike that noisy

[1] I mean by a *true cañon* one with perpendicular or practically perpendicular sides, although every precipitous and deep valley in the west is often called a cañon. With such an understanding, it would be impossible to tell where a cañon ended and a valley commenced.

[2] Named after Brevet Major-Gen. Nelson A. Miles, U.S. Army, commanding department of Columbia, in which Alaska is situated.

[1] This statement is asserted as a fact by some Indians and white traders, who state that the bear, in trespassing upon a swampy habitation of mosquitoes, instead of seeking safety in flight, rears upon his hind-quarters, and fights them bear-fashion, until his eyes are closed by their repeated attacks, when starvation is the real cause of death.

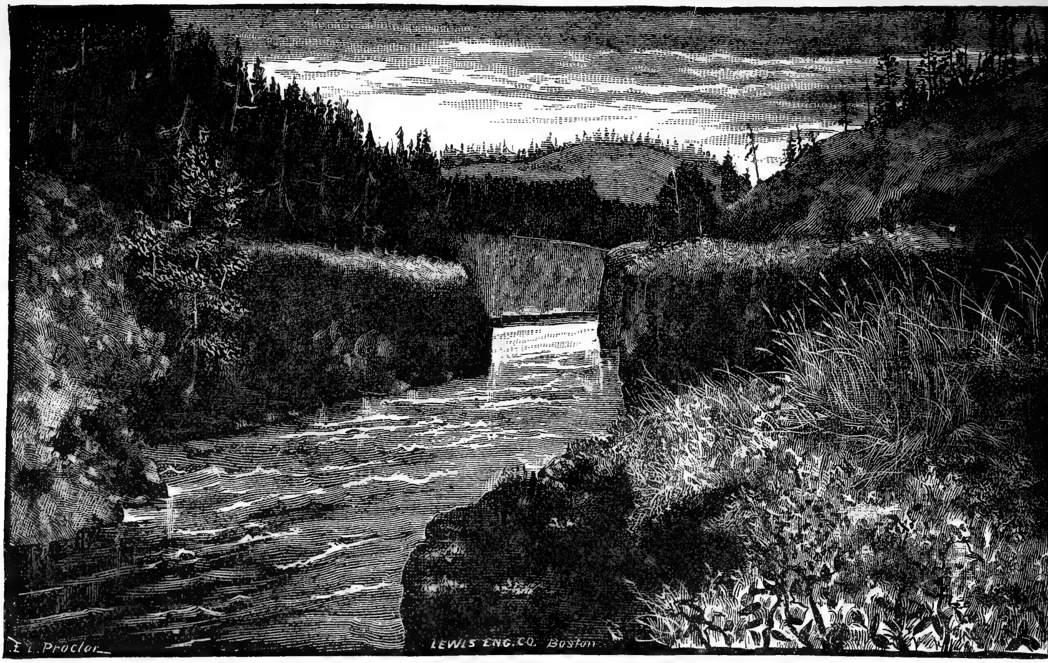
element; and the sky, too, was cloudless. A very light series of earthquake-shocks also seemed a poor theory; and there was but little left to attribute it to, except the cascades, which, I believe, have been known to cause earth-tremblings and analogous phenomena.

About noon on the 5th of July we passed the Tahk River (Tahk-heen-a of the Indians) coming in from the west, and which is probably two-thirds the size of the Tahk-heesh, as the Indians call the Yukon proper. While the former river is the smaller, its bed and valley apparently determine the general characteristics of the stream farther on, the Yukon here noticeably changing from high bold bluffs of clay to lower shores wooded to the water's edge. The last of the chain of lakes was reached the same day, and we were prevented from taking advantage of a good wind by a three-hours' detention on a sand-bar that the river had made almost entirely across its mouth. This lake was called by the Indians Kluk-tas-si; and, as it was one of the very few pronounceable Indian names of this section of the country, I retained it, although it is possible that this may be the Lake Labarge of some books, the fact that it is the first lake above old Selkirk being the only data in its favor, while its relation to other important points are equally against it. Like Lake Marsh, it is full of mud-banks; its emerging waters being clear, while its incoming supplies are loaded with deposit. So full of these is Kluk-tas-si, and so much more contracted is the water-way through them, that I think we were able to detect a slight current when making our way along in the blue water. This was especially noticeable when the wind died down to a calm. Despite all this, Kluk-tas-si was better for making landings on its shores than Marsh. It seems that it must be a mere matter of short geological time when these lakes will be filled by deposits, and converted into limited parts of the river. Such ancient lakes are noticeable in the course of the great stream farther on. The west bank of the last lake is very picturesque about fourteen or fifteen miles from its entrance, where large towers of red rocks throw up their conspicuous flanks on what seems to be a well-marked island, but which is really a part of the mainland, our Indians assured us. Here, also, comes in a river, say the same authorities, abounding in banks of the same material, and called by them the Red River. The frequency of this name in geographical nomenclature was sufficient reason to abandon it; and I named the rocks and river (the latter we never saw) Richthofen rocks and river, after Freiherr von Richthofen of Bonn, well known in geographical science. The right bank seems to be made of rounded hills of gray limestone, being picturesquely striped with the foliage of the dark evergreens growing in the ravines. A number of salmon-trout were caught in this last lake (the first one was secured in Lake Bove), the largest of which weighed over eight pounds, the limits of our pocket fish-scales.

On the 9th, at 10.30 A.M., we bade adieu to lake navigation, our hearts much lighter for the fact. That same day we saw a grizzly or immense brown bear, whose rapid departure gave us very little chance for close inspection. Our Indians say in regard to the scarcity of game, that the moose and caribou follow the snow-line as it retreats up the mountains in the spring and summer; also that the moose do not build 'yards' in the winter, as in Maine and the Canadian provinces. On the same day we passed the mouth of the Newberry River (after Professor John S. Newberry of New York), coming in from the east, about a hundred and twenty-five yards wide; and the Yukon at once became very much deeper, swifter, and the water of a darker hue, showing that the Newberry drained a considerable amount of 'tundra' land, or land where the water, saturated with the dyes extracted from dead leaves and mosses, is prevented from clarifying itself by percolating through the soil, by an impervious substratum of ice, and is carried off by superficial drainage directly into the river-beds. Forty miles farther on, measured along the stream, comes in the D'Abbadie,[1] over a hundred and fifty yards wide at its mouth, and said to be over two hundred and fifty miles in length. It notes an important point on the Yukon River as being the place at which gold in placer deposits commences. From the D'Abbadie to the very mouth of the great Yukon, a panful of 'dirt' taken from almost any bar or bank with any discretion, will, when washed, give several 'colors,' to use a miner's phrase. Another forty miles, and the Daly River comes in from the east, forming, with the Newberry and D'Abbadie, a singular triplet of almost similar rivers. The last I have named after Chief-Justice Daly of New York, a leading patron of my Franklin search expedition.

The prevalence of the larger rivers to the east showed this to be the main drainage area of the upper Yukon, a rule broken only by the Nordenskiöld River coming in from the west;

[1] M. Antoine D'Abbadie, membre de l'Institut de France, Paris.



VIEW IN MILES' CAÑON FROM ITS SOUTHERN ENTRANCE.
The only cañon, and head of navigation, on the Yukon, 1866 miles from Aphoon mouth.

fifty miles beyond the Daly, and the peer of any of the three. We passed its mouth the 11th, and that same day our Indians told us of a perilous rapid ahead that the Indians of the country sometimes shot with their small rafts; but they felt very anxious in regard to our very bulky and clumsy one of forty-two feet, as there were some sharp bends to make. Reaching the rapid on the 12th, I found it to be a contraction of the river-bed into about one-half its usual width of five hundred to seven hundred yards, and further impeded by a number of massive trap rocks, thirty to forty feet high, lying directly in the channel, and really converting it into three or four well-marked channels, the second one from the east being the usual one used by the Indians, but rejected by us on account of a necessary sharp turn. We essayed the extreme right-hand passage, although running waves three and four feet high were seen in its boiling current, but still the straightest, and therefore the best. On these rocks innumerable numbers of gulls had sought a breeding-ground, safe from all intrusion, and saluted us with a perfect din of screamings as we rushed by. This extreme right-hand channel through which we shot, I believe could be ascended by a river-steamer with a steam windlass, a sharp bend in the river-bank giving a short and secure hold; and, if I am right in my conjectures, Miles' Cañon and rapids mark the head of navigation on the Yukon for very light-draught but powerful river-boats, or a total navigable distance of eighteen hundred and sixty-six miles from the Aphoon mouth. I named this picturesque little rapid after Dr. Henry Rink of Copenhagen, a well-known Greenland authority.

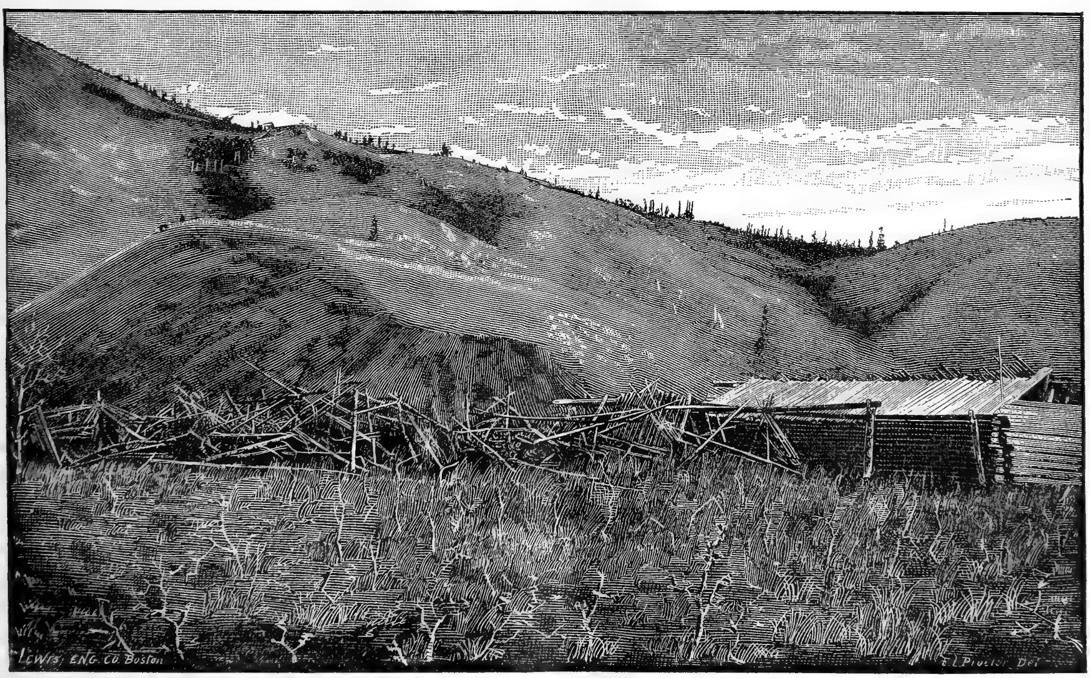
After the Yukon receives the many large rivers I have noticed, it swells out into quite formidable proportions, interspersed with many islands, all of which are so loaded with great piles of driftwood on their upper ends, that, when in one of these archipelagoes, the scene up and down the river is quite different. The river also becomes very tortuous in many places; and at the mouth of the Nordenskiöld a conspicuous bald butte could be seen directly in front of our raft no less than seven times, on as many different stretches of the river. I called it Tantalus Butte on the map.

The day we shot the Rink Rapids we also saw our first moose ploughing through the willow-brush like a hurricane in his endeavors to escape, — an undertaking in which he was successful. That same night we camped near the first Indian village we had met on the river, and even it was deserted. It is called Kit[l]-

ah-gon (meaning the place between high hills), consists of one log house about eighteen by thirty, and a score of the brush houses usual in this country; that is, three main poles, one much longer than the rest, and serving as a ridge-pole on which to pile evergreen brush to complete the house. This brush is sometimes replaced by the most thoroughly ventilated reindeer or moose skin, and in rare cases by an old piece of canvas. Such are the almost constant habitations of these abject creatures. In the spring Kit^{l}-ah-gon is deserted by the Indians, who then ascend the river with loads so light that they can be carried on their backs. By the close approach of winter-time they have worked so far away, accumulating the little salmon, moose, black bear, and caribou, on which they are to subsist, that they build a light raft from the driftwood on the islands, and float down to live in squalor through the winter. These rafts are almost their sole means of navigation from Miles' Cañon to Fort Selkirk, and the triangular houses almost their only abodes; and all this in a country teeming with good enough timber for log-houses, and plenty of birchbark for canoes. Kit^{l}-ah-gon is in a beautiful large valley,[1] as its name would impart; and I was surprised to see it drained by so small a stream as the one, but ten or fifteen yards wide, which goes out at its foot. Its proximity to the Pelly forbids its draining a great area, yet its valley is much the more conspicuous of the two. Photographs of it and adjacent scenes on the river were secured before departing, and a rough 'prospect' in the valley showed 'color' enough to brighten the hopes of some enthusiastic miner for something he would prize more highly.

[1] Von Wilczek valley, after Graf von Wilczek of Vienna.

From Kit^{l}-ah-gon to old Selkirk is but a little over twenty miles; and the river is so full of islands in many places, that for long stretches we could hardly see both banks at a time. This, I think, is one of the ancient lakes to which I have alluded, although the report of a professional geologist would be needed to settle such a matter. I was very anxious to determine the relative sizes of the two rivers that joined just above Selkirk, as upon this determination rested whether the Pelly or the Lewis River of the old Hudson-bay traders was the Yukon proper; and I was fully prepared to make exact measurements, soundings, rate of current, and other data if necessary, to settle the point. This was only needed in a rough manner, however, as the preponderance of the Lewis River was too evident to require any exactness to confirm it.



INDIAN VILLAGE OF KIT^{L}-AH-GON IN THE VON WILCZEK VALLEY.

It is deserted in summer, and occupied in winter.

The ratio of widths is about five to three, with about the ratio of five to four in depth; the latter, however, being a very rough approximation. At old Fort Selkirk nothing but the chimneys, three in number, are left standing: the fate of this post has been alluded to in an earlier part of the article.

The latitude of Fort Selkirk is 62° 45′ 46″ north, and its longitude 137° 22′ 45″ west (Greenwich). Altogether on the Yukon River, this far, there had been taken thirty-four astronomical observations, four hundred and twenty-five with the prismatic compass, and two for variation of compass. I hope they have been sufficiently accurate; at least, to subserve all practical purposes of exploration in this country, until more exact surveys are demanded by the opening of some industry or commerce, should that time ever come. No meteorological observations were taken, the party not being furnished with instruments, and the rapid passage through a vast tract of country making their usefulness to science highly problematical. The nearest point to the upper Yukon, at which regular observations of this character are recorded, is the Chilcat salmon-cannery of the North-west trading company on Chilcat Inlet. The two are separated by the Kotusk Mountains, making meteorological inferences, therefore, very unreliable. Nearly a hundred botanical specimens were collected on the upper Yukon, and have been placed in the able hands of Mr. Watson, curator of the Harvard herbarium, for analysis. While only a limited and crude amateur's collection, it may throw some little light on the general character of the flora, as limited to the river-bed, which we seldom left in our more important duties connected with the main object of the reconnoissance.

The map is necessarily condensed for so large an area; and having been made hurriedly, and expressly for this article, it is not wrought so much for topographical effect as exactness within the limits possible under such circumstances. The map which will accompany my official report is on a much larger scale, and much better prepared in details. To Mr. Homan, my topographical assistant, is due all the credit relating to the map-making department, except simply the astronomical observations, and in those requiring an assistant, when he acted as recorder. The above account has mostly been taken in chronological sequence from my daily journal, and matters of the same character have thus been separated in different parts of the article. If, with all these defects, I have made clear my small addition to geographical research to the readers of *Science*, I shall feel deeply repaid for the great labor I had in securing it.

In my geographical nomenclature I have tried to observe the following rules. Wherever a descriptive name would assist any future traveller in identifying the object, I have applied it, to the exclusion of all others, Indian or civilized; as, Red Butte, Bald Hill, Cone-Hill River, Haystack Island, etc. Where Indian names are simple, I have tried to retain them, as Kotusk, Tahk-o, Tahk-heen-a, Kluk-tas-si, Dayay, etc. In all other cases, where the object was deserving of being named, I have not hesitated to attach the names of men worthy of such distinction, both personal friends in all branches of science, and those who have done something for geographical research, and without regard to country. In my larger map I have also added the native names, where they could be secured.

The total length of part first, the part explored and surveyed by this reconnoissance, was 538.8 miles; the total length of the raft-journey on part first, from camp on Lake Lindeman to Fort Selkirk, 486.8 miles; the total length of the raft-journey on Yukon River, from Lake Lindeman to Nuklakayet (being the longest raft-journey in the interest of geographical science), 1,303.2 miles; the length of Yukon River, 2,043.5 miles.

FRED'K SCHWATKA,
Lieut. U. S. Army.

NOTE ON THE FLORA OF THE UPPER YUKON.

LIEUT. SCHWATKA was able to make a small botanical collection from about the head waters of the Yukon, which is of considerable interest as an indication of the climate of the region, and as showing the range northward into the Yukon valley, of some species previously known scarcely beyond the British boundary. Lieut. Schwatka, ascending from the head of Chilcoot Inlet, crossed the main coast-range by the Perrier Pass at an altitude of 4,100 feet, coming at once upon the source of the Yukon River, in latitude 59° 40′. A descent of twelve miles brought him to Lake Lindeman; and upon the borders of this and other lakes within a distance of twenty-five miles, nearly equally on both sides of the sixtieth parallel, the larger part of the collection was made, between the 12th and 15th of June. The specimens gathered even at this date were in full bloom, excepting a few indicated in the following list

by parentheses, and the sedges and grasses, which were well developed.

Anemone parviflora.
Aquilegia formosa.
Aconitum Napellus, var.
Barbarea vulgaris.
Arabis petraea.
Cardamine hirsuta, var.
Viola cucullata.
Lupinus arcticus.
Rubus Chamaemorus.
(Poterium Sitchense?)
Saxifraga tricuspidata.
Saxifraga leucanthemifolia.
Parnassia fimbriata.
Ribes rubrum.
Epilobium spicatum.
Epilobium latifolium.
(Heracleum lanatum.)
Cornus Canadensis.
Antennaria alpina.
Arnica latifolia.
(Senecio triangularis.)
Vaccinium parvifolium.
Arctostaphylos Uva-ursi.
Bryanthus empetriformis.
Kalmia glauca.
Ledum latifolium.
(Moneses uniflora.)
Pyrola secunda.
Dodecatheon Meadia, var.
Polemonium humile.
Mertensia paniculata.
Polygonum viviparum.
(Betula glandulosa.)
(Alnus viridis.)
Salix glauca.
Salix Sitchensis.
Habenaria dilatata.
Streptopus roseus.
Carex (2 sp.).
Deyeuxia Langsdorffii.
Festuca ovina.
Lycopodium complanatum.
Lycopodium annotinum.

The rest of the collection was made as opportunity offered, during the descent to Fort Selkirk in latitude 62° 45′, which point was reached on the 13th of July. It included the following species: —

Anemone multifida.
Ranunculus Flammula, var.
Erysimum parviflorum.
Cerastium arvense.
Arenaria lateriflora.
Arenaria physodes.
Montia fontana.
Linum perenne.
Hedysarum boreale.
Rubus arcticus.
Fragaria vesca (?)
Potentilla fruticosa.
Amelanchier alnifolia.
Parnassia palustris.
Bupleurum ranunculoides.
Galium boreale.
Aster Sibiricus.
Achillea millefolium.
Artemisia vulgaris.
Arnica alpina.
Arnica Chamissonis.
Pyrola rotundifolia, var.
Primula Sibirica.
Myosotis sylvatica, var.
Pentstemon confertus.
Pentstemon glaucus (?).
Pedicularis flammea.
Chenopodium album.
Polygonum aviculare.
Zygadenus elegans.
Hordeum jubatum.

The species new to so northern a latitude are marked by italics. The season appears to have been as forward as I found it in 1868 in the lower mountain ranges rising from the plateau of western Nevada in latitude 40°.

SERENO WATSON.

THE INTELLIGENCE OF SNAKES.

NEITHER among the scanty early references to the serpents found in New Jersey, nor in more recent herpetological literature, are there to be found statements that bear directly upon the subject of the intelligence of snakes. Gabriel Thomas, writing of West New Jersey as long ago as 1698, quite ignores the fourteen species with which we are favored. Thomas Campanius, in his history of New Sweden, published in 1702, and which is based on the notes made by his grandfather during his brief stay in Pennsylvania sixty years before, also ignores our harmless snakes, but remarks of the rattlesnake (Crotalus horridus), "It has a head like a dog, and can bite off a man's leg as clear as if it had been hewn down with an axe." What may we not expect, when such statements as this are made by men of intelligence? Assertions equally absurd are not uncommonly made, even in these later days, when a correct knowledge of our common animals is supposed to prevail.

Nearly half a century later than the date of publication of Campanius' history, Peter Kalm, the Swedish naturalist, travelled in New Jersey, and spent much time, particularly in the southern counties of the state. In his entertaining volumes, he has made many references to our snakes, although not enumerating all of them, and mentioning some that certainly do not now exist. This author relates several wonderful stories of the fierceness of the black snake, as they were told to him, and likewise gives his personal experience with this same serpent, which, to his surprise, did not accord with what he had heard. The reason is plain enough. Kalm desired to know the truth, and took the experimental way of learning it. His knowledge of the snakes was gained by familiar out-of-doors intercourse with them, and it has stood the test of time. All that was needed, when he wrote, was the moral courage to say to the narrators of the marvellous stories, 'You are mistaken;' or perhaps, more wisely, he might have kept silent. The most conscientious man, if afraid of snakes, cannot tell the truth about them; and even in the case of the truly poisonous species, it is well to remember that 'the devil is not so black as he is painted.' Stress has been laid upon the exaggerated statements of authors when treating of snakes, for the reason, that, if there were any foundation for the marvellous stories narrated, it would prove conclusively that the serpent was indeed wise. But setting aside all the literature of the subject, and going directly to the woods and fields, what evidence do we find there of the intelligence of snakes?

On the farm of the writer there have been found eleven species of snakes, which is but four less than the whole number found in New Jersey. Of these eleven species, no one is venomous; and, it may be added, all are perfectly harmless, and, indeed, cowardly. It is true that when cornered they will show fight,

but it is the veriest make-believe; and it is very questionable if there is a snake among them all which could harm the smallest child, even if disposed to do so. This is strangely at variance with the current newspaper stories, I know; but those, like the anecdotes related by Kalm, are simply not true.

Of our common snakes, the most formidable in appearance is the black snake (Bascanion constrictor), and of this species scores of most wonderful stories have been told; yet the species is really very cowardly, and not disposed to resent interference at any time. It is, however, probably the most active, as it is the largest, of our serpents, and therefore is one well calculated to exhibit evidences of the possession of intelligence, and the best to study in regard to this subject. What, then, do we learn, when we seek out these black snakes in their chosen haunts? To find them, one must proceed cautiously; for they are possessed of a quick sense of hearing, and are on the alert the moment any suspicious noises are heard. Is it for this reason that they are considered quite rare in many places where they really are abundant? They have apparently learned wisdom by experience, and, knowing that if discovered they will be pursued, conceal themselves quickly if they suspect danger. I can in no other way satisfactorily describe such actions of these snakes as I have often witnessed; and the use of the phrase 'learning wisdom,' and of the word 'suspect,' implies necessarily the possession, on the part of the snakes, of a considerable degree of intelligence. How far the black snake is cunning, I have not been able to determine; but a chance remark in Heckewelder's 'Indian nations' would seem to indicate that the Indians had long been convinced that it was a cunning serpent, and I am disposed to accept their testimony in such matters as essentially correct. Heckewelder says the Indians gave to Gen. Wayne the name of 'Black Snake,' "because they say he had all the cunning of this animal, who is superior to all other snakes in the manner of procuring his food. He hides himself in the grass, with his head, only, above it, watching all around to see where the birds are building their nests, that he may know where to find the young ones when they are hatched."

Assuming this to be true, we have here an instance, not only of cunning, but of a very excellent memory. This seems incredible; but Mr. Romanes, in his volume on animal intelligence, remarks that snakes "are well able to distinguish persons, and that they remember their friends for a period of at least six weeks." If, therefore, a tamed snake can remember a person for six weeks, there is nothing very remarkable in its retaining the localities of birds' nests for a shorter period; for, between the building of the nest and hatching of the eggs, less than half that time elapses. The elaborate treatises on the power of black snakes to charm birds and squirrels may be passed by in this connection. That these snakes frighten little birds out of their wits by staring at them is occasionally true; but that the snake intentionally 'charms' its prey, as has been so elaborately and pathetically described, is sheer nonsense. Still, considering the black snake in a practical way, and seeing him under ordinary, not extraordinary, circumstances, it must be admitted that he possesses a considerable degree of intelligence. Indeed, the fact that this snake has, notwithstanding incessant persecution, been able to hold its own in the most thickly settled neighborhoods, is of itself a conclusive argument that it possesses decided intellectual power. It has at least sufficient wit to elude a host of enemies.

A far more abundant species, and one that is even better known and more dreaded than the black snake, is the harmless and very resentful hog-nosed snake (Heterodon platyrhinos). It has a variety of common names, — such as 'adder,' 'viper,' and 'flat-head,' — of which the last alone is at all appropriate. It is true that it flattens its head, hisses loudly, springs menacingly, and snaps fiercely; but it is harmless nevertheless.

As an object of study, it presents much that is of peculiar interest. Without fangs, or even teeth of sufficient length to produce a wound beyond a mere pin-prick, it presents the outward appearance, and has the pose and movement, of the deadly rattlesnake. Wholly unable to inflict the slightest injury, it has always puzzled me to understand why it should not, like all our other snakes, seek safety in flight. May we hold that it realizes the full meaning of the peculiar powers of the venomous serpent it mimics so admirably, and trusts to its being mistaken for a rattlesnake? Indeed, this mimicry has been perfect in some instances that I have witnessed; inasmuch as the tail of the snake was rapidly vibrated against dead leaves, and so produced a sound that was strikingly similar to that of the rattlesnake. This similarity was, of course, accidental, as it was by mere chance that dry leaves were lying about; but, at various other times, I have noticed that the tail was held in the same position, and vibrated in precisely the same

manner, as that of the rattlesnake. In these instances I thought I detected a faint whirring sound, or a buzzing; but on this point I am not positive.

Mimicry on the part of snakes is a ready way of explaining some of their habits; but, even when accepted, it remains to be shown how it originated. Is there any evidence that in former times the hog-nosed snake and rattlesnake were intimately associated? I find none, and certainly at present the two species are not found together. I have endeavored to detect something in their habits, haunts, and anatomy, that could throw light upon this question, but as yet all in vain. I can only say that the snake is in appearance a deadly rattler, but that it has neither the rattles nor the fangs. A veritable impostor is he, sailing under false colors throughout his whole life. How far has conscious mimicry had to do with this? If any thing, a high degree of intelligence is implied; but, even if the peculiar habits of the species were acquired without reference to other snakes, does not the fact that it relies upon worthless means of safety imply that it recognizes them as calculated to strike terror in the breast of its tormentor? That this snake should generally refuse to seek safety by running away, but depend upon actions which cause no harm to its enemies, seems, at first glance, to be the height of stupidity; but, when we recall the fact that it is a perfect imitation of the defensive movements of a venomous species found in the immediate neighborhood, then the question arises whether it may not be conscious imitation. If so, this snake, which is really quite sluggish in its movements, may be far more cunning than we suspect.

There is another species that to a certain extent imitates the rattlesnake, but whether intentionally or not, remains to be determined. This is the milk snake (Ophibolus doliatus). This species, when found in the woods coiled upon a heap of dead leaves, will often closely imitate the peculiar rattle of the Crotalus by vibrating the tail with great rapidity, and in such a manner as to strike the leaves beneath it. This I thought to be accidental in the case of the hog-nosed snake, but believe to be intentional in this instance. I do not go so far as to state that it is an intentional imitation of the rattle of the Crotalus, but that the snake vibrated its tail against the dead leaves that a decided volume of sound might be produced. This implies that it believed that a defensive pose at the time, coupled with a rattling sound, would cause the intruder to withdraw: at least, it depended upon them rather than upon running away, when surprised. We certainly have, in such cases, exhibitions of choice, on the part of snakes, between two means of defence when overtaken by enemies. Does not the exercise of choice between two equally available means of accomplishing an object imply the possession of a considerable degree of intelligence? A beautiful green snake (Liopeltis vernalis), which I kept in semi-confinement for several months, exhibited many evidences of considerable intelligence. It became very tame, and evidently recognized me. Although allowed considerable liberty, it did not seem to be very active during the day, but was restless in the evening. It seemed to be more sensitive to cold than any of our other snakes, and remained under its little blanket when the day was rainy, or a strong east wind prevailed. It fed upon flies, which it would take from my hand, seizing them very leisurely, and swallowing them deliberately. There was nothing of the snap and gulp of a salamander or toad about the process. When, however, the snake went fly-hunting on its own account, there was a very different state of affairs. There was still great deliberation, but only until the moment for action arrived; and then, with a snap, the fly was gone.

Occasionally this pet snake would creep among a number of pots of flowers, and coil about the green branches. At such times it would frequently extend some three or four inches of its body outward and beyond any support, and thus remain, as rigid and apparently lifeless as a twig. This, probably, was a habit common to the snake when free; but why it should be indulged in under such changed surroundings, I cannot imagine. Certainly it was not for the sake of seizing its food; for I noticed that the snake, after taking a hearty meal, would assume this position, and that it did not ordinarily assume it when asleep. In its proper home, such a habit, on the part of a small snake of this color, would render it for the time very secure against such enemies as were guided only by sight. Even when standing very near the rose-bush upon which my pet rested, I found it, when in this position, a very inconspicuous object.

If this position, then, was assumed as a means of safety, it is a habit indicative of much cunning; for it acquires thereby the best chances for seeing about it, with the least probability of being noticed.

Of the seven other species of snakes found here, I have nothing special to remark. It is sufficient to say that the general impression

which these snakes give me, as I chance upon them in my rambles, is, that they are cowardly but cunning. Blessed with acute hearing and sharp sight, they use both of these faculties to the best advantage in the two important events of their daily lives, — the capture of their food, and eluding their enemies. After thirty years of familiarity with the snakes found in this neighborhood, I can truly say of them, as serpents they are *wise*, and add, they are harmless as doves.

CHARLES C. ABBOTT, M.D.

PRESENTATION OF THE RUMFORD MEDALS TO PROFESSOR ROWLAND.

THE special business announced for the meeting of the American academy of arts and sciences on the evening of Feb. 13 was the presentation of the Rumford medals, which, at the annual meeting in May, had been awarded to Prof. Henry A. Rowland of Baltimore. Before presenting the medals, the president of the academy, Professor JOSEPH LOVERING, made the following address: —

The medals awarded to Professor Rowland have been struck at the Philadelphia mint, and appropriately engraved under the direction of the Rumford committee. Their delivery to the recipient has been postponed for several meetings, under the hope and expectation that Professor Rowland would find it convenient to be present, and receive the medals in person. His attendance with us now is warmly welcomed, and adds greatly to the interest of the occasion. I ask your kind attention to a brief statement of so much of the scientific work of Professor Rowland as justifies the award of the Rumford premium, and of the relation in which these researches stand to the present condition and needs of physical science.

Astronomy, at least that part of it which relates to celestial mechanics, has presented for many generations unchallenged claims to a precision not attainable in any other science. The comparative simplicity of its problems, involving only the familiar and measurable units of mass, space, and time, has enabled it to attain and to hold this distinguished position, in spite of the fact that all the senses except vision are excluded from its study. If it has received any assistance from the experimental laws of mechanics, much more have these laws been illuminated by the motion of the planets, where friction and other resistances do not interfere.

After Grove, in 1842–43, had published his lectures on the correlation of the various physical forces; after Mayer, Helmholtz, and others had published their conclusions (the deductions partly of theory, and partly of experiment) that these different forces were mutually convertible; and after the view first seized in prophetic vision by Bacon, Locke, and Winthrop, was experimentally established by Rumford, Davy, Joule, and numerous coadjutors, and with ever-increasing clearness, that the assumed caloric was imaginary, and that heat was only one kind of motion in ordinary matter, — then it was possible to introduce unity, harmony, and precision into all the physical sciences by making the familiar units of measurement universal. As other forms of energy (mechanical, electrical, magnetic, chemical, capillary, radiant, and gravitation) can be converted, directly or indirectly, into heat-energy, heat has become a universal standard of energy, current everywhere in science, and redeemable. Hence it has become of prime importance to determine the mechanical equivalent of heat: the amount of heat, for example, which corresponds in energy to a given mass falling through a given height in a given latitude. In this way heat and all its dependencies will be measured by the units of ordinary work. For more than forty years, physicists in difference countries, and by various methods, led by Joule, have been engrossed with this measurement, reaching results which have slowly but happily converged towards a common agreement.

Professor Rowland, after a historical and critical review of the methods and results of older cultivators in this rich field, has turned up the soil anew, deepening the furrows.

The fruits of his long and patient labor were made known to the academy in 1879, in vol. xv. of the Proceedings. New apparatus was devised; the comparative merits of mercurial and air thermometers were discussed; and the various constants of science which enter into the case were re-examined. The research is a model of ingenious and conscientious experimentation, and was not published until it had received from its author the same severe criticism which he had applied to the work of others. That his final conclusion harmonizes so well with the best of Joule's, increases our confidence in both. A larger discrepancy might have given a greater show of originality; but science would have paid for the novelty by a loss of security, and another revision of the whole subject would have been entailed upon it.

When Newton announced his dynamical theory of the solar system, as simple as it was comprehensive, it made slow headway against the fanciful hypothesis of Descartes which was intrenched in all the universities of Europe. And yet Newton's theory reposed upon a firm mathematical foundation; while that of Descartes submitted to no quantitative tests, and contradicted all the known laws of mechanics. The history of astronomy from that time almost to the present moment tells of ever new victories achieved by the combined attacks of the telescope and mathematical analysis in the province of celestial mechanics, presenting the law of gravitation as supreme dictator to planetary and sidereal systems. But these triumphs, complete in their details, and grand in their cosmical range, were limited to questions which concern the distances, motions, dimensions, and masses of the heavenly bodies. The law of gravitation can assign a value to the quantity of matter in planets and binary stars; but it asks and can answer no question in regard to the quality of this matter,

only so far as a comparison of the size and mass of a body gives a measure of its density. That an instrument would be invented or developed which would complement the mechanics of the heavens by the chemistry of planets, comets, and stars, so that a physical observatory would become a necessary adjunct of the old observatory, was beyond the hope of the most sanguine astronomer, down to the moment of its actual realization.

Newton owes his singular fame, not exclusively to his discovery and expansion of the law of gravitation, but partly to his experimental researches in optics. That he did not recognize the dark lines in the solar spectrum has been explained by the statement that he was obliged to use the eye of an assistant in these experiments, on account of an injury to his own. Be this as it may, the existence of these lines was first known to Wollaston in 1802; and from that moment the spectroscope and spectrum-analysis, as we now understand them, were possibilities.

Although Fraunhofer made a careful study of these lines in 1824, and Brewster, Herschel, Talbot, Draper, and many others pursued the inquiry by way of experiment and explanation, and stood upon the threshold of a great discovery, the spectroscope and spectrum-analysis, as practical realities, date from the investigations of Kirchhoff and Bunsen in 1862. Not only does the spectroscope carry chemistry into regions tenanted only by planets, comets, stars, and nebulae, and reveal motions in the direction of the line of vision, otherwise hopelessly beyond recognition, but it competes with the ordinary chemical analysis of bodies which can be handled, and has detected new substances which had escaped the vigilance of the chemist. Some of these results can be realized with simple instruments: others require a compound spectroscope consisting of a battery of prisms. It was a great step in the way of simplicity and ease of manipulation, when the diffraction-spectrum, produced by fine lines ruled upon glass or metal, was substituted for the spectrum produced by the combined refractions of many prisms. And here we touch upon the researches of Professor Rowland in light, which enhance his claim to the Rumford premium.

Professor Rowland's improvements in the diffraction-spectrum are manifold. 1. He has substituted for the flat plate on which the grating was formerly ruled a spherical or cylindrical surface. 2. He has ruled these lines to such a degree of fineness that 5,000, or 42,000, or even 160,000, have covered only one inch. 3. This exquisite work was executed by a machine of his own invention, and produced spectra free from the so-called ghosts which result from periodical inequalities in the ruling. 4. By making the curvature of the ruled plate discharge the office of a lens, he has avoided absorption at the violet end of the spectrum. 5. By his simple mechanical arrangements, different parts of the spectrum can be photographed with a great economy of time, and with such excellence of definition that old lines are subdivided, and new ones spring into visibility: in the words of a competent authority on the subject, 'the gratings of Mr. Rowland make a new departure in spectrum-analysis.' 6. Finally, his mathematical exposition of the theory of gratings has explained observed anomalies, indicated the conditions of success, and prophesied the limits at which future improvements in spectrum-analysis must stop.

PROFESSOR ROWLAND, It is now my duty, and certainly it is a most agreeable one, to present to you, in the name of the academy, the gold and silver medals which constitute the Rumford premium. Count Rumford, in conveying this trust to the academy through President John Adams, expressed a preference for such discoveries as should, in the opinion of the academy, tend most to promote the good of mankind. The practical applications of science are

numerous and valuable, and are sure of popular recognition and reward; but they often come from the most unexpected quarters. No one can predict what wonderful points of contact may be suddenly revealed between a purely theoretical investigation and the practical utilities of life. Meanwhile, a deeper insight into the laws of the material universe, extorted from a reluctant nature only after long and patient labor and thought, and many disappointments, becomes a permanent possession for mankind; and, as long as man does not live by bread alone, it is for him a perennial blessing. The academy, in awarding the Rumford premium to you, has indicated the kind of scientific work which, in its opinion, tends most to promote the *highest* good of mankind.

I ask you to accept, with these medals, my warm congratulations, and the cordial good wishes of all the members of the academy here assembled to administer Count Rumford's trust.

On receiving the medals, Professor ROWLAND spoke as follows: —

MR. PRESIDENT, AND GENTLEMEN OF THE ACADEMY, I thank you for the honor you have conferred upon me, which I can but regard as the greatest honor of my life.

In receiving these medals, I am pleased to think that they have been conferred upon work which is not the result of a happy accident, but of long and persistent endeavor.

There are some investigators whose disposition permits them to follow their aim, inspired by the mere love of the labor and the work. There are others to whom the sunshine of appreciation is necessary. To either class, appreciation, when it comes, is always acceptable; and I assure you that the judgment set upon my investigations by this academy is highly valued by me.

It has been intimated that a short account of my work would be of interest to the members of the academy. My attention was first called to the construction of dividing-engines by an inspection of a dividing-engine constructed by Prof. W. A. Rogers, at Waltham, in this state. On returning to Baltimore, I devoted much time to the general problem of such machines; and, through the liberality of the trustees of the Johns Hopkins university, I was enabled to construct an engine. In about a year this engine was finished. It worked perfectly the moment it was put together, and it has not been touched since. In order to rule diffraction-gratings, I reflected that it was necessary that the screw should be perfect, and that the rests for the plate which receives the ruling should also be as perfectly adjusted as is necessary in optical experiments.

The process of making the screw consisted in grinding it in a long nut in which it was constantly reversed. When this screw was finished, there was not an error of half a wave-length, although the screw was nine inches long.

When the dividing-engine was completed, my mind was occupied with the problem of the best form of surface to receive the ruling. I speedily discovered, that, by ruling the lines on a concave mirror of long focus, I could dispense with a collimator and with the ordinary arrangement of lenses. I now rule gratings six inches long, with various numbers of lines to the inch. I find that there is no especial advantage in having more than fourteen thousand to the inch, with the ordinary conditions of ruling. Having made the concave grating, I invented a simple arrangement for mounting it, so that a photographic camera should move along the arc of a circle at one end of a diameter, upon the other end of which the grating was placed, and always remain in focus. With this apparatus, one can do in an hour what formerly took days. Moreover, the spectra obtained are always normal spectra, and every inch on a photograph represents a certain number of wave-lengths.

After finishing my apparatus, I found it necessary to study photography; and I therefore devoted much time to this subject, and made a special study of all known emulsions. I discovered that an emulsion containing eocene enabled me to photograph from the violet down to the D line; and other emulsions were used for the red rays. I have also been engaged in enlarging my negatives and in printing from these negatives. On these enlarged photographs lines are doubled which have always been supposed to be single. The E line is easily doubled. My map of wave-lengths is based upon Prof. Charles S. Peirce's measurements of the wave-length of a line in the green portion of the spectrum.

At the conclusion of Professor Rowland's remarks, many questions were asked in regard to his beautiful device for photographing the spectrum, and the enlarged photographs which he showed were carefully examined.

PROGRESS OF ELECTRICAL SCIENCE DURING 1883.

THE subject of electrical science has become so broad that he who desires to keep abreast of the line of advance, and also to be on some points in advance of others, must read an immense amount in the English, French, German, and Italian journals, and in the patent-office reports of the various civilized nations. This is generally recognized; and courses in electrical engineering have been established in England, and are about to be established in America. This increase of intelligent appreciation of the magnitude of the subject of electricity is one of the features of the past year.

Perhaps the most important text-book that has appeared during the year is the English translation of Mascart and Joubert's treatise on electricity, with new notes by the authors. Clausius, also, has published a treatise on the theory of the dynamo-electric machine; and there have been numerous articles in various magazines upon the general subject of mathematical electricity.

The electrical congress which met in Paris, October,

1882, discussed the following questions: 1°. A redetermination of the ohm. 2°. (*a*) Atmospheric electricity; (*b*) protection against damage from telegraphic, telephonic, and electric-light wires; (*c*) terrestrial currents on telegraphic wires; (*d*) establishment of an international telemeteorographic line. 3°. Determination of a standard of light.

After a prolonged discussion, it was concluded that further experiments upon the unit of electrical resistance were necessary before a standard ohm could be adopted; and the governments participating in the congress were invited to encourage independent determinations of this unit. The section on earth-currents and lightning-conductors recommended also that the various governments should favor systematic observations, and that independent lines should be provided for the study of earth-currents; that long subterranean telegraphic lines should be used also for this purpose. The section on the standard of light were in favor of employing as a standard the light emitted by a square centimetre of melting platinum. The congress was adjourned to October, 1883; and afterwards the French government notified the various governments participating in the congress, that April, 1884, would be a more agreeable time to the majority of the congress than October. It is probable, therefore, that the congress will re-assemble during the coming spring.

Since the last meeting of the congress, various new determinations of the ohm have been made. E. Dorn, by a modification of Weber's second method, used also by Kohlrausch, has obtained the following value:—

$$1 \text{ S. E.} = 0.9482 \times 10^{10} \frac{m\,m}{\text{sec.}},$$

where S. E. denotes the Siemens or mercury unit. Lord Rayleigh has obtained .986 as the mean of the results of three independent determinations of the British association unit. Professor Rowland is at present engaged upon a careful redetermination of the ohm, using his apparatus for determining the mechanical equivalent of heat as a check upon the electromagnetic methods.

The subject of the cause of electromotive force obtains and deserves attention. Exner has maintained that there is no known case of chemical action without the development of electricity, and also of the development of electricity without chemical action. Braun controverts this conclusion. Exner finds that in a cell with zinc and platinum electrodes, and iodine or bromine as the liquid, a difference of electrical potential is obtained, notwithstanding the fact that iodine and bromine are elements, and cannot, therefore, be electrolytes. Exner believes the cause of this current is to be sought in chemical change. Braun shows that Exner did not take sufficient precautions to insure the purity of the iodine and bromine, and also to prevent the disturbing influence of the aqueous vapor in the air. He shows that there are numerous cases in which we have a development of electricity without chemical action, and also strong chemical action without the development of electricity. It is beginning to be perceived that the subject of thermal chemistry requires also a consideration of electromotive force.

In a voluminous paper containing a large series of observations, Quincke endeavors to verify Maxwell's conclusion that the square root of the dielectric constant must be equal to the index of refraction for light of the same substance. The several methods adopted give results which are not in accordance with Maxwell's theory of light. Quincke explains the different results obtained by different observers, as follows: 1°. Experiments show a fluctuation in the values of the index of refraction which is due to the electric force; 2°. A comparatively long duration of the electric pressure causes a fall in the value of the index of refraction equivalent to the effect of a rise of temperature between 0.0001° and 0.1° C. (this increases with the difference in potential between the electrodes, and can be attributed to internal friction caused by electric attractions and repulsions between the particles of the fluid); 3°. The phenomena of the change of the index of refraction show that the electric pressure has no analogy with hydrostatic pressure; 4°. These changes in the index indicate changes in hydrostatic pressure in the interior of the fluid, which are caused by the electrical pressure, the fluid being set into vertical movements thereby; 5°. The electrical effects appear to be transmitted through the fluid by impulses, and not in a continuous manner.

Julius Elster and Hans Geilel show that Zamboni's dry piles can be used as accumulators. The copper pole of the pile is connected with the positive, and the tin pole with the negative, pole of a Holtz machine. After the latter has been worked for a few minutes, the dry pile is found to be charged. After repeated discharges, the pile is found to contain a charge of considerable intensity. The authors recommend the following form of pile. The plates of the pile are strung, by means of a needle, upon a silk thread, and then stretched between the poles of a Holtz machine. A pile of eleven thousand pairs of plates, of one square centimetre surface, after ten minutes' charging, gave sparks one millimetre long, and made a Geissler tube luminous. The light of the tube was continuous at first, and afterwards intermittent. These piles are well suited to exhibit to a large audience the principle of Planté's or Faure's accumulators.

An interesting report upon the transmission of power by electricity was presented by Cornu to the French academy in April, 1883. This report was that of a commission appointed to examine the experiments of Depretz. It was found that the work absorbed by the generatrix, and transmitted to the receptrix, increases with the velocity of the generatrix. Depretz has succeeded in transmitting nearly four and a half horse-power through a resistance of a hundred and sixty ohms, which represents a double telegraph-line of eight and five-tenths kilometres. The work received was thirty-seven and a half per cent of that spent. With a greater velocity of the generatrix, it seems possible to transmit power to greater distances than Depretz has attained. This

amounts to saying that a high electromotive force is necessary for this end.

Many experiments continue to be made upon the magnetizing-function of steel and nickel. Hugo Meyer has experimented with weak magnetizing-forces, and finds that, 1°, the magnetizing-function has a positive value for a diminishing magnetizing-force; 2°, it increases at first with the magnetizing-force; 3°, it increases, for weak magnetizing-forces, with the temperature. Professor Ewing of Tokio, Japan, maintains that soft iron can be far more retentive of magnetism than steel. His results and detailed experiments are awaited with great interest.

Experiments made in the physical laboratory of Harvard university during the year have shown that the action of magnetism upon the conduction of heat, which has been maintained by several investigators, does not exist in magnetic fields which are at least ten thousand times the strength of the earth's field in Cambridge; and doubts are thrown upon such an action in general.

Hall's phenomenon continues to attract attention. As is well known, Mr. Hall has shown that an electrical current, traversing a thin plate of metal which is placed in a strong magnetic field perpendicular to the lines of magnetic force, has an electromotive force exerted upon it. At first it was supposed that this showed that an electrical current could be affected independently of the medium through which it passes. Mr. Hall, however, showed that the effect was different in different metals, and that the first conclusion was untenable. Aug. Righi has modified Mr. Hall's apparatus, and has discovered that the action in bismuth is extraordinary, being five thousand times as strong as in gold. The effect in bismuth can be obtained with a permanent magnet; and Righi hopes to show the phenomenon by means of so feeble a force as the earth's magnetism.

Edlund has broached a theory that a vacuum conducts electricity, and that the high resistance in rarified tubes is due to a contrary electromotive force at the electrodes in the Geissler tubes. He showed, that, without the employment of electrodes, one can excite an induction current in a Geissler tube which is sufficient to produce light. He maintains that this would be impossible if the highly rarified gas were an insulator.

Among the comparatively new electrical instruments which have been described during the year, are modifications of Lippman's electrometer. This consists, as is well known, of a capillary tube, connecting at one end with a comparatively large receptacle of mercury, and at the other with a vessel containing diluted nitric acid. The superficial tension at the end of the thread of mercury in the capillary tube is changed by a difference of electrical potential. The terminals of a Daniell cell — connected, one with the acid, and the other with mercury — cause a movement in the mercury-column, which gives a standard by which electromotive forces in general can be estimated. The instrument is very sensitive, but requires great care to prevent inaccurate measurements. A. Chevet has devised a modification of Lippman's instrument, which he claims will show a difference of potential of $\frac{1}{1000}$ to $\frac{1}{10000}$ of a Daniell cell. Two flasks, with lateral orifices on the same horizontal line, are connected through these orifices by the tube of a thermometer open at both ends. The bulb-end enters the flask *A*, which is filled with mercury. The capillary end enters the flask *B*. This latter flask is filled partly with mercury, and partly with water acidulated with a tenth part of sulphuric acid. The capillary end of the thermometer enters the acidulated water. A platinum wire, *P*, insulated by a vitreous covering so as not to be in contact with the acidulated water, is in contact with the mercury of flask *B*. Another platinum wire, *N*, is in contact with the mercury of the flask *A*. By means of a commutator a difference of potential can be intercalated between the ends of *P* and *N*. The heights of the mercury and water in the flasks *A* and *B* are such, that, *P* and *N* being connected by a metal wire, the surfaces of separation of the liquids are in the region of the capillary portion of the larger end of the thermometer-tube. The movements of the meniscus is observed with an eye-piece. Electrometers of the class of Lippman's can be constructed by any one at comparatively no expense, and are already used by physiologists. Hard-headed physicists, however, regard such instruments with considerable doubt when quantitative measurements are to be made. The subject of electrometers in general is very important from the point of view of the exigencies of meteorological bureaus and the signal-service. Modifications of Sir William Thomson's instruments still maintain their pre-eminence. Among these modifications is an instrument invented by Edelmann of Munich, in which the box-shaped quadrants of Thomson are replaced by cylinders, and the flat needle also by a suspended cylinder-shaped needle. The writer of this article remembers to have seen, ten years ago, an instrument similar to that of Edelmann, which had been devised by Mr. Moses G. Farmer, formerly of the U. S. torpedo station at Newport. It is said that the insulation of Edelmann's instrument is not perfect.

The cause of the electricity of the atmosphere is still unknown. The experiments of Freeman and Blake have apparently shown that the evaporation of pure water does not produce electricity. Kalischer has lately tested the question whether the condensation of aqueous vapor is a source of electricity. He used a modification of Thomson's electrometer, and connected it, with suitable precautions, with twelve large beakers which were covered with tinfoil and were filled with ice. These beakers, in turn, were protected from extraneous electrical influences. The condensation of aqueous vapor upon the beakers produced no electrical effect which could be observed. The criticism that can be made upon the experiments of Blake and Freeman is, that on the earth's surface an immense evaporation results from salt water, and impurities in the water may produce a state of electrification. Moreover, it is impossible to experiment on evaporation on a sufficiently large scale in a laboratory. An infinitesimal amount of electricity may

be produced by evaporation, which, although too small to be observed, may yet be integrated over the surface of the earth into a large sum.

In looking back over the electrical year, we do not find any great discoveries. We notice, however, great activity in the process of refining old methods. The electrical exhibition at Vienna showed a host of applications of electricity to the arts. There was, however, no striking new invention like the telephone. In all civilized countries, the year has brought forth innumerable modifications of telephones and telephonic apparatus. When it had once been shown that even an imperfect sentence could be transmitted by electricity, the dullest inventor could discover, among the *débris* of his laboratory, magnets and electromagnets which needed but a slight twist here and there to be made into telephones. A touch of genius was necessary for the first twist; and then the whole electrical world had the seed of the invention. It is rumored that long-distance telephoning will soon be attempted with wires of low resistance.

Electric lighting continues to attract great attention; and more correct calculations are daily made, which will soon enable us to judge of the relative economy of incandescent lighting compared with gas. In an address to the Society of arts in London, the lamented Dr. Siemens — whose sudden death last December has been such a loss not only to electrical science, but to science in general — made an elaborate calculation of the cost of lighting large areas in cities, taking the parish of St. James in London as an example and also as a unit. He estimated that to light London to twenty-five per cent of its total lighting-requirements would require an expenditure of capital of fourteen million pounds, without including lamps and fittings; making an average capital expenditure of a hundred thousand pounds per district. Siemens estimated the cost of lighting by incandescence as twenty-one shillings and nine and a half pence per lamp per year; while to produce the same luminous effects in a good Argand burner costs twenty-nine shillings per year. This apparently shows that incandescent lighting is cheaper than lighting by gas, at the present price of gas.

Electric lighting seems to gain in the estimation of the public. Even the argument that if the electric-light companies were compelled to put their wires under ground the companies could not pay their expenses, and consequently that the public would lose the benefits of the electric light, has a strong influence upon many who prefer light to darkness in our city streets. The public, however, are only beginning to realize the dangers from the present method of running electric-light wires. A heavy storm at night might cause at any time disastrous conflagrations, from the electric-light wires coming in contact with other wires and with wood-work. The bulletins published by the Edison electric-light company show the great extension of his system. His plants are to be found in almost every civilized country; and the company are paying great attention to village plants.

The writer of this article is informed that the cost of lighting the great steamboat, The Pilgrim, is not far from that of gas, with a far better quality of light than gas could give. Lighting by incandescence is a great luxury; and, as soon as the public imagination has been sufficiently stimulated, it promises to become a necessity in many quarters. Other systems besides that of Edison are competing for the field opened for enterprise.

The practical applications of the storage of electricity, so called, have not been numerous during the year. It is maintained that it is more economical to use electrical accumulators than to light directly from dynamo-electric machines. There is still a wholesome fear of having several tons of lead left on one's hands in a disintegrated condition. Further experiments are necessary on an extended scale, with especial reference to a large factor of time, before electrical accumulators can be pronounced a practical success.

John Trowbridge.

BIOGRAPHIES OF NATURALISTS.

Heroes of science: botanists, zoölogists, and geologists. By Prof. P. Martin Duncan, F.R.S., F.L.S., etc. (London society for promoting Christian knowledge.) New York, *E. & J. B. Young & Co.* 348 p. 12°.

The plan of the several volumes designated by the common title 'Heroes of science' is worthy of much commendation. It is a frequent and irritating experience of those who have become interested in scientific men's lives to find that they have a scant place in biographical encyclopaedias, and that even the greatest figures in that line of human activity are dismissed with epitaphal brevity of description. The proper way to meet this difficulty would be by preparing an encyclopaedia containing only the names of those who had contributed something to the store of science. 'Heroes of science' has a far simpler aim. Twenty-one names from the great muster-roll of men who may be termed naturalists are all that appear in this book. The first is that of Aristotle; the last, that of Lyell. The aim of the author is clearly to show how these men have played their parts, and something of the way in which they turned the course of science in their time. In this aim it seems to the present writer that Professor Duncan has attained a very substantial success. Within the slender space of two hundred and fifty small pages it is, of course, impossible to do any thing that can be called justice, to more than a score of very notable men, mostly of rich and varied lives; yet the reader will get a sense of their value to the world from the book, that he will not obtain elsewhere. Take, for instance, the life of Lamarck: though all too briefly told for true proportion, it is the best short account of

that true hero that can be accessible to the ordinary reader.

The greatest fault of the book is that the length of the text bears no sort of proportion to the importance of the men or their possible interest to the reader. Lamarck's life is one of the most picturesque of all scientific lives: it is more heroic in quality than that of any other given in the series. Lamarck gave as much or more to natural science than any other naturalist whose name appears here; yet to this man's eventful history but fifteen pages are given, while Sir Roderick Impey Murchison, from whom the world had little profit, who will find his place among naturalists of the second or third order, has twice the space allotted to him. Singularly enough, the one man who should have the first place among the modern men is not named at all. Darwin, who could have claimed a place in all the three divisions of the book as botanist, zoölogist, and geologist, is passed by. It may be that the book was prepared before the death of this great naturalist, and thus that the date does not represent the time of its printing. This is the only possible explanation of this startling omission.

The book is well printed. It has a sufficient table of contents, but no index.

GORDON'S ELECTRICITY AND MAGNETISM.

A physical treatise on electricity and magnetism. By J. E. H. GORDON. Second edition, revised, rearranged, and enlarged, in 2 vols. London, *Sampson Low*, 1883. 343 p., 27 pl., 151 illustr.; 332 p., 46 pl., 161 illustr. 8°.

THE demand for a new edition of a work of this magnitude, within about three years of its first publication, is a sufficient indication of its real usefulness, especially when we consider the fact that the first edition was also republished in this country.

The general scope of this treatise is to detail every thing of importance which is known experimentally respecting electricity and magnetism, referring to, and following as closely as may be, the original memoirs.

The mathematical theory of the subject is omitted so far as possible; nevertheless, the connection between the experimental facts and the results of modern theory are constantly pointed out by very numerous citations and references, especially to Maxwell. Indeed, these may, perhaps, be best regarded as companion volumes to those of Maxwell, from which the reader may learn how far theory and facts are now known to be in accordance.

We feel, however, that the author's reading has been too much confined to what has been published in England, and that he has not gleaned the field with equal diligence elsewhere. For example: we find no notice of the remarkable discovery by E. H. Hall of a new action of the magnet on electrical currents.[1]

The principal enlargements of this new edition are contained in the three chapters, 33, 35, and 36.

Chapter 33 contains an account of the beautiful experiments of Mr. Tribe in determining the variations of potential along the surface of a metallic conductor immersed in a fluid-cell by means of the electrolytic deposit upon the conductor.

Chapter 35 gives an account of the hydrodynamical experiments of Professor Bjerkens, on the apparent attractions and repulsions between bodies which are pulsating or vibrating in a fluid, which attractions are due to the mutual action of the currents set in motion by the pulsations. The importance of these experiments lies in the fact that they afford a possible clew to the nature of the mechanism which transmits electric and magnetic forces through space. In the course of these experiments, Bjerkens succeeded in imitating mechanically most of the ordinary magnetic phenomena, and showed that his field of force was similar to the magnetic field.

Chapter 36 details the subsequent researches of Mr. Stroh, respecting the same phenomena. Mr. Stroh used air instead of water as the medium in which the currents were set in motion. In this medium it was possible to explore the field of force much more completely than in water, and so to arrive at a much more exact knowledge of the facts and their explanation.

The author reserves what he has to say upon the subject of electric lighting for another work, which he has nearly completed, and which is to be specially devoted to that subject.

BASSLER'S WEATHER.

The weather: a practical guide to its changes, showing signal-service system, and how to foretell local weather. By S. S. BASSLER. Cincinnati, *Robert Clarke & Co.*, 1883. 54 p., illustr. 8°.

IN spite of our ten years' familiarity with the weather predictions of the signal-service as published in the newspapers, the general reader has as yet a very slight acquaintance with the principles and methods of weather study. The official circular on the 'Practical use of mete-

[1] *Amer. journ. math.*, ii. No. 3.

orological reports and weather-maps,' published in 1871, to aid in popularizing the work of the signal-service, is not sufficiently detailed, and has never had a great circulation. Another edition of it, with additional illustration and mention of the many facts discovered by studies of the ten years of signal-service observations, is now much needed; for we have no book in this country occupying the place held in England by the excellent little volume on 'Weather-charts and storm-warnings,' prepared by Mr. Scott of the British meteorological office. An attempt in this direction has, however, recently been made by Mr. S. S. Bassler of the Cincinnati *Commercial gazette*, who aims to make "a practical guide to weather-changes, and a help to a better understanding of the weather reports and predictions daily issued," with especial adaptation to the Ohio valley. The ordinary sequence of atmospheric conditions accompanying barometric maxima and minima is briefly described and roughly illustrated; but we regret to find in the field of popular instruction, where conciseness, clearness, and accuracy are of prime importance, so many departures from these essentials. Error and inaccuracy of statement, as well as the omission of many important facts, for which ample space might be found by avoiding needless repetitions, indicate lack of acquaintance with the subject; and although the preface says that "it is not proposed to consider any of the conflicting scientific theories, many of them still mere assumptions that have been accepted as explaining the phenomena daily presented in our atmosphere," we find on p. 36 the following obscure and inaccurate statement concerning the origin of storms: —

> "The warm, light, vaporized air may move high over the land, frequently over strata of dry cool air, in great volume, from the central meteorological zone, gradually sinking down and forming the germs of barometric fields of low pressure, which spread and develop into extensive storm areas. It is in such fields that the heat of the sun is concentrated and storm centres originated. The earth absorbing electricity from the air, electric disturbances of more or less violence, according to the intensity of the condition, are experienced. The absorption or withdrawal of electricity from the vaporized air produces sudden condensation, excessive precipitation, and change of temperature."

It is said farther on, that the tornado "has its origin in the enormous electric tension caused by the friction of opposing atmospheric currents of different temperature; and electricity is undoubtedly the active agent producing the appalling effects of tornadoes." Some physical demonstration of this very popular and very erroneous assumption would not be out of place after so unqualified an assertion. The pamphlet is better than nothing, but it is by no means a satisfactory piece of work.

ART-CATALOGUE OF THE NEW-ENGLAND MANUFACTURERS' INSTITUTE.

Catalogue of the art department of the New-England manufacturers' and mechanics' institute. Boston, *Cupples, Upham, & Co.*, 1883. 4°.

This catalogue certainly has a very alluring exterior, and leaves little to be desired in its general presentation of reproductions of certain sketches and pictures which were exhibited at the fair of 1883 in Boston. It is not our function to criticise the pictures, but the methods of reproducing the pictures and sketches by the various mechanical processes exhibited in the catalogue fall within the province of *Science.*

Still, a critic of the various methods of reproduction of pictures cannot limit himself entirely to a mere consideration of the thoroughness of the technical processes involved in such reproductions; for he would appeal only to the ardent follower of the albertype process, or to an etching process. He must decide as impartially as possible, which of the various methods exhibited, for instance, in this catalogue, gives an idea of the pictures which appeals to the artistic sense in the fullest way. From this point of view there is no doubt that the wood-engravings and the etchings in this catalogue are superior to the specimens of the albertypes, and to those of the photographic processes in general. No photolithographic process represents the values of the lights and shades of a picture except in the most solid and implacable manner. Witness the 'View on the Nile,' which represents a darbeah in the foreground, with some figures on the river-bank near it, a stretch of river and of low-lying hills. The reproduction has an air of *vraisemblance*, but nothing more. It is not artistic. The little picture entitled 'Give me a swing,' representing a pretty little girl leaning against a tree near a hammock, and coquettishly entreating some passer-by, is a better specimen of what an albertype can do. The remaining specimens of albertypes lose whatever clearness of definition a real photograph might possess, and render the blackness of shadow of many photographs in a still more pronounced way; so that the albertypes presented in this volume have the appearance of poor photographs. There are certain subjects, however, for the reproduction of which the albertype is suitable.

'The spring near Orange, N.J.,' for instance, renders the peculiar mistiness and indefiniteness of a New Jersey landscape at that time of the year with considerable truth. The fascination of a new process of reproduction makes one eager to extend it to all subjects; and it is only after a long period of comparison that one can get far enough away from this fascination to obtain clear judgment of the possibilities of the method. He who discovers for himself the possibilities of a pot of red paint in decorative art is at first apt to apply the paint to every thing.

The wood-engraver and the etcher have nothing to fear at present from the various lithographic and photolithographic processes, save in the cheap market. The various gelatine processes must necessarily intensify the want of half-lights which is a characteristic of many photographs, and must obliterate even the faint differences in the degree of darkness of shadows which the original photograph may show.

Heliotypes and similar processes stand in the same relation to the pictures they reproduce that music-boxes stand to the performance by the musician of the piece of music they strive to reproduce. The delicacy and freedom of the original performance is lost. This cannot be said of wood-engraving and etching. The wood-engravings and etchings in this catalogue are superior to the other methods of reproduction, and show a capacity for interpreting the sentiment and the skill of the artist, even to the extent, sometimes, of improving on the originals of which they are the reproductions. The progress of one's art-culture is generally from photographs to engravings, and from engravings to etchings; and a half-hour's study of this illustrated catalogue would hasten one's culture in this generally accepted way.

YARROW'S CHECK-LIST OF AMERICAN REPTILES.

Check-list of North-American Reptilia and Batrachia; with catalogue of specimens in U. S. national museum. By H. C. YARROW, M.D. Washington, *Government*, 1883. (Bull. U.S. nat. mus., 24.) 8 + 249 p. 8°.

IN this catalogue are included the names of three hundred and thirty-seven species and sub-species of reptiles, and one hundred and thirty batrachians, found in North America north of Cape San Lucas and Key West. The trinomial system of expressing the variations of widely distributed and variable species is adopted, as in the recent check-lists of birds; and the sub-species are numbered with the species. Each species and sub-species has been furnished with an 'English' name, although very few of them have any distinctive vernacular appellation in fact. The author observes, that to the task of ascertaining the English names in actual use has been added "the very laborious one of translating as literally as possible some of the polysyllable Greek and Latin names." This, it seems to us, has been a wholly profitless task. It is no gain to any one to call Amblystoma jeffersonianum platineum the 'slender salamander,' while the related Batrachoseps attenuatus is the 'slender lizard.' Nor is it evident why most, but not all, of the species of Plethodon, are called 'lizards,' while those of related genera are chiefly 'tritons' or 'salamanders.' Hemidactylium scutatum, although in no proper sense a lizard, and not scaly, is called the 'scaly lizard,' instead of the 'shielded little half-toe,' as its name would imply. Perhaps these English names of Dr. Yarrow are as good as any other set of made-up vernacular names; but, if so, it is time to protest against the whole business. Scientific names themselves are sufficiently trying without this additional incubus.

The classification and nomenclature of Dr. Yarrow's list is essentially that of the check-list of Professor Cope. Several additions have been made, and a few changes of name; most of the latter being in the group of turtles, and due to the studies of Mr. F. W. True. Some further changes in nomenclature must take place; as the substitution (already suggested by M. Boulenger) of 'Cryptobranchus' for 'Menopoma,' of 'Necturus maculatus' for 'N. lateralis,' and the suppression of the generic name 'Muraenopsis,' pre-occupied among the eels.

After the check-list, follows a list of the specimens of each species in the National museum. This list is of very high importance as a contribution to our exact knowledge of the geographical distribution of species, and is, in fact, the *raison d'être* of the whole memoir. The bulletin is completed with a list of species desired by the museum, and with full index to scientific and vernacular names of species, and to the localities and names of persons mentioned.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Mount Shasta. — In *Science*, No. 48, was mentioned Mr. Gilbert Thompson's suggestion, that Mount Shasta, in northern California, would be a good point upon which to establish a permanent meteorological station like those on the summits of Mount Washington and Pike's Peak. The following notes, obtained from Mr. Thompson, will perhaps make more apparent its suitability for that purpose.

Mount Shasta is a volcanic peak having an altitude of 14,511 feet above sea-level, and situated in latitude 41° 24′ 30″, and longitude 122° 11′ 34″. So prominent is it, that it rivets the attention even at a distance of over a hundred miles; and at Berryvale, where it rises over 11,000 feet in a distance of ten miles, its appearance is majestic. It is not part of a mountain range, and no mountains within a radius of forty miles from it attain the elevation of 9,000 feet. The greatest length of the north-west slope is sixteen miles to the edge of Little Shasta valley, which has an elevation of 3,000 feet. The south-western slope to Elk Flat (where the elevation is 4,000 feet) has a length of eight miles. The highest divide, six miles to the north-west, has an altitude of 6,000 feet; while the divide of the Sacramento River, ten miles to the westward, has an altitude of only 3,500 feet. The distance from the summit in any direction, to the contour of 8,000 feet, will not exceed four miles. The prominence and isolation of this volcanic cone are therefore obvious.

The point at which the growth of timber receives its greatest check is at an elevation of 8,200 feet. This limiting-line is a conspicuous feature in the view of the mountain as seen from a distance of forty or fifty miles, as it contrasts sharply with the snow. The last tree (so small that it was put in the vest-pocket) was found at 10,130 feet.

The streams that have their origin in the melting of the snows of Mount Shasta make their appearance suddenly as rushing torrents, which subside during the night, leaving only pools of clear water, which also gradually disappear. On the east side they have eroded deep cañons, in two of which are waterfalls 400 feet in height. After the first snow, the flow of water from the mountain ceases until the following spring. Only two streams can be considered as permanent. There are but few springs; as all this water sinks near the base of the peak, to re-appear at distant places in an unexpected manner as springs of immense size. The hot sulphur-springs, or solfataras as perhaps they should properly be termed, which are now in active operation at the summit of the peak, once extended considerably farther to the south-east. An additional spring was discovered last summer, under the summit to the eastward. The myth of the Win-tún Indians, that Mount Shasta is the assembly-house of the gods, probably had its origin in the existence of these springs. The more prosaic imagination of the topographer suggests that the steam from these vents might be utilized to heat a station built on the summit of the mountain.

Topographic work in the southern Appalachians. — Party No. 2 of the southern Appalachian division, Morris Bien in charge, was engaged during the past season in the north-eastern part of Tennessee, the north-western part of North Carolina, south-western Virginia, and southern West Virginia, — an area of about six thousand square miles, lying between parallels 36° and 37° 30′, and meridians 81° and 83° 30′.

The topography of this area is of the same character as that found by party No. 3 in the Tennessee valley; except, that, in the portion lying in North Carolina, the character of the former is combined with a system of spurs radiating from a sort of central knot, — a feature reminding one somewhat of the Rocky Mountains. This similarity to western topography increases as we go southward on the eastern side of the range, until, in the Black Mountains, it becomes very marked. Another striking difference is, that here there is no apparent underground drainage of the sink-hole nature. In south-western Virginia, however, the drainage is similar to that of the Tennessee valley, and quite as striking.

A curious example of the sinking and re-appearing of streams is found in Scott county, Va. There is a completely enclosed basin in which a considerable creek gathers, and flows toward the Clinch River, from which it is separated by a continuous ridge about three hundred feet high. At the foot of this ridge the stream disappears, and, as has been proved by marked slabs, flows beneath the ridge and under the river, appearing as a spring about half a mile from the river, and on the opposite side of it. The underground course of the stream must be somewhat like an inverted siphon. The sink of the creek is about twenty feet higher than the river, and nearly the same height above its outlet at the spring.

In the same county is the natural tunnel of Stock Creek. At about eight miles from its head, the ravine in which Stock Creek flows is closed in by a distinct cross-ridge about four hundred and fifty feet high. The creek, which is about fifteen feet wide and three feet deep, has made an S-shaped tunnel through the ridge about nine hundred feet long, and averaging fifty feet in width. It is nowhere less than ten feet high, rising at the entrance and outlet to over sixty feet.

The entrance is an almost perfect archway in a perpendicular rock wall which is nearly four hundred feet high, while the outlet is in a remarkable perfectly dome-shaped rotunda of which about half is wanting. The highest point of the dome is about four hundred and fifty feet above the creek-bed. Curiously enough, when visited last September, the creek sank entirely at the entrance, and re-appeared only at the outlet, not a drop of water being visible in the tunnel; whereas during high water a roaring torrent rushes through it. A preliminary line of the South Atlantic and Ohio railroad has been located in the

tunnel; and they propose to make a secondary tunnel, cutting an angle of the S in the natural tunnel.

There are enormous quantities of marketable timber throughout this whole section; cherry, walnut, oak, chestnut, poplar, hickory, etc., growing everywhere. In the extreme south-west of Virginia, fine large poplars are found in great abundance. In Shady Valley, Tenn., is an extensive forest of several thousand acres, in which are to be found most magnificent pines, straight as an arrow, and many over a hundred and fifty feet high.

The mineral wealth of the country has just begun to receive proper attention. Within the past few years the well-known Cranberry iron-mines have been opened, the ore from which is of very fine quality; and it is claimed that the same body can be traced, almost continuously, far north into Virginia. There are several copper-mines in the north-western part of North Carolina which await only the influx of capital to produce in large quantities. Gold has also been found in this section in small amount.

Throughout that part of south-western Virginia lying north-west of Clinch Mountains, coal is found in almost every ridge, and, at Pocahontas, is mined in large quantities. Copper and iron have also been found scattered throughout this section. This region needs only railroad facilities to become one of the richest districts in the east. It can supply coal and timber in enormous quantities; and, from all accounts, iron and copper mining would also be profitable.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Franklin institute, Philadelphia.

Feb. 20. — Mr. S. Lloyd Wiegand presented a further communication respecting the use of cast-iron in the construction of steam-boilers; illustrating his remarks by bursting, under hydrostatic pressure, a model of the exploded Gaffney boiler, which had been the cause of a protracted legal controversy in Philadelphia. Mr. Wiegand protested against the sweeping condemnation of cast-iron as a material for steam-boiler heads, and especially deprecated the effort that had been made to commit the institute as a scientific body, to suit an expression of opinion without experimental verification. On Mr. Washington Jones's motion, a resolution was adopted, in which the national Congress is urged to appoint a commission of experts for the testing of iron, steel, and other materials used for structural purposes, and to make a suitable appropriation for the work of the commission. —— Mr. David Cooper exhibited a remarkably fine suite of specimens of direct life-size camera portraits, admirably illustrating the progress which has lately been made in dry-plate photography. These pictures were taken with dry plates prepared by the Eastwick dry-plate company of New York.

Canadian institute, Toronto.

Feb. 16. — Prof. J. Playfair McMurrich read a paper on the osteology of Amiurus catus, one of a series on the morphology and development of that fish. The paper treated particularly of the high specialization of Amiurus, as instanced by the small amount of cartilage in the skull, and by the great modification of the maxillae and of the pectoral and dorsal fins.

Princeton science club.

Feb. 14. — Professor George Macloskie reported his researches on the tracheal organs of insects, by which it appears that their spiral filaments are not independent structures, but crenulations or inward foldings, with thickening of the chitinous wall; that the spirals are really tubular, fissured at the line of infolding, and continuous with the enclosing wall. The function of aeration is discharged by air passing, not through the wall into the blood, but directly to the tissues by lung-like terminal cells, long ago described by Louis Agassiz, and shown by Max Schultze to be especially abundant near the luminous organs of the glow-worm.

Prof. H. F. Osborn reported, that in the opossum, unlike the kangaroos, the superior and inferior mesenteric arteries and coeliac axis arise from a common trunk above the renal arteries, — a reduction similar to that found in the monotremes.

Prof. W. B. Scott stated that the hind-foot of the American miocene Enteledon shows, like the European, the third and fourth metatarsals greatly enlarged, the second and eighth very rudimentary. The third is borne entirely by the external cuneiform; the middle cuneiform is very small, and coalesced with the external cuneiform; and the internal is very narrow, and articulates above with the navicular, and below with a hook-like process of the third metatarsal. The rudimentary second metatarsal is wedged in between the middle and internal cuneiforms. This type of foot corresponds to Kovalevsky's 'inadaptive type of reduction,' nearly half of the bearing-surface of the tarsus being unemployed.

Dr. McCay called the attention of the club to a letter in the last number of the *Jahrbuch für mineralogie*, from Professor Sandberger of Würzburg. In a pamphlet which appeared recently in Germany, McCay had attacked Sandberger respecting his alleged discovery of the rhombic modification of speiskobalt. McCay has proven that the honor of the discovery is due to Breithaupt of Freiberg; and Sandberger, convinced by the ample evidence, has in his letter admitted the correctness of the arguments advanced, and signified his readiness to withdraw his name 'spathiopyrite,' and to substitute in its place the Breithaupt term, 'safflorite.' Dr. McCay further reported upon eight analyses of argillaceous limestones, several of which seemed admirably fitted for making hydraulic cement.

Prof. C. G. Rockwood and Mr. Fine gave synthetic

demonstrations of the formula for the prismatoid, one section being made at will. —— Mr. Smith gave a new and simple demonstration of the ellipse of stress. —— Mr. Magie gave a proof for the movement of liquids in capillary tubes, both cylindrical and conical. —— Mr. M. McNeill gave a method for reducing to the mean time of observation a series of micrometer measures of distance and position angle, when one of the objects has such a large proper motion that these quantities do not vary proportionally with the time.

Society of arts, Massachusetts institute of technology.

Jan. 24. — Capt. D. A. Lyle, U.S.A., read a paper on the rise, progress, and methods of the U. S. life-saving service. The first organized attempt at saving life imperilled by wreckage was inaugurated by the Massachusetts humane society in 1782, but the true inception of the U. S. service was in 1848; and since that time, in spite of reverses, inadequate appropriations, etc., the service has steadily advanced in efficiency. It was established on its present enlarged basis in 1878, after several years of struggle. At present the whole number of stations is 189, of which 139 are on the Atlantic coast. The following statistics for the year ending June 30, 1882, will show the efficiency of the service: disasters, 345; property involved, $4,766,000; property saved, $3,106,000; persons involved, 2,398, of whom all but 12 were saved; total expense, $594,889.74, or at the rate of less than $250 per person, without considering the value of property saved. During the more inclement months, dangerous shores are constantly patroled; and upon discovering a wreck, a projectile is fired over the vessel, carrying a line, by means of which the sailors draw out a cable, which they secure to the mast, and on which a life-car or a breeches-buoy is run back and forth, by which those on board are carried to the shore. Capt. Lyle explained all the details of the methods used, by means of a model. —— Mr. N. M. Lowe exhibited a model showing a method of transmitting power by belting, designed to replace the ordinary fast and loose pulley.

Academy of natural sciences, Philadelphia.

Jan. 15. — Prof. H. C. Lewis exhibited a specimen of limestone from Utah which emitted a lurid red light when struck, scratched, or heated. The glow lasted from half a second, when lightly struck, to a much longer time as the result of a blow. On examination, the specimen proved to be an almost perfectly pure carbonate of lime, with but a slight percentage of impurities. It is loose-grained, white, and crystalline, the grains being but slightly coherent, thus giving the rock the appearance of a soft sandstone. It crumbles easily between the fingers, forming a coarse sand. When heated in a glass tube over a flame, it glows with a deep red light, which lasts for a minute or more after withdrawing the flame. After two or three heatings the phosphorescent property disappears. A search through the collection of the academy for limestones having similar properties resulted in finding specimens from Kaghberry, India, which glowed with a strong yellow phosphorescence when heated, although no such effect was produced by scratching or striking. It was of great interest to find that the Indian limestone alone, of all in the collection, had the precise external characters of that from Utah. This similarity is more than a coincidence. It confirms Becquerel's view that phosphorescence depends upon physical rather than chemical conditions. In the rocks referred to, it is probably dependent upon a disturbance of their loosely aggregated crystalline particles, whether such be produced by percussion, friction, heat, or decrepitation.

Dr. J. Leidy communicated the results of a recent trip made to Atlantic City for the purpose of collecting and studying some of the life-forms thrown up on the beach by the storm of Jan. 8. The shore at the highest line reached by the tide was for miles covered with millions of bushels of the common beach-clam, Mactra solidissima. In many places they were closely packed together in extensive patches. Besides those visible, it is probable that at least as many more were covered by the sand thrown up at the same time, or had buried themselves in the beach. Until this evidence of the storm he had no suspicion that the mollusk was so exceedingly abundant on the coast; though he had been well aware that it was very common, having repeatedly seen large quantities thrown on shore under similar circumstances. With the Mactra were other mollusks, which, although numerous enough, appeared to be few, compared to the former. These were Fulgur carica, and F. canaliculata, Natica heros, N. duplicata, and N. obsoleta. Hermit crabs were also abundant, — Eupagurus pollicaris in the shells of Natica and Fulgur, and E. longicarpus in shells of Natica. Spider-crabs were common, and a few half-grown horseshoe-crabs were also observed. Some bunches of the common edible mussels were collected.

It seemed remarkable, on the other hand, that some of the commonest mollusks were conspicuous by their absence; few or no oysters, clams (Venus mercenaria), squirt-clams, or horse-mussels, having been seen. Scarcely any traces of annelids were observed, except masses of dead Serpula. There were also no echinoderms, except one, Caudina arenata, which occurred at some places in considerable numbers. It was believed that this was the first time the animal had been observed on the coast of New Jersey. They usually range from three to four inches in length, but several were found upward of six inches, and over an inch in diameter at the thicker portion of the body. They present but little resemblance to the forms commonly recognized as echinoderms or sea-urchins, looking much like large fleshy worms. Dissection, however, at once reveals their true relationship.

It is an interesting question as to what becomes of the vast quantity of Mactra and other shells incessantly cast on shore. Storms annually oblige the ocean to contribute, from its inexhaustible stores, multitudes of mollusks and other animals to the sandy beach. By exposure to the influence of the weather, the air, the sun, the rain, frosts, and other destructive influences, the calcareous shells are broken

and decomposed, and in a comparatively few years entirely disappear. Carbonic acid of the rain-water must be a potent agent in their ultimate solution, as it percolates through the sand. While the beach receives its constant supplies of shells, no trace of these is to be found in the sand immediately back of the shore, which in former times received the same incessant contributions. For similar reasons, no doubt, calcareous fossils are comparatively rare in sandstones, though in many cases their impressions are well preserved.

NOTES AND NEWS.

LUDWIG LIEBRECHT of Lippstadt, in Westphalia, is endeavoring to obtain subscriptions from all countries to establish a memorial in honor of the late Dr. Hermann Müller, whose biography was briefly given in No. 36 of *Science*. The income is to be applied to the support of his family during the life of his widow, and thereafter to aid students of the natural sciences educated at the public school of Lippstadt.

— Professor John LeConte has contributed a series of physical studies of Lake Tahoe to the recent numbers of the *Overland monthly* (San Francisco), in which he sums up what is known of the lake, and suggests lines of work for studious observers to follow. The greatest depth sounded was sixteen hundred and forty-five feet, and the lowest temperature found was at the bottom, 39°.2 F. Like most deep lakes, this one does not freeze, because the winters are not long or strong enough to reduce its entire volume to a cold below this temperature of maximum density. The transparency and color of the water are discussed at length, and an abstract of the recent Swiss studies of lake-oscillations, or *seiches*, is given; as there is every reason to suppose they must occur in our lakes, although not yet recognized here. According to the most reasonable estimates of mean depth, the duration of the longitudinal *seiche* of Lake Tahoe, calculated by Forel's formula, would be eighteen or nineteen minutes; and of the transverse, about thirteen minutes. The lake-basin is regarded as a 'plication hollow' or trough produced between two adjacent and parallel mountain ranges.

— E. and F. N. Spon announce as in preparation 'A history of electricity and of the electric telegraph,' by J. J. Fahie.

— Messrs. Barry, an old wine and coffee firm of London, have since the middle of the last century kept a scale for the amusement of their customers. The results of the weighings have been regularly entered in books kept for the purpose, together with the ages and any remarks called for by the clothing or other condition of the person weighed. Francis Galton, in his search for statistical information of the progress of man, has examined these records, and published a notice of the results in *Nature* for Jan. 17. The weights of the nobility he especially studied, and they show that the variation in weight of this class during the year has steadily declined in the past hundred years from seven to five pounds. Not only is there this evidence of a more regular and healthy life, but the age of greatest weight, which, with the generation from 1740 to 1769, was reached at forty-five, being at that age about sixteen pounds more than the weight of the 1800–1829 generation at the same age. While from that age the entire generation declined in weight, the tables show that the English nobility born in the early part of this century continued to increase in weight till at least their seventieth year; at their sixty-second year reaching that of their grandparents of the same age, who had been growing lighter for nearly twenty years, the later generation rising in weight at almost the same rate at which the earlier declined. The men of the last century seemed to grow stout in early manhood, then to fall off, while those of the present increase steadily with their age.

— Prof. G. Seguenza continues his studies of the quaternary formation of Rizzolo. His last contribution is devoted to the Ostracoda, and comprises about thirty-two pages quarto, with an excellent plate. About thirty-five species are mentioned, and more are to follow. Ten species are well figured. These often elegantly ornamented little creatures have an enormous range; some of these Sicilian fossils being common to Norway, New Zealand, and Sicily, either living or fossil. A number of new species are described.

— Late signatures of the Proceedings of the U. S. national museum contain a catalogue of mollusca and echinodermata dredged on the coast of Labrador by the expedition under the direction of Mr. W. A. Stearns in 1882. This list, which is carefully annotated, covers eleven pages, is illustrated by a plate, and is more complete than any thing hitherto published. It is due to Miss Katherine J. Bush of New Haven. This, and another paper by Rosa Smith in the same issue, would seem to indicate, that at last, if somewhat tardily, women are about to claim their share of work and honors by serious zoölogical investigations.

— Herr R. J. Runeberg, who has been examining the Angara River between Yeniseisk and Irkutsk at the request of Sibiriakoff, has returned to St. Petersburg. He reports that the rapids which obstruct navigation on the upper part of the Angara may be easily removed so as to admit of regular traffic on this important Siberian waterway.

— In a lecture by the Russian academician, Fr. Schmidt, on the Vega voyage, the author sees strong reasons for doubting the sanguine view of Nordenskiöld, that commerce may generally or even frequently find a waterway along the coasts of the Siberian Sea. He recalls, among other evidence, the experience of Rakhmanin, who wintered twice at Spitzbergen, and not less than twenty-six times in Novaia Zemlaia, and who found the way to the Yenisei open on only five occasions.

— A society of natural history has been organized at Sedalia, Mo.; and an address by F. A. Sampson, indicating the objects specially in view, was printed in the Sedalia *Daily democrat* of Feb. 13.

—In 1835 the British House of Commons ordered an inquiry for the purpose of ascertaining "the best means of extending a knowledge of the arts and of the principles of design among the people, especially the manufacturing population of the country." The immediate outcome of the inquiry was a school of design, which began its existence in June, 1837, with an appropriation of fifteen hundred pounds. From this has developed 'The science and art department,' which was formally created in 1856, and has now under its control some twelve different institutions, of which the most noted are the South Kensington museum, the National art training school (transferred to South Kensington in 1856–57), and the Normal school of science and royal school of mines (re-organized as one institution in 1881). In addition to these schools, museums, etc., the department maintains a system of instruction in science and art that extends over the United Kingdom, and in 1882 embraced 977,797 pupils, of whom 68,581 attended science schools and classes, and 909,216 received instruction in art. These numbers do not include the attendants upon the lectures given under the auspices of the department, amounting, during the year, to 8,288.

The appropriation for the year ending March 31, 1883, was £351,400, while the department disbursed during the same time £345,363 14*s.* 7*d.* The grants for building are not included in these estimates, as they pass through Her Majesty's office of works. It will readily be seen that the scheme of instruction and examination maintained by the department has a powerful effect upon the development of science, pure and applied. While it was the only important agent concerned in the work, its dicta passed without opposition: now that other institutions have taken up the service, particularly the City and guilds of London institute, the methods of the department are closely scrutinized, and not a little adverse criticism is heard. On account of the system of examinations and grants, elementary teachers are particularly watchful; and this year they have been very pronounced in their complaints. It is urged by them that the papers set for elementary pupils are impracticable and unfair, betraying total ignorance of the capacity and condition of the class of pupils to be tested. As a result of the wide-spread dissatisfaction, a union of teachers of science and art was effected last June, whose objects are, 1°, the advancement of the profession; 2°, the redress of grievances.

The presidency of this association for a year has been accepted by Professor Huxley, who, perhaps, of all English scientific men, is best fitted to give counsel on the educational aspects. As science examiner and president of the Normal school of science and royal school of mines, Professor Huxley has every advantage for understanding the aims and motives of the department; while his relations with the City and guilds institute and with the Royal society, of which he is president, preclude the possibility of narrow views.

Nothing is more freely conceded in England at this time than the importance of sound instruction in science. The efforts recently made, through the Royal commission, to ascertain the provision for this work upon the continent, have been noted in this country. It is not, perhaps, so generally known, that the English authorities attach great importance to what we are accomplishing in the same direction. It has been repeatedly stated that America surpasses England in this respect. In a public address last November, Dr. Kerr, her Majesty's senior inspector of schools, after an account of the leading institutions of Germany which he had just visited, added, that he believed the finest science school of the world was at St. Louis, America. In his address, Dec. 10, on the occasion of the distribution of prizes to the students of Finsbury technical college, Professor Huxley called attention to the fact that on the American side of the Atlantic there was a people of the same stock, blood, race, and power, as the English, who would run them harder than any competitors had hitherto done.

We were indeed earlier than the English in making provision for the new demands in modern education. The Rensselaer polytechnic school dates back eleven years from the House of Commons' inquiry; and out of eighty-six schools of science, tabulated in the last report of the commissioner of education, twenty-two were organized prior to 1862, the date of the much-abused land-grant. The state appropriations to these institutions for the year are estimated at $298,919, a small proportion of their total expense. The lecture-system maintained by the British department of science and art is a feature that may be studied with profit in this country.

— The subject of the preparation of catalogues of the meteorological literature of different countries was discussed by the meteorological congress of Rome in 1879, and has been repeatedly considered in the sessions of the international committee. At the last meeting, held in Copenhagen in 1882, it was decided that "the prospects of the preparation of a general catalogue of meteorological bibliography were not favorable to its execution, and that the only action for the committee to take was to invite the heads of the different institutes to prepare catalogues of the meteorological literature of their respective countries." The first publication to appear, in accordance with this decision, is the work of Dr. Hellmann. This deserves more than a passing notice, on account of its special merit, as well as the peculiar characteristics which make it much more than a simple catalogue of scientific papers and observations. It is limited to the country of Germany, and treats of the work of the Germans in meteorology from the earliest times to the year 1881. The greater part, containing seven hundred and forty-four pages, is devoted to a list of the scientific papers, arranged, first, according to authors and institutions, and, second, according to subjects. In the former division, which includes the names of about thirty-four hundred persons and eighty-three hundred memoirs, a valuable characteristic is the condensed biographical sketch of each author, usually but a few lines in length. The latter division is of special value to those who wish to know what has been done in special subjects of investigation.

The second part, of a hundred and twenty-three pages, is devoted to meteorological observations, and contains indices arranged according to stations, countries, and observers. The third part is historical, and contains an outline of the history of meteorological observations in Germany to the present time, followed by chronological and statistical tables.

It need not be said that the work of Dr. Hellmann is of great value, and will be a useful work of reference for students. It is somewhat of a disappointment, however, to find that the work is strictly confined to Germany and German authors, instead of including all meteorological writers who make use of the German language. On account of this limitation, Austria is not represented, though the part borne by that country in meteorological work of a high order is to-day so prominent. A similar catalogue for the latter country is needed to supplement the work of Hellmann.

— The New Hebrides, discovered by Quiros, and explored by Bougainville and by Cook, remained neglected until the failure of sandal-wood in China; and the need of laborers in the cotton plantations of Australia and Fiji, brought them again into notice. Mr. Roberjot relates, in the *Bulletin* of the French geographical society, the story of a visit to these islands in the French vessel le Segond. Of the natives of Tanna the writer says, 'As were the natives of this island in the days of Forster and Cook, such are they to-day.' Their dress is a cincture only, arranged in clumsy fashion. On the island of Sandwich is a novel fashion of exhibiting wealth. The houses in a palisade face the centre of the space, which is ornamented with posts, whereon hang dried hogs' jaws. Now, as wealth there consists in the abundance of swine, there is some vanity in showing how many one has eaten. The houses on this island are much better than those on the neighboring islands. Moreover, a certain number of constructions appear to serve the purpose of meetings or of storing provisions. A little distance from the houses were many trunks of trees planted in the earth. Each one of them has at its upper extremity two holes communicating, and their surfaces are ornamented with carved devices. Each of these trunks is a veritable instrument, and their union forms an orchestra. The report of Mr. Roberjot is full of interesting information, and several short vocabularies are given.

— Dr. Daniel G. Brinton has published, in the *Folk-lore journal* for August last, a paper on the folk-lore of Yucatan, founded on unpublished material which has fallen into his hands. A very interesting fact brought out by the author is the curious mixture of the old paganism with christianity. In the language of Garcia, with reference to the conversion of the natives, 'the only difference was, that the natives were changed from pagan idolaters to christian idolaters.' The ancient imposing rituals have passed away; but the belief in sorcerers, witchcraft, and magic is as strong as it ever was. These wise men divine with a rock-crystal, and have great influence over growing crops. The four cardinal points are named after the sacred four (*pah-ah-tun*) of the ancient religion, and also after four saints of the catholic calendar. These points of the compass are also the seats of the winds, and are denoted by separate colors. There still continue to be relics of an ancient form of fire-worship. Another of the modern ceremonies which is imbued with the notions common to primitive peoples is the 'feast of the food of the soul.' Along with these there are many minor superstitions connected with the growth of crops and fruits. Men and women are alike possessed of this magical power, which fact is confirmed by a witch-story recited by Berendt.

To the Maya, the woods, the air, and the darkness are filled with mysterious beings, who are ever ready to do him injury or service. Among these beings, the most familiar friendly spirits are the *Balams*. They are great smokers, and the shooting-stars are supposed to be huge cigar-stumps thrown by them down the sky. Another spirit is *Che Vinic*, 'the man of the woods,' a huge fellow without bones. Another ugly customer is *Culcalkin*, 'the priest without a neck.' There are also dwarfs and imps to worry the poor Maya, the most common among whom are the *H'lox*, 'the strong clay images;' the *Chan Pal*, 'little boy;' the *X'bolon thoroch*, 'the feminine imp who magnifies the sound of the spindle;' *X tabai*, 'the (female) deceiver;' and *X Thoh Chaltun*, 'Miss Pound-the-stones.' Many superstitions cling around the animal world also, and the sorcerers often claim the power of changing themselves into some animal.

— The project of cutting the Perekop Isthmus, which unites the Krimea to the mainland, has been approved, and the chief question now under discussion is the best manner of obtaining the necessary funds for carrying on the work.

— The extensive collection of mammals obtained by Mr. J. C. Zeledon in Costa Rica has been forwarded to Messrs. Godman and Salvin in London, to be used in their work upon the *Biologia Centrali-Americani*.

— The treaty for settling the Russo-Persian frontier has been decided upon, and the work of settling certain doubtful points in regard to the boundary has been going on during the past season. The treaty recognizes Merv as Russian, and Kelati and Udiré as Persian territory, but remains subject to modification in minor details consequent upon the surveys now in progress.

— The nematods, trematods, and acanthocephali collected by Fedtschenko in Turkestan have been worked up by von Linstow. There were a hundred and nineteen alcoholic and forty-five microscopic preparations, representing ninety-seven species, of which thirty-six were new. There was one new genus, Aprocta. Forty-seven species are known from other parts of the world, five being cosmopolitan, and fourteen known in America, Europe, and Asia. Of these last, eleven infest man or domestic animals: hence their distribution is probably artificial. With our present imperfect knowledge, it is impossible to study the geographical distribution of helminths.

SCIENCE.

FRIDAY, MARCH 7, 1884.

COMMENT AND CRITICISM.

In the rapid progress which animal morphology has been making in this country during the past few years, we doubt whether the vertebrates have had their due share of attention. With the exception of Cornell, we believe that the larger laboratories are turning their students principally to investigation among the invertebrates, — among this class, Cambridge and Baltimore. We do not for a moment under-estimate the immense value of this work, or the high standard it has attained; but are we not slighting the rare opportunities the United States afford for vertebrate research, and allowing it to be done by foreigners? To illustrate by a few examples out of many. In embryology the alligator and the urodele amphibia present the most important field of work. As regards the former, Professor Kitchen Parker of London has just completed a monograph upon the development of the skull, principally based upon American material. As regards the latter, is it not surprising, that, with an abundance of living specimens at ready command, the best work upon the angiology of the group is coming from Boas in Denmark; and upon the anatomy and embryology, from Wiedersheim and others in German laboratories; while here we have only to show a few current researches upon the neurology? Our large avian fauna invites the kind of systematic anatomical work which the late W. A. Forbes, and his predecessor as prosector, A. H. Garrod, undertook in the London zoölogical gardens. But there is another quarter where the harvest is still greater and the laborers fewer; that is, vertebrate paleontology. We can count upon the fingers of one hand the investigators in this magnificent field; yet there is enough work for several lifetimes in the fossils already exhumed, without mention of those which lie waiting the collecting-sack of the explorer.

However just "Professor Rowland's vigorous denunciation of American science text-books" may be in respect to the sciences with which he is conversant, it need not be forgotten that in at least three departments of natural history this country has been seasonably provided, by its most competent hands, with text-books, which, for their purpose and scope, have not been surpassed in any other part of the world. It is a remarkable fact that two of them, Dana's Mineralogy and his Geology, are from the same hand.

The suggestions regarding the preservation of our few important aboriginal monuments, made by the curator of the Peabody museum to its trustees at their recent annual meeting, is one that should excite general interest and attention. These monuments are fast disappearing under the plough and harrow, and many are further endangered by the growth of population in their neighborhood. As a rule, the land about them could be purchased of their present owners for comparatively small sums; and trusty keepers could be installed at no expense beyond the free lease of the reserves, with liberty to till such outlying portions as could do no harm to the monuments.

It would be eminently proper for the states in which these monuments exist to take efficient action for the preservation of the most important; but, if the states are likely to delay in the movement, the townships or local societies should at once secure the works from further destruction. These failing in immediate action, why cannot an association be formed for the purchase and care of ancient monuments; the association to hold them, until, by legislative action, each state shall take those within its borders under perpetual care? or perhaps it would prove the speediest and most satisfactory method of all, if persons specially interested in the preservation of certain of them

would combine to purchase the sites, and transfer the custody of the same to the trustees of the Peabody museum at Cambridge, which, as the only institution in the country specially devoted to American archeology, would be a fitting and safe almoner of such a trust.

A FEW months ago a piece of vandalism which shocked the scientific and artistic worlds was perpetrated in Munich. Some fiend took it into his head to disfigure the beautiful new marble statue of Liebig by staining it with a dark liquid. It was at first thought that it would be impossible to remove the stains, as they were found to have affected the marble to some depth beneath the surface. A commission of chemists, consisting of Professors von Pettenkopper and Baeyer, Liebig's successor, and Dr. Zimmermann, was appointed to investigate the matter, with a view to determine the nature of the stains, and to remove them if possible. It was found that nitrate of silver had been used, with which some permanganate of potassium had probably been mixed. It is gratifying to learn that the work of the commission has been entirely successful, the stains having been completely removed without injury of any kind to the statue. The method used consisted in transforming the metals, silver and manganese, into the sulphides by treating the spots with sulphide of ammonium, and then with cyanide of potassium. The chemicals were used in the form of pastes, made by mixing them with finely-powdered porcelain-clay.

GEN. TENNANT has recently called attention to a possible cause of variation in the rates of chronometers, which has never before been considered; namely, the humidity of the air. The subject is well worthy of investigation; and it is to be hoped that those interested in determining the rates of chronometers will also make observations on the humidity of the air around the chronometer, in order to determine whether any such effect is really produced. Gen. Tennant's results are not presented in such a form that a positive conclusion can be reached.

THE appointment of Professor Flower to succeed Sir Richard Owen as superintendent of the natural-history department of the British museum is as gratifying to American naturalists as it is to the majority of those in England. The removal of this section of the museum to the new building, South Kensington, will, of course, sever it still further from the control of the chief librarian, who is technically the head of the entire organization; while the new policy of making it an educational museum, as well as a museum of research and record, adds much to the responsibilities of its officers. Professor Owen, having brought his career as an active investigator to a wonderfully satisfactory conclusion, is glad to be relieved of administrative duties, and to retire to his country home near Richmond, to devote his few remaining years to quiet study. Professor Flower, who succeeded him as conservator of the museum of the Royal college of surgeons, has demonstrated in that capacity his ability as a museum director. His work as an investigator has been extensive and important; and there is no naturalist in England who is more deservedly popular, or who could command a more unanimous support among his fellow-workers. Seconded, as he is, by three such experienced assistants, — Dr. Gunther, keeper of the zoölogical collections; Dr. Woodward, keeper of the geological collections; and Dr. Carruthers, keeper of the botanical collections, — there can be no doubt that Professor Flower will be able to add very much to the efficiency of what is already the most extensive natural-history museum in existence.

WE referred, a few weeks since, to the favorable opportunity now afforded for observations upon Saturn. At the January meeting of the Royal astronomical society of London, there was an interesting discussion upon the markings upon the planet observed by Mr. Pratt of Brighton, and other members of the society. The planet was described as having on each side of its equator a zone of creamy tint, unusually free from markings. At about latitude 10° south, there was a strong narrow belt sharp-

ly defined on its equatorial side, diffused upon its polar side, and gathered in places into wispy notches and curved markings. The color was a vandyke brown. Several other belts of different tints were interposed between this one and the pole. Other observers mention the existence of loops somewhat resembling the markings on Jupiter. The planet is now too far past its opposition to be well observed during the present season; but the opposition of December next will be yet more favorable for observations, and will, we hope, be taken advantage of by all possessors of telescopes.

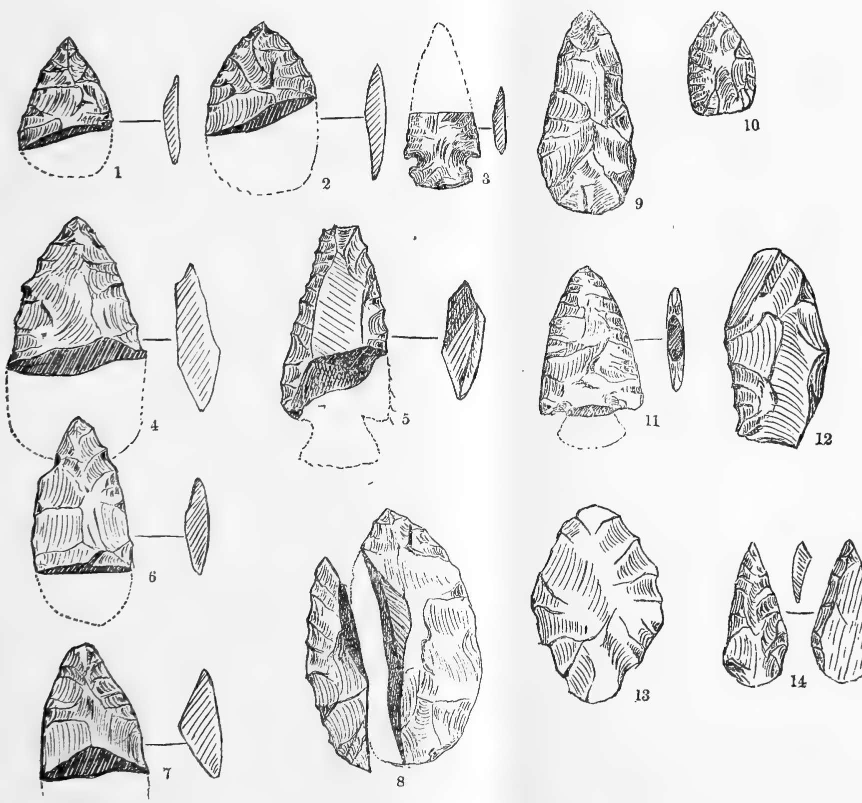
Arrow-points at Evanston, Ill.

In the sand-ridge at Evanston, just back from the beach, and which follows the shore more or less continuously for a number of miles south, there are exposed intervals where the frequent violence of the lake-winds does not permit the usual growth of vegetation. These places are often scattered with flint-chippings for an area of several square yards, marking spots where formerly stone implements were chipped. The very fresh appearance of the chippings upon the surface at this remote day, as if just dropped there, is accounted for by the sweeping of the wind from the exposed quarter over such localities, winnowing the particles of sand from the heavier flint. The chippings scattered in the light soil around the operator, while he fashioned the implements, remain at the original site; but, as the sand is gradually blown away, they appear at a lower level than before, and strewed over the hard, smooth surface which the wind has left.

In protected places, on the other hand, where the blowing sand accumulates in drifts, chippings, instead of being exposed, have been covered to a considerable depth, as excavations in the vicinity often show.

The mineral used was in all cases a reddish chert of various shades, found abundantly in the shape of rounded stones upon the beach. The chippings are irregular flakes, amounting in certain localities to what might readily fill a bushel basket; and search nearly always reveals some broken and unfinished arrow-points of the same mineral. The successive stages occur, from the rough chert flake to the completed implement; the most common being simply a half-arrow point, presenting a fracture across the shorter diameter: more rarely, specimens show a longitudinal fracture. The abundance of specimens indicates that occasionally, after an implement had assumed nearly the desired shape, an unskilful stroke split it; and the pieces were allowed to fall with the



waste chips. Nos. 1–8 and 11 are such supposable instances. Both parts of No. 8 were picked up. Few entire or finished implements occur, as they would not be left in these places unless lost. Nos. 9 and 10 are complete; Nos. 12–14, roughly chipped and supposably unfinished.

Proximity to the supply of chert has doubtless determined this common occurrence of chippings in the sandy stretches near the lake. There is no evidence at hand of greater antiquity than the Indian.

Illusive memory.

For some time past, I have been investigating a curious psychical or psycho-pathological experience which is alluded to by many writers upon psychology, and is not infrequently met with in general literature. It is that vague sentiment of familiarity we sometimes have upon entering a new experience, best expressed in the words, 'I have seen or known all this before.' It has been explained by various writers, upon two widely different theories. The first is, that this 'double perception,' 'double thinking,' 'double presentation,' as it has been variously named, arises from the dual structure of the brain, resulting in cases of imperfectly correlated action in two images or impressions not absolutely simultaneous: the latter, therefore, is a repetition of the former, and gives rise to a sentiment that it has passed through the mind at some indefinite previous time. This theory, it will be observed, is a physiological one. The other theory is, that the phenomenon is a purely psychical one; that the false or illusory memory (Erinnerungstäuschung, Sander) has a real basis in some actual past presentation which is identical, or closely similar, with the present one; or in some past images of the waking imagination, or dream-life, that, although these cannot be recalled into consciousness, they are sufficient to give us the conviction that the present event is the repetition of a former one — why, or how, we do not know. There are several cases upon record, where this sentiment has assumed a pathological character, and become a continual delusion, attending every experience.

Two years ago, in the hope of obtaining more information, I distributed a question upon the subject among a large number of persons, principally college-students. It may now be given in somewhat amplified form, as follows: —

Have you come suddenly upon an entirely new scene, and, while certain of its novelty, felt inwardly that you had seen it before — with a conviction that you were revisiting a dimly familiar locality? Mention, if you can, an instance or two in which this has occurred. Has any satisfactory explanation of this experience ever suggested itself to you? How frequent is the experience in your case? Was it more frequent in childhood than at present? How soon do you usually become conscious of the deception? Does it occur more frequently in connection with some kinds of experience than with others?

A quantity of material upon this subject has already been collected in this and other ways, which I hope to publish in a review article in April. In the mean while, any information bearing upon this question will be of great assistance and value to me.

HENRY F. OSBORN.

Princeton, N.Y., Feb. 23.

Ripple-marks in limestone.

The alternating limestones, shales, and sandstones of the upper coal-measures of Kansas are well exposed along the ridges and water-courses near Eureka. Some of the limestone is thin-bedded, apparently due to interlaminated sheets of argillaceous material. The layers of limestone, however, seem to contain little foreign matter, certainly not more than the Trenton limestones (Buff) of Wisconsin and Minnesota. The organic remains consist largely of crinoid columns, shells of brachiopods and lamellibranchs, and a few gastropod shells and cup corals. Nearly every layer of limestone shows these remains in great abundance firmly bound together by the highly crystalline matrix.

I have been thus particular in describing the limestone, that the conditions which made the following feature possible may be understood. Some six or eight slabs of this limestone in one of our sidewalks are clearly and distinctly ripple-marked. This is the first instance of the kind that has fallen under my observation during ten years of state and private work in nearly as many states of the Union.

The occurrence of ripple-marks in calcareous mud containing the remains of deep-sea, clear-water animals, and interlaminated with argillaceous mud, is a combination not quite in accordance with the teachings of our text-books in geology.

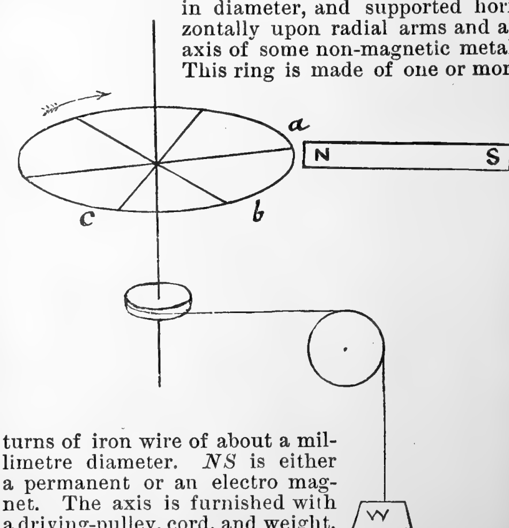
Eureka, Kan., Feb. 23.

A novel magnetic engine.

It is a well-known fact that iron, when heated to a red heat, ceases to be magnetic; so that an armature, after being heated to redness, may be removed from its magnet by the expenditure of only a small fraction of the energy which is developed by the attraction of the same armature when it has cooled.

Manifestly this fact might be employed in the construction of a motor, which, while of no practical value, is of theoretical interest, in which a permanent magnet should act as the direct motive force. This has been done in the following manner. In the figure, *a b c* represents a ring thirteen centimetres in diameter, and supported horizontally upon radial arms and an axis of some non-magnetic metal. This ring is made of one or more



turns of iron wire of about a millimetre diameter. *NS* is either a permanent or an electro magnet. The axis is furnished with a driving-pulley, cord, and weight, as shown in the figure.

That part of the ring which lies between *a* and *c* is heated to bright redness by means of two or three Bunsen burners. The magnet then exerts a preponderating attraction upon the farther or cool side of the ring, and the latter revolves as indicated by the

arrow. As fast as the ring enters the space $a\,b\,c$, it becomes red-hot and non-magnetic, and a lack of equilibrium is thus maintained which results in a continuous rotation.

The motion is necessarily quite slow on account of the considerable time required to heat the iron ring. In the actual experiment, moreover, considerable difficulty was experienced from the distortion which the ring underwent when softened by the heat, in consequence of which the speed of rotation became very irregular. With a permanent steel magnet, a speed of about one revolution in two minutes was obtained; and with a powerful electro-magnet, a weight of six grams was raised fifty centimetres in six minutes, and, in a second experiment (the ring having become quite distorted), ninety centimetres in thirty minutes.

Of course, the source of energy is the Bunsen burners; and the experiment leads at once to the fact, that the specific heat of magnetized iron is greater than that of unmagnetized. CHAS. K. MCGEE.

Congenital deafness in animals.

The communication of Professor Bell in No. 54 of *Science*, in reference to Mr. Lawson Tait's statement that no other animals than cats are affected with congenital deafness, calls to my mind the fact, that in my early boyhood I had a dog which was thus afflicted. I got him when a puppy; and, so far as we could determine, he was never able to distinguish any sounds. He was of the breed usually known as 'fist,' and, so far as my memory serves me, was of a yellow color: certainly he was not pure white. What renders this instance the more interesting, is the further fact, that a playmate of mine also had a deaf dog. I think he was of the same family, but not, I believe, of the same litter. That congenital deafness should be rare among wild animals, I can readily understand, since, in the struggle for existence, their defect would lead to an early extinction; but under domestication, where their conditions approach more nearly to those of man, I can see no reason why a defect of physical organization should not be transmitted by inheritance, as I believe it to have been in the cases above cited. It is a fact well known to aurists, that in some families there is a tendency to become hard of hearing, or even deaf, at about the same age; owing, doubtless, to certain evolutions which take place in their physical structure at that time. SWAN M. BURNETT, M.D.

Washington, Feb. 22.

A singular optical phenomenon.

The windows of our office are provided with fly-screens having the ordinary mesh of something less than an eighth of an inch. Thirty feet across the way is a building whose windows are protected by a coarse screen having a mesh a little less than half an inch in size. Standing about ten feet back from and looking through the fly-screen at the coarse screen, an inverted, magnified image of the latter is seen in mid-air, between the observer and the fly-screen; the inversion, of course, being only detected by the apparent movement made by the image on changing the position of the eyes. The explanation of the phenomenon is not difficult. The lines of the coarse screen throw nominally a single ray of light, which is inverted through the particular mesh of the fly-screen directly in line with it and the observer. Any other substance, such as a paper wad introduced in the coarse screen, will not appear in the image. It may not be uninteresting to mention in this connection the fact, that while a short-sighted person, to whom I endeavored to show the same phenomenon in my home, using as an object the slats of a blind in a house a hundred and fifty feet away, was unable to see the actual slats, owing to their remoteness, their image was distinctly visible to her. F. J. S.

Deflective effect of the earth's rotation.

In a letter of mine, published in *Science*, ii. No. 26, I suggested that the deflecting force produced by the rotation of the earth on bodies moving on its surface is not wholly represented by the rotation of a tangent plane, but depends, in part, on the centrifugal force resulting from the body's relative motion in longitude, and is therefore greatest when the motion is perpendicular to the meridian.

That my suggestion is *not* true, and that the force is the *same* for all directions of the motion, may be demonstrated very simply, as follows: —

From the proposition announced in section 25 of Peirce's 'Analytical mechanics,' it follows that any tangent plane whose latitude is λ rotates about an axis normal to that plane with an angular velocity equal to ω cosec. λ, ω denoting the angular velocity of the earth about its polar axis.

Therefore if P represent the point where the normal axis pierces the surface of the sphere, and if a body be caused to move in any direction over the point P with a velocity v, it will, by the rotation of the tangent plane, be constrained to describe in space the spiral of Archimedes, whose equation is $u = a\theta$; and when $\theta = 2\pi$, $u = v$ multiplied by the time of one rotation of the tangent plane. Hence, if one hour be the unit of time, $u = 24\,v$ cosec. λ; and $\frac{1}{2}a$, = the radius of curvature at the origin of the spiral, $= 6\,v \div \pi \sin\lambda$.

Now, the deflecting force at P is equal to the centrifugal force due the velocity v at the origin of the spiral, which is represented by $v^2 \div \frac{1}{2}a$:

$$\therefore f = \tfrac{1}{6}\,v\,\pi \sin\lambda.$$

But the centrifugal force, $V^2 \div R$, due the rotation of the earth at the equator, is known to be $\frac{1}{289}mg$; mg denoting the weight of the body, and $V = \frac{1}{12}\pi R$:

$$\therefore f : \tfrac{1}{289}\,mg :: \tfrac{1}{6}\,v\,\pi \sin\lambda : V^2 \div R;$$

whence, substituting for V^2, we get,

$$f = \frac{\frac{1}{289}\,mg\;24\,v \sin\lambda}{\pi R}.$$

The centrifugal force resulting from the body's relative motion in longitude affects only the origin of the spiral, and not at all its elements, and hence has no influence on the value of f: consequently f is the total deflecting force, and is independent of the direction of the motion. J. E. HENDRICKS.

Des Moines, Io., Feb. 14.

A carboniferous genus of sharks still living.

I observe that in a late number of *Science*, Mr. Garman describes a new genus of sharks from the Japanese seas, under the name of Chlamydoselachus. The figure of the teeth which he gives shows the animal characterized by Mr. Garman to be a species of the genus Didymodus (Cope, Proceedings Philadelphia Academy, 1883, p. 108, equal to Diplodus Agass. Poiss. fossiles, pre-occupied in recent fishes), which has hitherto been supposed to be confined to the carboniferous and Permian periods. The species possess two, three, or four denticles. Material in my possession enables me to fix the position of this genus, which I will endeavor to explain in the next (April) number of the *American naturalist*. Didymodus

becomes by this discovery the oldest living type of vertebrata. E. D. COPE.

Philadelphia, Feb. 28.

Artificial production of rain.

I give below an instance which came under my own observation, of the artificial production of rain, which may be interesting, read in connection with the article in *Science*, No. 55.

Many years ago, during my residence in Virginia, the whole of the eastern portion of that state had been suffering one summer from a long-continued drought. For several months not enough rain had fallen at any one time to moisten the ground to the depth of half an inch. The atmosphere was gray, and full of dust. The sun, even at noonday, was 'shorn of his beams,' and could be looked at directly without paining the eyes. The temperature was not unusually high; but the weather was very oppressive, being what is called in the country, 'muggy.' One of my neighbors had several months before cut down, and left lying where it fell, a young forest of scrub pines from a field of about forty acres in extent. These pines had, of course, become, during the long drought, completely dry. One August morning, the meteorological conditions remaining exactly as they had been for months before, my neighbor caused fire to be set to this clearing at several points on the circumference at the same time. The fire ran over the whole tract with wonderful rapidity. An immense column of inky smoke rose perpendicularly (there was no wind) to a great height. Upon reaching a stratum of air of its own density, the black column spread out horizontally into the form of a gigantic mushroom, rapidly changed color from jet black to gray, and soon thunder was heard in the top of the ascending and spreading column. The fuel was gradually consumed, and the smoke ceased; but the cloud continued to spread, and rain began to fall in a little more than an hour from the time the clearing was fired.

The thunder gradually ceased; but rain continued to fall until sunset, when the sky cleared. For the remainder of the season, showers and rain-storms occurred with ordinary frequency, as if the conditions favorable to the continuance of the drought had been permanently broken up. Observations of temperature, the dew-point, and of the barometer, would have been valuable; but I had unfortunately no instruments at hand for obtaining them.

While the artificial production of rain can have no economical importance, — depending, as it necessarily must, upon many meteorological conditions, which, to be effectual, must be synchronous, — yet an example of a rainfall of several hours' duration, which was undoubtedly produced by an ascending column of heated air artificially supplied, seems worthy of record. L.

Annual growth of the 'Tree of heaven.'

I have in the cabinet of Cumberland university two remarkable shoots of Ailanthus glandulosus, Desf., a description of which may be of interest to botanists. They grew in a lot near one of the university buildings during the summer of 1883. They sprang from small stumps, and are entirely the growth of one season. They give the following measurements:—

No. 1. — Length, 10 feet 6 inches; circumference at base, 5.1 inches; circumference at middle, 4.13 inches.

No. 2. — Length, 11 feet 1.5 inches; circumference at base, 4.1 inches; circumference at middle, 3 inches.

J. I. D. HINDS.

Lebanon, Tenn.

GOUVERNEUR KEMBLE WARREN.

IN the death of Gen. Gouverneur Kemble Warren of the Corps of engineers, U.S. Army, the country has lost not only one of the ablest military leaders developed by the civil war, but also a scientific man of high attainments, whose life was devoted to profound investigations connected with several of the most important works of internal improvement undertaken by the general government.

He was born on Jan. 8, 1830, at the little village of Cold Spring, upon the Hudson, where his surroundings were all calculated to excite a love for the military service in the mind of an active and intelligent boy. West Point lay in plain sight from his home. The old field-works of the revolution, grass grown and crumbling, were associated with his earliest recollections; and the charm thrown by Washington Irving over this classic ground of American history entered into and stimulated his youthful imagination to ideas above the prosaic monotony of every-day life in the nineteenth century. The Mexican war added fuel to the flame; and at the early age of sixteen he sought and obtained an appointment as cadet at the Military academy. He was graduated in 1850 with very high class rank, and was at once assigned to the corps of topographical engineers.

The great problem then beginning to attract attention was the Pacific railroad. The recent discovery of gold in California, and the consequent rush of immigration to the west, demanded increased facilities for transit across the continent; but a broad belt of wilderness, intersected by lofty ranges of mountains, and almost unknown, barred the way. It was in this field that the young officer did his first important scientific work.

Congress made large appropriations for exploring several routes between the Mississippi River and the Pacific Ocean; and the work, under the direction of Gen. (then Capt.) Humphreys, was performed by officers of U.S. engineers. As usual in such cases, the results were expected at once; and Lieut. Warren, who had already shown his ability on the surveys of the Mississippi delta, was detailed as principal assistant in the general office at Washington.

His duties were twofold. He assisted Capt. Humphreys, then laboring under great pressure, in digesting the preliminary reports, in investigating the various problems connected with railroad transportation, in making the comparative estimates of cost, and in preparing

the general report. His labors were so valuable in this connection that his chief placed their names jointly on the titlepage of what was a very able document. In addition to this work, Lieut. Warren was specially charged with compiling a general map of the entire region covered by the surveys. This labor demanded powers of analysis of a high order. It was needful to thoroughly study the work of all explorers to date, and, by assigning proper weight to each, to combine the material, often conflicting and discordant, into one consistent and harmonious whole. This task Warren accomplished with surprising success, as has been proved by accurate surveys subsequently extended over much of the ground. His memoir and map, which appeared in the eleventh volume of the final quarto edition of the Pacific railroad reports, will remain a standard authority to geographers studying the early history of exploration in that region.

As might naturally be supposed, an ambitious young officer would not be satisfied with office-work alone, when laurels were to be won in a field involving no little hardship and risk from the semi-hostile Indian tribes which then roamed unsubdued over the vast plains west of the Mississippi. He sought and obtained direction of three separate explorations in Dakota and Nebraska, in the years 1855, 1856, and 1857; and, while thus collecting much valuable information needful for opening the country to civilization, he gratified his own strong passion for geological research, and laid the foundation for subsequent generalizations which have attracted the attention of men eminent in that special branch.

Space forbids any notice of Gen. Warren's war record here. Suffice it to say, that, entering the volunteer service among the very first of the officers of the regular army (on May 14, 1861), in two years and three months he fought his way from the grade of lieutenant-colonel to that of major-general commanding an army corps. He was present at all the great battles of the army of the Potomac, and was justly regarded as one of the best generals and most gallant officers made known by the war. He was twice wounded in battle, and had several horses shot under him.

Immediately after the fighting ceased, he returned to duty as major in the Corps of engineers, and soon began to perform an amount of labor in the civil branches of his profession which would have broken down a man of less nervous energy. To simply enumerate the various works with which he was charged between the

end of the war and the date of his death on Aug. 8, 1882, would extend this notice beyond reasonable limits. They can only be classified and briefly explained.

As an expert in railroad-engineering, Gen. Warren served on three different commissions to inspect and report upon the construction of the Union Pacific and Central Pacific roads and their branches, and to indicate their proper point of junction.

His military experience caused him to be selected to make the detailed surveys of the battle-field of Gettysburg, and of the vicinity of Groveton, Va., in connection with the Fitz-John Porter investigation.

As an hydraulic engineer, his labors covered several of the most important works in the United States, and gave him great eminence. He was a member of the board to report upon the Fort St. Philip canal project, and was president of the commission of engineers appointed by special act of Congress to report upon the best method of protecting the alluvial region of the Mississippi against overflow. He conducted a very elaborate survey and investigation with a view to improve the navigation of the Fox and Wisconsin rivers; and his report, a model of excellence, has borne the test of practical trial subsequently applied. His surveys and reports upon the improvement of the upper Mississippi and of the Minnesota River are also of standard authority. His name is identified with the improvement of the Connecticut River, and with various harbor improvements upon the coast of Massachusetts, Rhode Island, and Connecticut; and his labors in hydraulic engineering at other special localities are too numerous to mention.

Gen. Warren also contributed much to the subject of bridge-construction. The Rock Island bridge was built essentially upon his plans and specifications; and his services upon boards ordered to report upon bridges projected or constructed at many important localities involved great labor and research. His reputation in this branch of engineering, however, will chiefly rest upon his monograph upon bridging the Mississippi River between St. Paul and St. Louis. This work was unique in character. The investigation was ordered by Congress to collect data for harmonizing the conflicting interests of navigation and of railroad transportation; and the subject was treated exhaustively, not only from an engineering, but also from a legal point of view. The investigations extended over a period of more than eleven years; and the report is a standard authority to be consulted in any future bridge-projects over navigable western waters.

Gen. Warren's natural fondness for geological research has already been mentioned. His extensive explorations in Dakota and Nebraska; his numerous surveys for determining the topographical features of the valleys of many rivers in Minnesota, Wisconsin, Iowa, and Illinois; his investigations in respect to foundations for bridges in this district; and his thorough familiarity with all the geological and topographical reports upon this vast region, and north of it in British America, — enabled him to frame an hypothesis as to geological changes that have occurred, and are now occurring there, which is both novel and brilliant. He first announced it in a paper read at the Chicago meeting of the American association for the advancement of science in 1868, and subsequently elaborated it in his report upon the Minnesota River and in that upon bridging the Mississippi.

Very briefly outlined, it is the following. Lake Winnipeg formerly covered much more space than at present, and extended southward to the head of the Minnesota valley, through which it drained, thus forming the source of the Mississippi. The present outlet to Hudson Bay (Nelson River) did not then exist. The change of drainage has been effected by an elevation of the southern, and a subsidence of the northern, portions of the continent, which have been in slow progress for a vast period of time. When this change began, it caused a decreasing river-slope in the northern portions, and a diminishing power to erode. The resistance due to the granite ledges extending over a hundred miles below Big Stone Lake, in the bed of the upper Minnesota, checked further erosion there, and formed a growing lake above it, which finally found a new outlet to Hudson Bay through the loose drift near Nelson River. This was rapidly eroded, thus reducing the old lake-surface to the present level of Lake Winnipeg, which is about three hundred and sixty feet below the present sources of Minnesota River. Like changes, due to the same cause, by which Lake Michigan has been cut off from the Illinois River, and Lake Winnebago from the Wisconsin River, may be traced.

Gen. Warren discussed this hypothesis in detail, and showed, by so many facts as almost to amount to a demonstration, that, since the glacial epoch, two secular oscillations of this character have occurred in this region. The reasoning is masterly, and illustrates both his breadth of conception, and his care to conclude no farther than the facts warrant.

Although modest and retiring to a fault, the

earnest scientific work which he had done and was doing was appreciated; and in 1876 he was elected a member of the National academy of sciences. He had long been a member of other learned societies, and was widely known and respected among scientific men.

In person, Gen. Warren was of medium height, and slightly built. His mind was intensely active. Nervous in temperament, and sometimes irritated at trifling annoyances, he became instantly cool and self-poised in times of real danger or difficulty. In close logical reasoning he had few superiors. His mental habits were those of an investigator, — never satisfied until he had studied the matter in hand in all its bearings; but in action he was impetuous, indomitable, and gallant in the extreme. His reading was extensive, both in science and literature, — due largely to his habit of seeking mental rest by working in a new direction. His sense of humor was keen, and his conversation was often brilliant as well as instructive. In disposition he was kindly and sympathetic, and he never failed to give others full credit for whatever good work they had done. He loved justice for its own sake; and the natural tendency of his mind was always to assist the weak, and to strive to redress wrongs wherever found. These traits of character endeared him to his friends; and his memory is cherished with mingled feelings of respect and regard, not easy to express.

HENRY L. ABBOT.

APPENDAGES OF THE TRILOBITE.

THROUGH the kindness of Mr. D. A. McCord, the owner of the trilobite described by Professor John Mickleborough (*Cinc. journ. nat. hist.*, vi. 200, 1883), I have had an opportunity to study the original specimen, and prepare a few notes upon it.

When received, the specimens — i.e., matrix and relief — were not free from the grease and dirt acquired in the process of taking casts and frequent handling. On giving them a thorough washing in a solution of potash, this was removed, and also a thin film of decomposed rock on the parts beneath the pygidium. Turning to the laboratory window, to have the sunlight strike across the specimens while still wet, much to my surprise, the appendages shown beneath the pygidium were seen to be of the same character as those beneath the thorax, a number showing in some instances two and three joints attached to the basal joint. On a more careful examination, numerous fine slender filaments were discovered, both beneath the thorax and pygidium, and also near the posterior end of the latter slender jointed appendages not half a millimetre in diameter. Having cut up over two thousand trilobites without discovering any 'branchigerous' appendages beneath the pygidium, other than the spiral and ribbon-like branchial filaments, — such as were attached to the basal joints of the thoracic legs, — naturalists can appreciate the feeling of satisfaction that the discovery of these jointed appendages, so much like those found in cutting sections of Ceraurus and Calymene, gave the writer.

The breaking-apart of the surfaces carrying the legs and their matrix left the legs beneath the thorax in relief; but beneath the pygidium the joints were broken longitudinally, and only a plain outline section is seen. It is probably owing to this that these were overlooked by Professor Mickleborough, and the space beneath the pygidium considered as showing leaf-like or foliaceous appendages. For the purpose of clearly indicating the actual relations of the portion of the Ohio trilobite showing the legs, to the entire dorsal shell of the same species, a figure of the under side of the shell was outlined; and then the Ohio specimen was carefully drawn as if resting in it, as shown in fig. 1. In the specimens, some of the appendages are shown more distinctly in the matrix, and others in the relief. In the drawing, the two are combined so as to give, without restoration, what is actually present in the specimens. Twenty-six pairs of appendages are clearly discernible. Of these, nine are situated beneath the thorax, one beneath the posterior margin of the head, and sixteen beneath the pygidium. From the character of the appendages beneath the thorax, none of them appear to have belonged to the manducatory apparatus; the ninth posterior pair having been crowded forward from beneath the pygidium. The anterior pair beneath the head is very imperfect; but sufficient remains to show that these appendages were intimately associated with the cavity of the head, which is now filled with calcite, and they probably represent a portion of the posterior pair of manducatory appendages. In Calymene senaria and Ceraurus pleurexanthemus, the posterior pair of manducatory appendages are always provided with a large basal joint, and undoubtedly the same was the case with other genera of trilobites. The appendages beneath the pygidium are, however, of the greatest interest. I have seen many trilobites, when cutting sections, that had the cephalic and thoracic legs clearly and distinctly defined; but, owing to the small size of the pygidium of Calymene

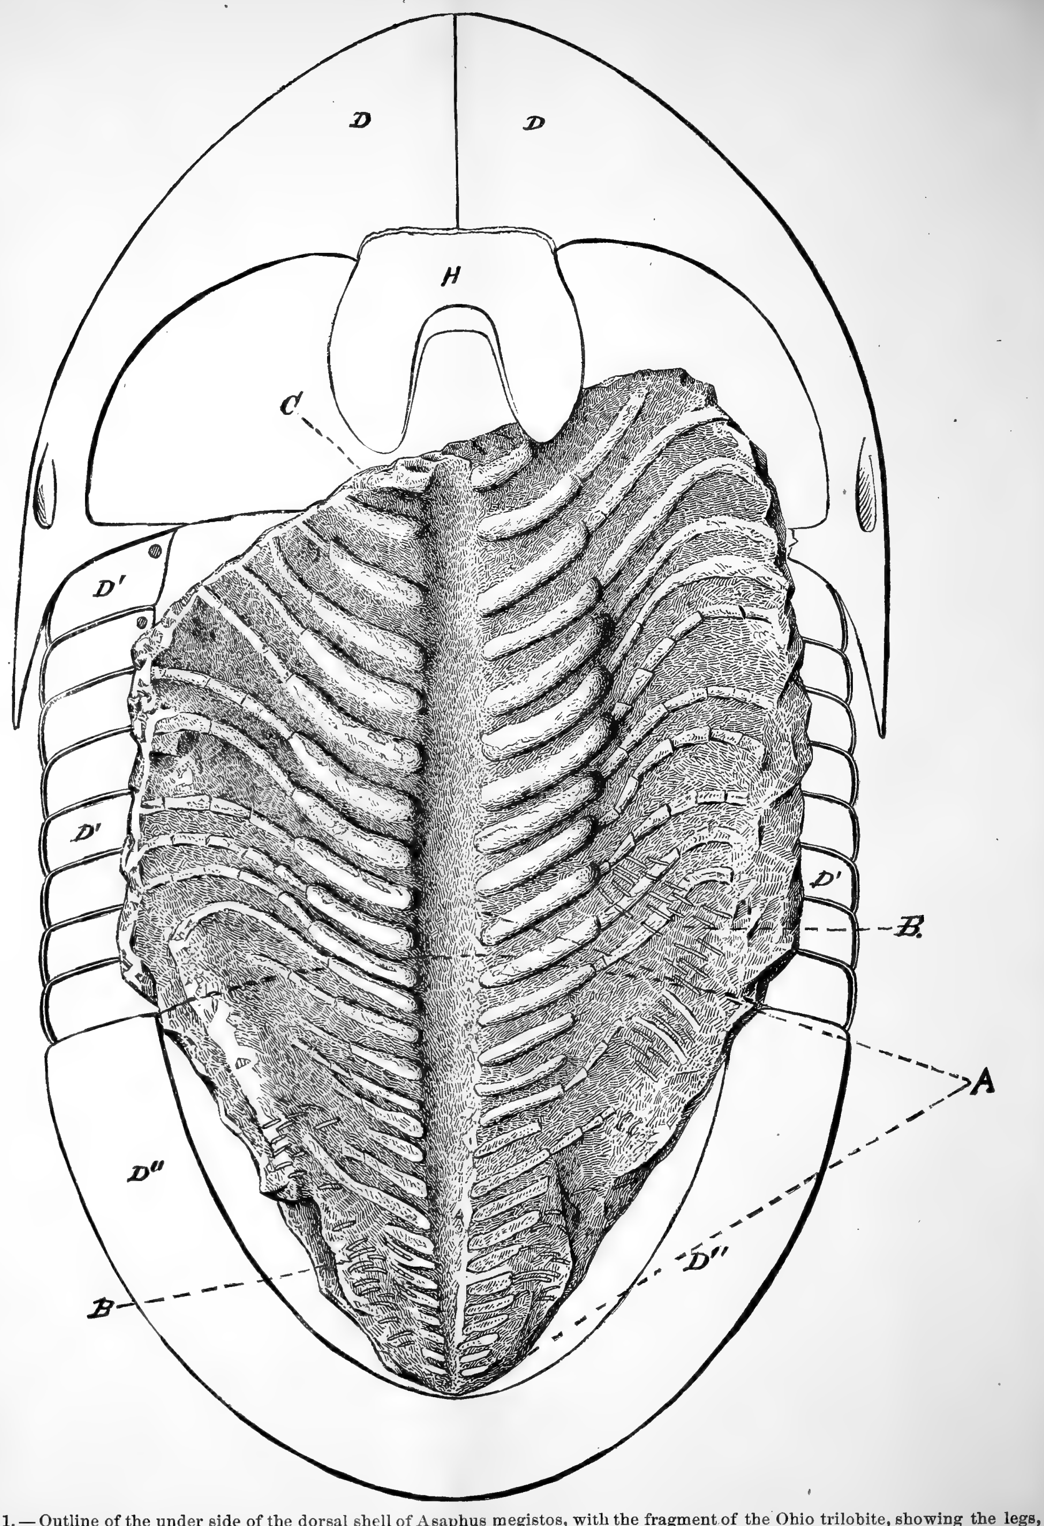

FIG. 1. — Outline of the under side of the dorsal shell of Asaphus megistos, with the fragment of the Ohio trilobite, showing the legs, resting in it. *H*, hypostoma; *D*, doublure or infolded margin of the dorsal shell; *D'*, same of the thoracic segments; *D''*, same of pygidium; *C*, portion of posterior pair of cephalic appendages; *A*, abdominal appendages; *B*, branchial filaments. The latter are enlarged to show their position.

and Ceraurus, there was always some doubt about the number of appendages that were to be assigned to the pygidium. That they were jointed and not foliaceous appendages, I had no doubt, and so stated it in the text,[1] and also in the restoration, of which fig. 2 is a copy.

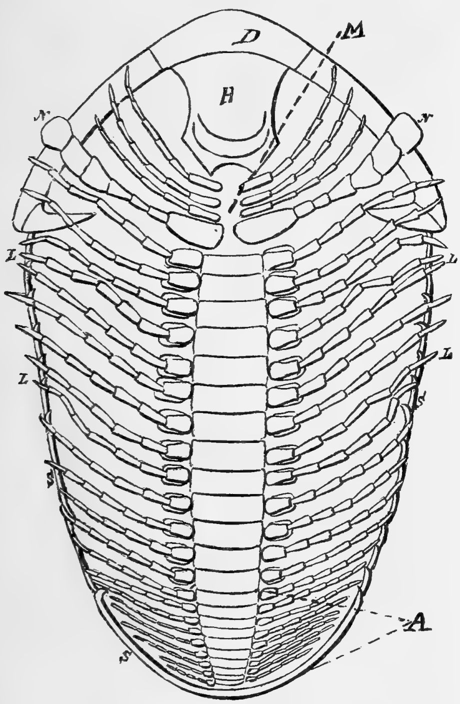

Fig. 2.—Under side of Calymene senaria as figured in *Bull. mus. comp. zoöl.*, vol. viii. pl. vi., 1881. *H*, hypostoma; *M*, mouth; *A*, abdominal appendages.

The leg beneath the thorax of the Ohio trilobite shows seven joints in two instances: the character of the terminal joint is unknown.

The discovery of this unique specimen fully establishes the correctness of the restoration made by the writer of the ambulatory appendages of Calymene, as shown in fig. 2. The few traces of the branchial filaments do not differ from those described as occurring in the genera Calymene, Ceraurus, and Acidaspis.

From the evidence given, there appears to be no necessity for a change in the classification of the trilobites given on pp. 209, 210 (*ibid.*): —

Class, Poecilopoda; sub-class, Palaeadae; order, Trilobita.

Trilobita: ex., Asaphus, Calymene, etc.

1. Eyes sessile, compound. 2. Ocelli unknown. 3. Cephalic limbs serving as mouth-organs. 4. Thoracic segments bearing jointed legs and attached branchiae. 5. All segments bearing appendages. 6. Thoracic segments unanchylosed. 7. Abdominal segments anchylosed, and bearing jointed appendages. 8. Hypostoma large (metastoma unknown). To section 7 we now add '(similar to those of the thorax).'

The attempt to locate the branchial apparatus of the trilobite beneath the pygidium is not surprising when a comparison with Limulus and Serolis is made with those trilobites having a large pygidium; but in such genera as Conocephalites, Arionellus, and others having a pygidium very small, as compared with the remaining parts of the animal, the necessity for a different branchial system is at once apparent.

The director of the Geological survey of Canada having given permission to have the original specimen of Asaphus platycephalus, described by Mr. Billings as showing ambulatory legs, sent to me, Prof. J. F. Whiteaves kindly forwarded it; and the specimen was placed by the side of the Ohio trilobite for comparison. A glance showed that Mr. Billings's interpretation was the correct one, and that, as far as the thoracic legs are considered, the Canadian trilobite has a pair for each segment. Of the abdominal legs nothing is seen. The only addition to our knowledge of the structure of the trilobite, furnished by the Ohio specimen, is the verification of the hypothesis that the legs were jointed beneath the pygidium, as shown in the sections of Ceraurus and Calymene, and expressed in fig. 2.

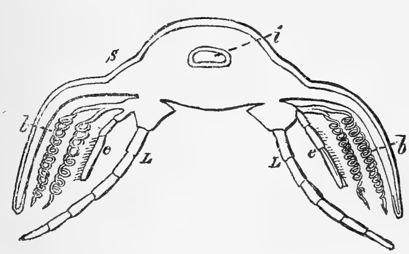

Fig. 3.—Cross-section of fig. 2. *s*, dorsal shell; *i*, alimentary canal; *B*, spiral branchiae; *e*, epipodite; *L*, leg. Taken from same plate as fig. 2. In some instances the branchial filaments or ribbons are straight and not spirally coiled.

That the trilobites and crustaceans were differentiated before the existence of the oldest Cambrian fauna we now know, is my present belief, the two classes coming down on two distinct lines of descent. In a paper now in the course of preparation, the entire subject will be reviewed, and illustrations given of the different orders of the class Poecilopoda.

Charles D. Walcott.

THE NEW BOGOSLOFF VOLCANO IN BERING SEA.[1]

On Tebenkoff's chart of Unalashka Island, and the adjacent passes from Unimak to Umnak Islands, there is placed in latitude 53° 51′ north, and longitude 167° 40′ west, an islet about half a mile in extent, with rocky, bold shores, and somewhat flattened top. It has deep water close around it, and no outlying dangers except to the north-north-west, where a small 'pinnacle rock,' or 'sail rock,' lies a few hundred yards distant.

The rocky islet is known as 'Bogosloff.' In his account of his voyages,[2] Cook says, that on the 29th of October, 1778, he discovered 'an elevated rock which appeared like a tower;' and he judged of its steepness below the surface of the sea by the circumstance that the sea (which was running very high) broke nowhere but against its sides.

I have plotted Cook's position with regard to this discovery, made when he was only four leagues to the south-westward of the islet, and was steering a north-easterly course. From his language, I cannot decide whether he passed on its northern or southern side.

His footnote says, that, though this mass had no place on the Russian map produced by Ismyloff,[3] it was indicated on the chart of Krenitzen and Levasheff. Cook placed it about seventeen miles north of the northern shore of the island of Umnak. His longitudes are all too great by more than a degree, but the relation of the islet to the adjacent islands fixes its position.

This reference to Cook's position is somewhat important; because, on an admiralty chart of Bering Sea and the Arctic Ocean (1859), and on a U. S. chart corrected to 1868 (Exploring expedition under Commander John Rodgers, U.S.N.), this islet is called the 'Bogosloff volcano;' and the statement is made that it rose in 1796, — eighteen years after Cook had described it.

Tebenkoff, in 1848 (perhaps following Saricheff in 1829), calls it 'St. John the theologian Island,' or, rather, 'rock,' and gives it a circumference of two miles. According to Saricheff, its height is about four hundred feet; but the navigators of the Russian-American company made it six hundred and twenty feet. Tebenkoff says Pillar Rock lies four hundred yards north-north-west of Bogosloff Island.

[1] Communicated by Prof. J. E. Hilgard, superintendent U.S. coast and geodetic survey. See also *Science*, No. 51.
[2] Vol. ii. p. 526. Third admiralty edition.
[3] Ismyloff was the principal trader at Unalashka, and had produced charts of several of the islands, etc., with which he was personally familiar, and showed them to Cook.

On the admiralty chart and on some of the Russian charts (including those of Saricheff), and even on the chart published by the U. S. hydrographic office in 1855, a dangerous reef is laid down between Bogosloff and the northern end of Umnak. The U. S. chart, corrected to 1868, repeats this danger; and it is even laid down on the U. S. circumpolar chart of 1882. Tebenkoff says this 'dangerous reef' does not exist: Veniaminoff says the natives deny the existence of the reef, but report great current or tide rips, which are dangerous to their bidarkas. In 1867 I had the same information from the Russian priest, Shayesnikeff, — a man of more than ordinary knowledge and capacity, and well acquainted with the islands, which he visited regularly in the course of his ministrations: also the Alaska commercial company's navigators have passed between Umnak and Bogosloff islands. Neither the Bogosloff, the reef, nor the northern part of Umnak, is on Kotzebue's chart of 1817.

The height of this volcanic island varies according to the authority from which the estimate has been obtained, as already indicated. Tebenkoff gives estimates, from two authorities, of four hundred and six hundred feet. On my chart I have a note stating the height to be eight hundred and forty-four feet, but I had forgotten to state the authority for that estimate. I suppose that I obtained it from one of the Russian navigators, in 1867. The captains employed by the Alaska commercial company, however, estimate the height at from two hundred and fifty to three hundred and fifty feet.

Of this islet I collate the following facts, without examining many authorities: —

1778. — Cook saw it, Oct. 29, in clear weather. He says it is on the charts of Krenitzen and Levasheff.

1796. — Veniaminoff, calling it 'St. John the theologian,' states that it arose out of the sea on May 7 of this year; and that, at the time, there were, according to Krusenstern and Langsdorff, earthquakes and eruptions.

1800. — It was smoking (Kotzebue).

1802. — It was smoking (Langsdorff). (At that time the volcano Makushin was throwing out volumes of smoke and fire.)

1804. — It was smoking from one crater (Kotzebue).

1806. — The burning lava was flowing down the north side (Langsdorff).

1814. — The crater threw out stones (Baranoff).

1815. — It was diminishing in height (Baranoff).

1816–17.—It had no activity (Eschscholtz).
1820.—It was smoking (Dr. Stein).
1823.—It was not smoking (Veniaminoff).
1832.—There was no smoke (Tebenkoff, Lütke).

Although frequently seen in later years by the navigators of the Russian-American and Alaska commercial companies, and by the whalers, no one has noticed it as exhibiting any signs of activity.

In an other part of Veniaminoff's work, in giving more particulars of earthquakes and volcanoes, he writes,—

"The new island, Bogosloff, in latitude 53° 58′ north,[1] and longitude 168° 5′ west, rose from the sea in the early part of May, 1796. Before the island appeared above the sea, there had been witnessed, for a long time in that spot, a column of smoke. On the 8th of May, after a strong subterranean noise, with the wind fresh from the north-west, the new small, black islet became visible through the fog; and from the summit great flames shot forth. At the same time there was a great earthquake in the mountains on the north-west part of Umnak Island, accompanied by a great noise like the cannonading of heavy guns; and the next day the flames and the earthquake continued. The flames and smoke were seen for a long time. Many masses of pumice-stone were ejected on the first appearance of the island."

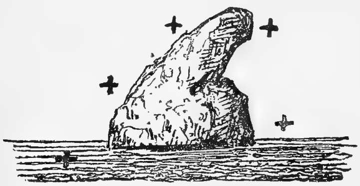
At that time it was, perhaps, only one-quarter the size of its present dimensions; and it increased in size, growing higher, and breaking down at the same time on all sides. Finally, about 1823, it seemed to become unchangeable. Until it ceased to increase in size, it was hot, as well as the sea-water around it; while smoke and steam arose from it continuously.

It is noticeable, also, in this connection, that Krenitzen and Levasheff, who made the voyage of discovery in 1768 and 1769 to endeavor to discover the track of Bering's voyage, have marked Bogosloff on their chart as situated forty miles west by south of Makushin volcano, and surrounded by sunken rocks. Their mark is a view (see sketch), and clearly indicates the peculiar shape of the islet at that time. Their course led them ten miles to the northward of it. So much for the older authorities.

Along the whole chain of the Aleutian Islands, from abreast of the Kamtchatka peninsula to the head of the peninsula of Alaska, there is a line of the greatest volcanic activity exhibited by about fifty volcanoes, of which many are living, and of which some are at times in a state of violent eruption. Some of them have an extreme elevation of about twelve thousand feet on the Alaska peninsula; while the Aleutian volcanoes range from three thousand to nine thousand feet.

[1] This latitude agrees with Cook's.

Of these living volcanoes, one is that of Makushin, on the north-western part of the large island of Unalashka, and directly overlooking Captain's Harbor, on the north side of that island; and another is the islet of Bogosloff, now under discussion, situated twenty-five miles to the westward of the north-western point of Unalashka. This islet has acquired unusual importance, because there has arisen alongside of it, from the depths of the ocean, a volcanic island over one thousand feet high. This fact also suggests inquiries into the condition of the island seen by Cook as 'an elevated rock which appeared like a tower,' and its condition in May, 1796, when it seems to have exhibited unusual signs of activity. Also it appeared, as before mentioned, to have increased in size, and continued so to do as late as 1823. It is possible that Cook saw the rock when in a state of inaction, as he made it out at a distance of four leagues, when working to the eastward under the northern shore of Unalashka; and the weather must have been clear. I conjecture that he sailed between it and Unalashka to save getting too far to leeward; and he must have had it in sight for several hours.



BOGOSLOFF ISLAND, DISTANT TEN MILES, AS SEEN BY KRENITZEN AND LEVASHEFF, 1768–69.

As late as September and October, 1883 (to come down to our own times), the island was seen by two captains in the service of the Alaska commercial company,—Hague and Anderson,—both of whom called upon me, described the character of this new formation, and enabled me to make a rough sketch of the islet as it appeared to them (see view). They both passed close to it, approaching from opposite sides, and thus were enabled to judge of its size, height, and general appearance. Capt. Anderson, in the schooner Matthew Turner, saw the island at daybreak (five A.M.) on the 27th of September, 1883, and passed it at half-past eight A.M. within three cables' lengths; heaving the lead as fast as practicable, with twenty fathoms of line, and finding no bottom, although the water was discolored and of a red color. The vessel first approached it on the eastern side, stood up to the north-westward, tacked ship, and passed to the west-

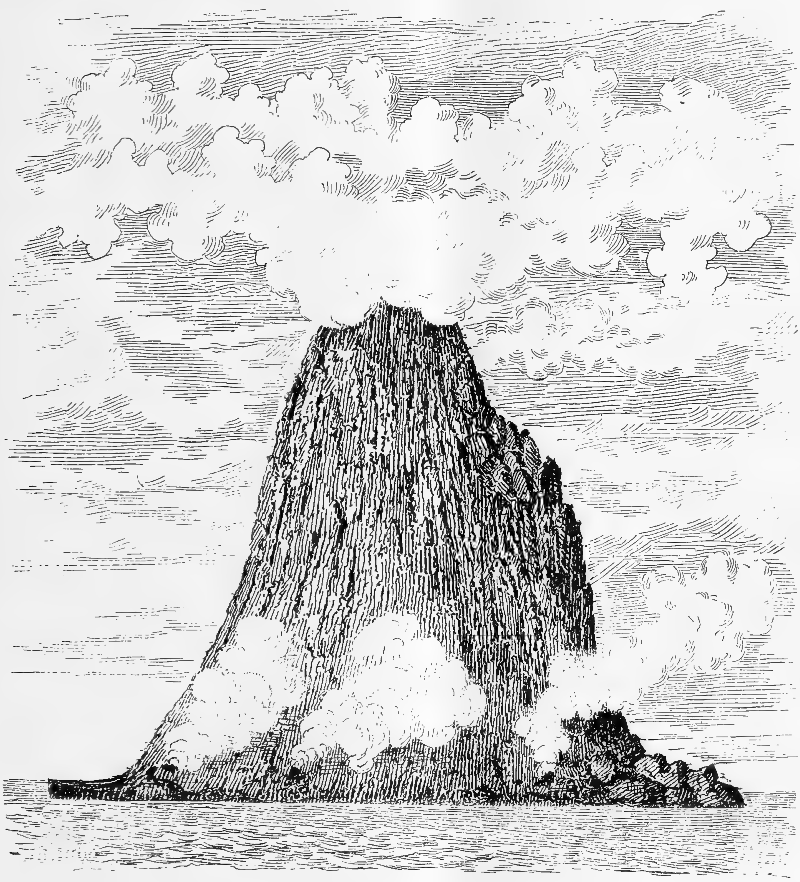
ward. The islet was surrounded by white smoke, like steam. The same evening, after nightfall, being then about twenty-five miles to windward of it, they saw the fire on the island.

On the 27th of October, 1883, just one month after Anderson's visit, Capt. Hague, of the Dora, saw the island at seven A.M., approaching it from the south-westward (just as Cook had done one hundred and five years before). He first passed through a streak of red water into a green streak beyond it (the water under both conditions having the appearance of being very deep), but, fearing shoals, tacked ship to avoid a nearer approach. He came no nearer than about one mile, and had the island in sight about three hours. At that time there was black smoke issuing from it, as if tar were burning. The weather was cloudy, and no observations could be had for position; but its proximity to the old Bogosloff fixes it with equal precision.

Both captains agree in saying that the island is larger than the old one, and is about half a mile north-north-west of it; that it rises very steeply, with a rough, ogee curve; and that the outline on the eastern side is broken on the shoulder and at the base by masses of rocks (see view, below). On the western side there is a level space just above water, and thirty or forty feet in extent, where a landing could be effected. The top was hidden by clouds; but white smoke or steam could be seen issuing from near the cloud-line, which was estimated to be from eight hundred to twelve hundred feet above the sea. The sides are very steep; and, apparently, it has arisen from the depths without developing outlying dangers, because, with a heavy swell running, no breakers were seen. Around the base are great steam-jets, somewhat like those near the summit. At night it looks as if the whole islet were in active eruption, and covered with fire (this



THE NEW VOLCANIC ISLAND OF BOGOSLOFF AS SEEN SEPTEMBER–OCTOBER, 1883.

may arise from the ignition of gases escaping from innumerable apertures in the flanks of the islet).

Tebenkoff, in his description, tabulates this islet as in latitude 53° 52′ north, and longitude 167° 39′ west.

I have no doubt that during the present year (1884) we shall obtain its exact geographical position, its physical conditions, and reliable measures of its size and height.

On the 20th of October, 1883, — seven days before Hague saw the island, — a shower of ashes took place, small quantities of which were collected at Iliuliuk, and a portion presented to the California academy of sciences. There seems some doubt, however, as to the point whence the ashes came; as the account from Iliuliuk places the date of their fall at Oct. 16, *wind being fresh from west-south-west*, with rain and sleet. It may be that this pumice-dust came from the eruption of Mount St. Augustin (see map of Alaska) on Oct. 6, under the influence of an upper current of air from the north-eastward; that mountain lying over seven hundred miles distant in that direction from Unalashka.

It is noticeable, that during the eruption from Bogosloff, or at least about that time, the two volcanoes on Akontan Island (about as far to the east-north-east of Makushin volcano as Bogosloff is to the west by north) ceased to smoke, and showed no signs of activity. These two volcanoes, only three miles apart, are 3,332 and 3,888 feet high respectively. Nothing was heard from Makushin: probably its summit was in the clouds, and might have been active.

As regards the distance to which the ashes from such eruptions are sometimes carried, it may be mentioned, that at the time of the eruption of volcano Iliamna, in March, 1867, the pumice-ashes fell on St. Paul, Kadiak Island, one hundred and sixty-five miles distant.

From the natives of Iliuliuk it was quite recently learned that they had seen smoke issuing from the new Bogosloff — or, rather, from the position of the Bogosloff — some time in 1882: the exact date could not be obtained.

GEORGE DAVIDSON,
Assistant U.S. coast and geodetic survey.

THE DANISH EXPEDITION TO EAST GREENLAND.

THE report of Lieut. Holm has appeared in the *Dagblad* of Copenhagen. He left Nanortalik on the 23d of July last, with a party of thirty-nine people, nine kayaks, and four umiaks, and reached Fredericksthal, the last European station, the same evening. Here they were assisted and entertained by missionary Broadbeck until the end of July, while the party was detained by the presence of floe-ice in the vicinity of Cape Farewell. From the 31st of July until Sept. 11 the party was not much incommoded by ice, only losing three days while detained in Lindenow Fiord.

The charts of East Greenland as far as latitude 61°, where the work terminated, will be notably changed, especially by the discovery of extensive fiords, until now unknown. Their shores are generally bare and vertical, or nearly so. In many places snow lies all summer. The sea-ice reaches to the bases of the cliffs, or even several miles into the fiords. Except at the extreme south, vegetation is even less abundant than in West Greenland, and is sometimes wholly absent. The southernmost of these fiords, some thirty-eight miles long, reaches within ten miles of the head of the Tasermint Fiord, which opens on the western coast. Both are full of ice. South of the sixty-first degree of latitude, and even a few miles northward from it, nothing could be seen of the inland ice characteristic of West Greenland. In that vicinity, from a mountain peak three thousand feet in height on Iluilek Island, they were able to see that the interior of the country for a great distance was composed of grand mountains, often rising over seven thousand feet above the sea.

In the fiords explored in 1883, there were found no remains of buildings erected by the Northmen, except those in Lindenow Fiord, the most southern of all, already described by Broadbeck. A great number of Eskimo ruins were noted in the different fiords. Sixty of these uncivilized natives were met going to trade with the people of West Greenland. They were much less like the typical Eskimo than those of the western coast. The men are almost always tall and slender, with long beards, and at a distance resemble Europeans. Some of them were even handsome, and the women were much prettier than those of West Greenland. In summer they lead a nomadic life, going from one fishing or hunting place to another. In winter several families unite to build huts covered with turf and stones, like those of West Greenland. They spend this season hunting seal and bears.

When the natives of Holm's party arrived at about latitude 61°, they refused to continue farther, fearing that the umiaks might be frozen in, as the ice began to knit together every night. On the most northern point attained, a hut was erected, and a depot made for the use of the expedition during the coming summer. Provisions and several boats were left here, and Holm returned with his party to Nanortalik. Here winter quarters were prepared, and a magnetic and meteorological observatory established. Magnetic observations are to be taken hourly from eight A.M. to midnight; on term days, every five minutes; and from four A.M. to four P.M., every minute. Arrangements have been made for simultaneous observations at the commercial stations of Denmark, in West Greenland.

After the winter quarters had been prepared, it was the intention of Holm to examine the fiord of Fredericksthal, and the region between it and Tasermint, which has not yet been explored with care.

It was his intention to start for the eastern coast about the end of April, or early in May, 1884; and during the winter of 1884–85 some members of the party were to remain there.

HUMIDITY AND CHRONOMETER RATES.

MAJOR-GEN. J. F. TENNANT, of her Majesty's mint, Calcutta, communicated to the Royal astronomical society in November last a paper on humidity as a cause of variation in the rate of chronometers. He had borrowed from the government-stores about the end of March, 1882, a chronometer, by Fletcher of London, which had been some time in India, but had not been cleaned since its arrival, and was said to have a good rate. From a gaining-rate of 6s.5, which it preserved fairly well for about two months, it suddenly fell to a gaining-rate of 2s.0; this being the commencement of a succession of rather abnormal fluctuations of rate which Major Tennant carefully observed and recorded for about eighteen months. These rates were first compared with a plot of the published daily mean temperatures of the meteorological observatory, with results not quite satisfactory; for, though it would seem at first sight that the rate depends on temperature, further examination showed that it can do so to a moderate extent only, and confirmed the belief, which Major Tennant had from general impressions, that rate does not depend on temperature. The extraordinary differences of rate at times of nearly equal temperature leave no doubt that there is a periodic change of rate; and the cause of this, Major Tennant believes to be humidity. His first suspicion of this was raised by the sudden fall in rate of this chronometer, in 1883, being coincident with the first heavy rains producing great damp; and by the fact, also, that the same thing occurred the year previous, and that the whole period of low gaining-rate was that of the rains, while the lowest was the warm time at the end of the rains, when the soil is generally loaded with moisture. The same phenomenon recurred. It is, however, much more difficult to compare the supposed cause and effect without special arrangements; and, in any case, it is doubtful whether air-humidity could be more than a rough guide.

If the oil in the arbors of the balance be hygroscopic, it is easy to see that it may become more fluid in damp weather, the arc of oscillation will increase, the balance-vibration take longer, and the chronometer lose; but the momentary humidity of the air will not correspond to the rate, as the temperature does more or less. Major Tennant, remarking the undoubted connection in this particular case, suggests special experimenting in the following directions: —

1°. Are chronometer-oils, or any of them, hygroscopic?

2°. Can they become so by exposure to a tropical climate?

In this latter case he conceives that the climatic influence cannot be imitated in Europe. The effect of the heat, and probably the light, are very destructive of some materials. Vulcanized india-rubber, for example, does not bear exposure in India, though it seems to answer in Europe, even in heat and damp.

Lastly, in estimating the effect of humidity on a given chronometer, it will probably be best to use one of the old hair or grass hygroscopes for the humidity, placing it in the case, enclosed with the chronometer. DAVID P. TODD.

THE GREAT COMET OF 1882.

THIS comet is one of the most interesting that has appeared for a number of years, owing to its very near approach to the sun-surface, and the resemblance of its orbit to the two great comets of 1843 and 1880. It was a brilliant object in the morning sky in September, 1882. Calculations of the orbit have been made recently by Dr. Morrison, Professor Frisby, and Dr. Kreutz. The periods obtained are as follows: Dr. Morrison, 712.1 years; Professor Frisby, 793.9; Dr. Kreutz, 843.1. These periods are, however, somewhat uncertain, owing to the peculiar nature of the nucleus of this comet. Instead of being a single bright body, there appeared to be a row of small nuclei, so that it was a mere matter of judgment with the observer what part of the comet he should observe. The observations were naturally made upon the middle of the row of points, and it is not possible to say with certainty that this corresponded to the centre of gravity of the comet. It is worthy of note, that bright comets are recorded in the year 370 B. C. and in A.D. 1132, both of which could be reconciled with the great comet of 1882 by supposing the period of 751 years.

THE WORK OF THE CAMBRIDGE ARCHAEOLOGICAL MUSEUM.

THE trustees of the museum of American archaeology and ethnology, founded by George Peabody, held their annual meeting on the 18th of February, the anniversary of the birth of the founder. The Hon. Robert C. Winthrop, president of the board, presided; and Professor Asa Gray, Dr. Henry Wheatland, Mr. John C. Phillips, Mr. Samuel H. Scudder, and Mr. F. W. Putnam (the curator of the museum) were present. The Hon. Stephen Salisbury of Worcester was prevented by temporary illness from attending, and the Hon. Theodore Lyman was unable to leave his duties in Congress.

The report of the treasurer, Mr. Phillips, showed that the $150,000 given by Mr. Peabody is well invested. Of the income of $8,334, only $5,186.50 was expended on account of the museum: $3,110 belonged to the building-fund, and the remaining $37.50 was expended on insurance. Mr. Winthrop

called attention to the wide-spread operations of the museum, which had so far exceeded the early expectations of the trustees as to have entirely outgrown its foundation. The original fund, although a munificent gift at the time, is now inadequate, owing to the unforeseen growth of the science. He hoped that in any account which might be given of this meeting, it would be clearly stated that this trust is in no way connected with the Archaeological institute of America, with which it has, no doubt, been confounded in some minds.

Mr. Putnam, the curator, presented his report of the operations of the year, in which he dwelt at length on the explorations which had been carried on by means of the subscriptions of several patrons of science. With about $1,600, the balance of the special subscription-fund of 1882–83, and less than $1,000 spared from the income, work has been continued in Nicaragua and Ohio, and, in a very limited manner, in Tennessee and North Carolina.

The work in Nicaragua has been conducted for the past five years by Dr. Flint, who has made very important collections from the ancient shell-heaps and burial-places. During the past year, on Deadman's Island, in a trench lined with stones, he found a burial-jar containing decayed human bones, with old Venetian beads, and two gold ornaments like those found in the graves at Chiriqui. This shows that gold ornaments of this type were used by the natives of Nicaragua after the Spanish conquest had furnished them with glass beads. As they are exceptional among Nicaraguan antiquities, and are identical with those from farther south, it is probable that their original source is Chiriqui. Dr. Flint has copied successfully many pictographs and cave-inscriptions, some of which are of great antiquity. But the most interesting discovery is what Dr. Flint believes to be human footprints in clay under several layers of lava-rock, on the borders of Lake Managua. Under date of Dec. 24, 1883, Dr. Flint writes that he has cut out several of these footprints, which, with fossil leaves from the same stratum, are now on their way to the museum.

The work in the Little Miami valley has been continued with remarkable success, and has resulted in discoveries of far greater importance than could have been anticipated from previous exploration of the mounds. A year ago attention was called to some early results of this exploration; but now, just as the means for continuing explorations are wanting, the discovery has been made, that, important as these mounds have proved to be, as much of interest is to be found beneath them. At the bottom of the largest mound, under a layer of burnt clay enclosed by a stone wall, trenching has brought to light a series of pits six to seven feet deep. These pits are connected with tunnels of clay a foot in diameter and seven to eight feet long, ending in upright tubes five inches in diameter and two feet long. Fine ashes were found on the bottom of the tunnels or flues, and on the sides a glossy substance, as if the product of condensation and crystallization of vapors. The pits were partly filled with ashes containing minute pieces of burnt bone, and the sides and bottom bore marks of fire. Two pits had dome-like covers of clay, in one of which were two small holes. A tube of clay opened into one pit opposite the flue. Although these facts seem to point out the manner of burning the dead in use among the people who built this group of tumuli, it would be premature to make such an assertion. This work has been under the direct supervision of the curator and Dr. Metz. It is unquestionably the most thorough and important exploration of a particular group of earth-works yet made in Ohio. Many mounds varying in structure, and evidently made at widely different times, have also been carefully opened; and several Indian burial-places and village sites have been examined. When this work in the Little Miami valley is completed, it will bring us nearer the solution of the problem, who built the mounds? Guessing will still go on, but thorough exploration by careful hands alone can give to science the answer it demands. The work is far more extensive than most persons imagine. The land has been hired by the museum, with exclusive right of excavation. It will be necessary to dig over a large area, including the whole altar-group, to trace in a systematic manner the underground works. A number of laborers will be required for months to come. Funds are therefore needed at once, that the work may be continued without interruption.

In closing his report, the curator urged the necessity of some immediate action for the preservation of the interesting monuments of aboriginal art, scattered over our western states. Probably nearly all which are in such condition as to be worth saving could be purchased at fair prices. Their owners, as a rule, would be glad to see the ancient works preserved, but do not feel able individually to sacrifice so large an amount of farming-land for the purpose. Special mention was made of the Hopeton works, with its twelve-feet embankments and large square and circle; the Cedar-Bank works, which are still well preserved, in the Scioto valley; the Great Serpent, 1,415 feet long, the only work of the kind in the country; the Stone Fort, enclosing fifty acres, known as Fort Hill, in the Brush-creek valley; Fort Ancient, with its four miles of wall, the largest of the many ancient fortifications in the United States, on the Little Miami River; Cahokia Mound in Illinois, the great pyramid of the Mississippi valley, and the largest tumulus in the country, nearly one hundred feet high, and covering an area of over eleven acres; and the singular group of low effigy-mounds in Wisconsin. Some of these mounds are more than a thousand feet long. Many other ancient works are equally worthy of preservation; but those mentioned had been recently inspected by the curator. With every year that passes, some mound or great embankment is levelled for economic purposes, or for the easier cultivation of the land; or the old walls of the hill-forts, which have stood for untold centuries, are thrown down. Forty years ago many of the works were perfect which are now nearly obliterated. Our children will not be able to trace their sites, unless destruction is immediately checked.

VORTEX RINGS.

A treatise on the motion of vortex rings. An essay to which the Adams prize was adjudged in 1882, in the University of Cambridge. By J. J. Thomson, Trinity college, Cambridge. London, 1883. 19 + 124 p. 8°.

Those cases of fluid motion in which no rotational motion is present, are, as is well known, readily amenable to analysis. Helmholtz [1] first called attention to the nature of the analysis by which rotational motion must be treated. This memoir was followed by Sir William Thomson's suggestive paper on vortex atoms,[2] and finally by his important mathematical memoir on vortex motion.[3] The very great mathematical difficulties of the theory have operated to prevent almost entirely farther progress in the investigation of this otherwise alluring subject. To the best of our remembrance this essay is the first systematic attempt, since 1869, to enlarge our knowledge of the theory of vortex rings. How great the difficulties to be vanquished are, may be imagined from the appearance of the pages of the essay before us, which bristle with periodic series and complicated expansions.

The scope of the essay may perhaps be best apprehended from its opening paragraphs, which we quote: —

"The theory that the properties of matter may be explained by supposing matter to be collections of vortex lines in a perfect fluid filling the universe has made the subject of vortex motion at present the most interesting and important branch of hydrodynamics. This theory, which was first started by Sir William Thomson as a consequence of the results obtained by Helmholtz in his epoch-making paper, *Ueber integrale der hydrodynamischen gleichnungen welche den wirbelbewegungen entsprechen*, has *à priori* very strong recommendations in its favor; for the vortex ring obviously possesses many of the qualities essential to a molecule that has to be the basis of a dynamical theory of gases. It is indestructible and indivisible; the strength of the vortex ring, and the volume of liquid composing it, remain forever unaltered; and if any vortex ring be knotted, or if two vortex rings be linked together in any way, they will retain forever the same kind of be-knottedness or linking. These properties seem to furnish us with good materials for explaining the permanent properties of the molecule. Again: the vortex ring, when free from the influence of other vortices, moves rapidly forward in a straight line. It can possess, in virtue of its motion of translation, kinetic energy; it can also vibrate about its circular form, and in this way possess internal energy: and thus it affords us promising materials for explaining the phenomena of heat and radiation.

"This theory cannot be said to explain what matter is, since it postulates the existence of a fluid possessing inertia; but it proposes to explain, by means of the laws of hydrodynamics, all the properties of bodies as consequences of the motion of this fluid. It is thus, evidently, of a very much more fundamental character than any theory hitherto started: it does not, for example, like the ordinary kinetic theory of gases, assume that the atoms attract each other with a force which varies as that power of the distance which is most convenient; nor can it hope to explain any property of bodies by giving the same property to the atom. Since this theory is the only one that attempts to give any account of the mechanism of the intermolecular forces, it enables us to form much the clearest mental representation of what goes on when one atom influences another. Though the theory is not sufficiently developed for us to say whether or not it succeeds in explaining all the properties of bodies, yet, since it gives to vortex motion the greater part of the interest it possesses, I shall not scruple to examine the consequences, according to this theory, of any results I may obtain.

"The present essay is divided into four parts: the first part, which is a necessary preliminary to the others, treats of some general propositions in vortex motion, and considers at some length the theory of the single vortex ring; the second part treats of the mutual action of two vortex rings which never approach closer than a large multiple of the diameter of either; it also treats of the effect of a solid body immersed in the fluid on a vortex ring passing near it; the third part treats of knotted and linked vortices; and the fourth part contains a sketch of a vortex theory of chemical combination, and the application of the results obtained in the preceding parts to the vortex-ring theory of gases.

"It will be seen that the work is almost entirely kinematical: we start with the fact that the vortex ring always consists of the same particles of fluid (the proof of which, however, requires dynamical considerations), and we find that the rest of the work is kinematical. This is further evidence that the vortex theory of matter is of a much more fundamental character than the ordinary solid particle theory; since the mutual action of two vortex rings can be found by kinematical principles, whilst the 'clash of atoms' in the ordinary theory introduces to forces which themselves demand a theory to explain them."

The great difficulty which inheres in the vortex theory of chemical combination is to sufficiently account for what takes place at the instant of chemical union by showing that vortex atoms can, without supposing other forces than those due to their motion, have any such attractions as are known to exist, and especially to account for the enormous quantities of heat liberated in many cases of chemical decomposition.

The author, however, postpones all extended application of the vortex theory of atoms to the dynamical theory of gases for consideration in a future paper, but, among other important conclusions, states that the phenomena attending the diffusion of gases through a porous diaphragm which separates portions of gas at different temperatures will probably furnish a crucial experimental test between the vortex atom theory and the ordinary kinetic theory.

THE SILK INDUSTRY IN THE UNITED STATES.

Silk-manufacture in the United States. Compiled by WILLIAM C. WYCKOFF, special agent of the tenth census.

UNDER the above title, Mr. W. C. Wyckoff has published a volume containing his report as special agent of the census of 1880, the tenth annual report of the Silk association of America, and a directory of silk-manufacturers. The first of these reports is reprinted on account of the very small edition of the bulletin issued by the census office, and deserves more notice than it has received, on account of its admirable historical account of the numerous attempts at silk-culture in this country, and of the rise of silk-manufacture. The interest in silk-culture has steadily grown of late years, while the interest in silk-manufacture was scarcely more marked during the early struggles to establish the industry than at this present time of tariff-reform agitation.

In the work before us, the first introduction of silk-culture into America is traced back to the Spanish conquest of Mexico. Mulberry-trees were planted near the city of Mexico by order of Cortes shortly after 1522; and in 1531 a quarter of an ounce of eggs was sent on public account from Spain to Francisco de Santa Cruz, a citizen of Mexico. The eggs were reared by Auditor Diego Delgadillo with the best of success, and two ounces were returned by him to Francisco. He was accused, however, of selling the remainder of the eggs, which were the property of the crown, to others for sixty dollars an ounce, was tried and convicted. This carries the beginning of silk-culture in America nearly a century back of previous records. The industry flourished for a while in Mexico, supplying the demands of the people, and even giving rise to a certain amount of export to Peru; but, by the end of the sixteenth century, few traces of its existence were left.

Early in the seventeenth century James I. of England, jealous of the growing prosperity of silk-culture in France, resolved upon its introduction into England and the American colonies. In 1619, after one disastrous attempt had been made ten years previous, eggs were received in Virginia from the Royal gardens at Oatland; and the settlers were enjoined, by promises of aid for diligence, and threats of punishment for negligence, to undertake the culture of the worms. Meanwhile the cultivation of tobacco was discouraged in every possible way. Nevertheless, the success of the silk-industry was but slight. Some silk was grown, as it was quoted among the market-prices of commodities grown in Virginia at that time; but, in spite of all encouragement, the industry did not flourish. Calculations were made whereby it was shown that the labor of slaves employed in growing silk would produce about twice as much value as in planting sugar and tobacco; and one writer even advised the sending of all the paupers and small criminals of the old country to the colonies to engage in the culture.

In South Carolina but little more was done; and in the twenty-five years of greatest production — between 1731 and 1755 — only 251 pounds were exported. Georgia did somewhat better. In 1735 a plot of ground near Savannah was planted with mulberries and vines at the public expense. In 1744 a filature was built and bounties were offered, and from 1750 to 1772 considerable amounts of silk were exported. Then came the war of the revolution, and mention of silk-culture for a time ceases.

Mr. Wyckoff then traces the early attempts to introduce the culture into New England. In each case the culture is traced from its rise in any particular colony to its extinction, and the various causes for failure are discussed. Some new facts are added to this portion of the work; but in the main it substantially coincides with other accounts, notably with Dr. Brockett's 'Silk-industry in America' (1876), — a not surprising fact, since both authors relied upon the same library. Nevertheless, this portion of the work, covering the most interesting periods in the history of the industry in America, is thoroughly concise, and full of valuable suggestions. The growth of the industry is followed, and shown to have been steady after the revolution, with no encouragement in the way of premiums or bounties. Connecticut became the chief seat of production, and the silk was consumed mainly in the manufacture of sewing-silk. This part of the history — during the close of the last and the beginning of the present century — shows pretty plainly, that, without interference or discriminating legislation, silk-culture and silk-manufacture would develop co-ordinately. During the third and fourth decades of the present century the general interest in the subject increased; and the encouragement given by the various states and by Congress, until the Morus multicaulis furore undid them all in 1839, transcended any similar efforts since made. In 1826 we find that three-fourths of the families in Mansfield were engaged in raising silk, and made annually, per family, from five to fifty pounds, or even a hundred pounds,

of 'raw silk.' The largest amount of raw silk produced in this country in any one year is given as thirty thousand pounds, in 1841.

There is a tendency, on Mr. Wyckoff's part, to intensify the dark side of silk-culture, and to depreciate the quantity and quality of silk produced, — a tendency that is natural, and doubtless unconscious, in an agent of an association of manufacturers. In most cases he makes the amount of silk raised much smaller than given by common report: but he does so in some instances by assuming that the term 'raw silk,' or 'raw-silk balls,' in older works and reports, meant cocoons, or that there was 'neglect in discriminating between cocoons and raw silk;' also by calculating that from ten to fourteen pounds of cocoons are necessary to make a pound of reeled silk. He by no means makes it clear that the term 'raw-silk balls' really meant cocoons; as it might apply to the twisted hanks of reeled silk, and the term 'cocoons' was in use at that time. It is also certainly not justifiable to assume that the cocoons were necessarily fresh, as they are not thus handled and marketed. This he does, however, in his estimates (p. 24). Four pounds of choked cocoons to a pound of reeled silk is a liberal estimate, and would give us in 1766, when twenty thousand pounds of cocoons were produced, five thousand pounds of 'raw silk;' while the maximum amount Mr. Wyckoff allows in any one year prior to 1772 is 'rarely exceeding a thousand pounds.' While sometimes misleading, therefore, this tendency to look on the dark side of silk-production has resulted in demonstrating some exaggeration and mis-statement on the part of earlier writers; and the establishment of the truth or falsity of such statements, which have again and again been put forth, is one of the most meritorious features of the work. The most striking case in point is where (p. 25) the oft-quoted statement as to the export of ten thousand pounds of raw silk in 1759 is pretty conclusively shown to have been based upon such confusion of terms and mis-statements as above indicated.

The summing-up of the present condition (1880) of silk-culture in the United States is worthy of quotation: —

"An inquiry was attempted by the writer to ascertain the amount of raw silk raised in the United States during the census year ending June 30, 1880. It was soon determined that the expense of making such an investigation thoroughly would be more than the result could be worth. The only instances of the use of native silk in manufacture were at Williamsburg, Kan., and at Salt Lake City, Utah. The latter experiment proved financially a failure, the raw silk costing much more than the Asiatic product. It may however be stated in a general way, without pretension to accuracy, that the amount of reeled silk produced in Utah territory during the year was less than a thousand pounds; the amount in Kansas was less than five hundred pounds, and the product in no other state was more than half as much. Missouri and North Carolina probably came next in amount of cocoons raised, and after those states Pennsylvania and New Jersey, the quantities produced there and in scattered localities throughout the country being inconsiderable."

With the exception of the penchant already alluded to, in favor of the manufacturing as against the productive part of the silk-industry, the author has done his work so well that it will remain as the best monograph on the subject we possess. It is, in fact, a model report, the material for which has been gathered with care and comprehensiveness, and put together in such compact and concise form that it will serve as a cyclopaedia for all future reference, and render it extremely difficult for future writers to add any thing of consequence.

We notice but one clerical error of any importance. 'Julius Stanislaus,' in the list of authors (p. 39), should be 'Stanislas Julien.' He was a member of the French institute, and professor of Chinese literature in the College of France.

No one can read this report without feeling that the silk-manufacture of the country has been built up to its present importance by our protective policy; and at first blush this would seem to be a very strong argument in favor of that policy. But it has at the same time had the effect to throttle and destroy the production and concomitant reeling of silk. The one industry is protected at the expense of the other. 'Raw silk,' as applied in the trade, is a misnomer: it should apply to the simple fibre upon the cocoon, whereas it really applies to the reeled silk, which is as much a manufactured article as any woven or sewing goods, having gone through an elaborate process by means of special skill and complicated machinery. On its successful establishment the silk-producing industry may be said to depend. Nothing is more clearly demonstrated by Mr. Wyckoff's report than that the chief cause of failure in this last, next to no reeling at all, has been the bad reeling of domestic silk. There was never any difficulty in rearing the worms, or in getting silk of the best quality; and, when good reeling could be had, 'native silk was found to be of superior quality and strength' (p. 35). Why, therefore, it will be asked, should one kind of manufacture be protected from foreign competition, and not the other? If protection is beneficial to the people in the

one case, why not in the other? With a native food-plant (Maclura aurantiaca) now known to be available over most of our domain, with a rapidly-increasing population, with increasing means of communication, and with the settlement of sections of the country that by climate are pre-eminently adapted to silk-culture, the present period has advantages for this culture possessed at no other period, and the question is pertinent. We do not propose to introduce a homily on free trade; but we think that the chief answer that can be given to the question is, that our silk-manufactures are established, and give employment to a large number of operatives, while silk-culture as an industry amounts to so little that there is nothing to protect. The same could have been said of silk-manufacture while it was struggling for establishment, and means little more than that we must keep up a discriminating policy, simply because we have begun it; and the more powerful and wealthy the manufacturing interest becomes, the more certain will it be kept up. This is the secret, in a nutshell, of the failure of silk-culture at the present time; and the prospect for what might otherwise become a valuable productive industry is certainly gloomy.

SCRIBNER'S WHERE DID LIFE BEGIN?

Where did life begin? a brief inquiry as to the probable place of beginning and the natural courses of migration therefrom of the flora and fauna of the earth. By G. HILTON SCRIBNER. New York, *Charles Scribner's Sons*, 1883. 6+64 p. 12°.

THIS little monograph is a full summary and straightforward statement of the principal grounds of the theory of the arctic origin of the plants and animals of the northern hemisphere. These grounds, in more condensed statement, are as follows: on any planet, organic life would first appear in the region first suited for its reception. On a planet cooling from an incandescent state, the polar regions would first acquire a habitable temperature, both because their deficiency of solar heat would accelerate cooling, — that deficiency being increased by polar flattening, which renders the sun's rays more oblique, and increases the radiating surface of the polar sides, — and because, underneath the polar sides, there is less matter to be cooled than underneath the equator. On our earth the polar regions are now too cold for life, and hence they have passed through the life-sustaining stage; and this was while more equatorial regions remained too hot. As the life-sustaining isothermals moved equatorially, animals and plants migrated correspondingly. The progress of climatic change was not more favorable to this faunal and floral migration than were the southward bottom flow of water in the general oceanic circulation, and the general meridional trend of the continental and oceanic configuration, or the prevailing surface-movement in the atmospheric circulation. All these conditions oppose transmeridional migrations. Confirmatory of these deductions are numerous facts of observation, — such as similarity of the fauna and flora at all parts of the same parallel of latitude; the remains of tropical and subtropical animals and plants in arctic regions; the degenerate condition of certain arctic species, as whales, seals, and others; and the fundamental affinities of different tribes of plants and animals which testify to a common origin.

Undoubtedly some of these considerations are entirely valid, and confer upon the theory a claim to sober consideration, not to mention the authority of names previously subscribed to it. What a hesitating believer would like to know further, is, whether the inferior polar radius of the earth would really accelerate or retard polar cooling, and whether the circulations of the sea and atmosphere have been such as to promote the migrations of plants and animals from high polar to equatorial latitudes. The deductions based on progress of planetary cooling are plausible: but the queries arise, whether circulations did not exist in the fluid planet before incrustation as well as in the fluids existing after incrustation; and whether such circulation must not have maintained polar and equatorial surface temperatures so nearly equal as to permit nearly simultaneous incrustation in all latitudes; and then, whether, after general incrustation, the crustal arrest of radiation must not have speedily diminished subcrustal influence to such an extent that climate depended chiefly on solar radiation, since less than half a mile of crust would fail to conduct sufficient heat to affect surface temperature more than a small fraction of a degree. Then, on the side of inductive data, we have to consider whether the secular southward progress of identical climatic conditions would not be incompatible with that continuity of sedimentary conditions, which, especially in North America, has been traced from the thirty-fifth to the sixty-fifth degree of latitude; and whether a similar progress of identical faunal conditions would not introduce a progressive change in the correlation of life to the age of the strata, leaving the same types in older strata northward, and newer strata southward, while observation testifies that the same Hamilton types,

for instance, stretch from Missouri to Arctic America, and are enclosed in sediments of similar character throughout these limits. Aside from defects of particular arguments, and aside from any weight attributable to this essay, the question is one which will undoubtedly provoke competent and deliberate discussion. Mr. Scribner's monograph is well written, with some local diffuseness, and an occasional sentence of intolerable length, but, on the whole, a timely, suggestive, and pleasant little volume.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Rocky Mountain division. — Upon the organization of the survey, the area of the United States was divided into eight districts, in order that the progress of the work might be systematically facilitated. Of the four western districts, the 'Rocky Mountain district' includes the state of Colorado and the territories of New Mexico, Wyoming, and Montana.

Geologic work. — Colorado has been the principal field of geologic activity in the district; and the work has been carried on under the supervision of Mr. S. F. Emmons, who is the geologist in charge, with headquarters at Denver. The mining-geology of the state has been made the subject of special study, and the investigations have been confined mainly to questions of direct economic importance. Prior to 1883 the work done was principally in the Leadville and Ten-mile regions. Last season an examination of the Silver Cliff mining-district was undertaken. The geologic work was begun by Mr. Whitman Cross about the 1st of July, and was carried on through the summer, and completed in September. The topographic work had been previously completed. The preparation of the geologic map was intrusted to Messrs. Cross and Chapman, assistant geologists. Messrs. Jacob and Eakins were detailed to report on the mines and ore-deposits, under the personal supervision of Mr. Emmons. Mr. S. S. Sackett was engaged in gathering statistics as to the reduction of the ores of the district, and secured material for a chapter on the mills and reduction-works of the district.

The report on this mining-district will be of especial value, as the Silver Cliff is a mining-camp of abortive processes, a true history of which may well serve as a warning, by pointing out the errors, which there led to the failures in mining and in the reduction of the ores.

From the Silver Cliff district a short trip was made to the Sangre de Christo range, which lies on the opposite side of the valley. This was made with a view to determine the geologic relations of the Silver Cliff ore-deposits to the rocks of the range. Some field-work was also done by Mr. Cross on the mesozoic rocks exposed in the vicinity of Golden and of Morrison. In the Denver coal-basin progress was somewhat retarded by the absence of Mr. Karl, who has charge of the topographic survey of the region. Although temporarily suspended during the summer, work in this basin can be carried forward during the winter months, when the snow causes the abandonment of the field in the mountainous sections of the state. The map of the basin is to include some thirty square miles, on a scale of one mile to one inch. Information on the subject of the artesian wells in this basin is being secured, and will be embodied in the report. Voluminous rock-collections were made during the season, especially in the Silver Cliff district; and a special trip was made to Buffalo Peaks for the collection of typical specimens of hypersthene-andesite.

Besides the field-work, considerable office-work was accomplished. The notes on the Ten-mile district were worked up, and a geological map and sections of the area were made. Manuscript for the following monographs by the 'Rocky Mountian division' are in advanced stages of preparation: viz., 1°, Geology and mining industry of Leadville, by S. F. Emmons (an abstract of this paper appeared in the second annual report of the survey); 2°, Geology and mining industry of Ten mile district; 3°, Geology and mining industry of the Silver Creek district; 4°, The basaltic mesas near Golden, and their relation to the contiguous tertiary and cretaceous beds. During the season the bulletin on hypersthene-andesite, by Mr. Whitman Cross of this division, was published.

Laboratory work. — The laboratory at Denver is in charge of Mr. W. F. Hillebrand, chemist, who has been busy with the chemical and lithological examination of the rocks collected in the district, and on the ores from the various mining-districts. Some of the details of his work have already been given in *Science*. Mr. Whitman Cross has carried on the microscopical examination of the numerous thin rock-sections made of the rocks collected in the district.

Topographic work. — Mr. Anton Karl has been carrying on the topographic surveys in the district, and during the season of 1883 was in the Elk Mountains, mapping the Gunnison mining-region. His triangulation was based on Snow Mass and West Elk Mountains, two points located by the Hayden survey. These were occupied, and a system of triangulation was extended from them over the whole area surveyed. The principal mines in the Ruby basin, lying between Mount Owen and Irwin Peak, were all located, as well as Anthracite Mountain and the property of the Denver and South Park coal company. Topographical data were obtained for

mapping the Ruby and Irwin regions preliminary to future geologic work. The country lying between Beckwith, Marcellina, and Anthracite Mountains was also worked up, and each of those points occupied, and the valley of Ohio Creek surveyed. In the early part of September, work was begun in Poverty and Washington gulches and in Baxter basin, and the East River valley, between Schofield, Gothic, and Crested Buttes. Fair results were obtained, although severe snow-storms impeded progress. About the middle of the month Mr. Karl was directed to coöperate with special agent J. A. Bently, of the Interior department, to ascertain the accuracy of the Land-office survey of the Maxwell grant in southern Colorado and northern New Mexico. He was occupied on this work the remainder of the season, and in the latter part of November presented to the court a map prepared by him in support of his evidence.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Chemical society, Washington.

Feb. 28. —Mr. W. H. Seaman exhibited and described a new form of burette, and also a graduated pipette, modelled after the ordinary medicine-dropper. —— Prof. F. W. Clarke exhibited a copy of Lothar Meyer's curve of atomic volumes, drawn to large scale, with the most recent data. With it, upon the same sheet, was compared a similar curve of melting-point.

Biological society, Washington.

Feb. 23. — Dr. Elliott Coues read a paper on the present state of North-American ornithology. In discussing the precontemporaneous history of the subject, he defined the following epochs: 1, The archaic (prior to 1700); 2, The pre-Linnean (1700–50); 3, The post-Linnean (1750–1800); 4, The Wilsonian (1800–25); 5, The Audubonian (1825–50); and, 6, The Bairdian (1850+). A number of periods were also defined as follows: 1. The Lawsonian (1700–30); 2. The Catesbian (1730–48); 3. The Edwardsian (1748–58); 4. The Linnean (1758–66); 5. The Fosterian (1766–85); 6. The Pennantian (1785–90); 7. The Bartramian (1790–99); 8. The Vieillotian (1800–1808); 9. The Wilsonian (1808–24); 10. The Bonapartian (1824–31); 11. The Richardsonio-Swainsonian (1831–32); 12. The Nuttallian (1832–34); 13. The Audubonian (1834–53); 14. The Cassinian (1853–58); 15. The Bairdian. The establishment of the American ornithologists' union, he thought, would probably mark the establishment of a new epoch, — one in which the existing intricacies of ornithological nomenclature will be replaced by a consistent system founded upon a rational code: the present is simply a period of transition. Dr. Coues laid before the society the plate proofs of the forthcoming new edition of his Key to North-American ornithology.

Mr. C. D. Walcott exhibited a second time the rocks from Maine, containing fossil corals. He stated, that having received a number of additional specimens of the granite-like rock containing fossils, Stromatopora, corals, plates of crinoid stems, etc., from Litchfield, Me., he found that he had been incorrect in calling the rock a granite, as it was of sedimentary origin, — a clastic rock, so changed in the specimens examined that it might be called a conglomerate gneiss.

Prof. Lester F. Ward exhibited a specimen of the 'diamond willow,' — a variety of Salix cordata occurring in the upper Missouri region, distinguished by a great exaggeration of the scars left by the early growths of limbs which form series of large diamond-shaped cavities along the stems. He also exhibited some canes carved by the people of that region, which show the so-called diamonds in a striking manner. Professor Seaman advanced the theory that these scars are caused by the influence of some fungus or of some insect which lays its eggs in the buds.

Linnaean society, New York.

Feb. 8. — The publication of vol. ii. of the Transactions was ordered. —— Dr. C. Hart Merriam read a biography of the muskrat (Ondatra zibethicus), giving its life-history as noted by him in the Adirondack region of north-eastern New York. The paper was followed by a general discussion as to its differing habits in a less boreal locality. —— A translation from the Spanish of Rafael Montes de Oca by L. S. Foster, and the subsequent discussion, developed many interesting facts concerning the Trochilidae. —— Mr. William Dutcher remarked upon the scarcity of the snowy owl (Nyctea scandiaca) this winter on Long Island, and upon the presence in considerable numbers of the thick-billed guillemot (Lomvia arra), as well as the razor-billed auk (Utamania torda); while not a single sea-dove (Alle nigricans) had come under his observation. His Long Island records for the Ipswich sparrow (Passerculus princeps) give the capture of thirty-three specimens since their arrival, Dec. 16, after a severe snow-storm.

Academy of natural sciences, Philadelphia.

Jan. 22. — Mr. F. W. Putnam made a communication on a group of mounds occurring on the Miami River, which in many respects he considered the most important in the country. The methods of investigation, and the objects found in the mounds referred to, were described in detail, and illustrated by means of specimens and photographs. While no doubt exists as to the construction of mounds by some of our existing Indians, those he described had absolutely nothing in common with the more modern structures, except in so far as they indicated the Mongoloid type.

As the essentially fresh-water character of the worm Manayunkia speciosa (the forms related to

which are all marine) had not heretofore been unquestionably established, Mr. Edward Potts believed that it would be of interest to record that he had in his possession specimens from the Schuylkill River above the dam, and therefore from absolutely fresh water. The currents produced by the cilia on the tentacles were claimed to be excurrent, and not incurrent, as might have been expected, the feeding processes in some cases being performed by the tentacles themselves.

Jan. 29. — Prof. J. Leidy directed attention to a collection of fossil bones which had been submitted to his examination by the Smithsonian institution. They were obtained at the mine of the American salt company, near New Iberia, La. They chiefly consist of remains of Mastodon americanus, of Equus major, of an Equus not distinguishable from the domestic horse, and of Mylodon Harlani. Of the Mastodon, the collection contained well-preserved molar teeth, and characteristic fragments of bones. Of the Equus major, there are vertebrae, fragments of long bones, and a number of teeth. Of Mylodon, there are several molar teeth, vertebrae, and other bones, mostly fragments. Among these are two mature and well-preserved tibiae, the best specimens yet discovered of the species. They are identical in form and size with those of M. robustus, indicating M. Harlani to have been a species of the same size as the former.

Prof. J. Leidy stated that he had recently received for examination, from Mr. B. W. Thomas of Chicago, several glass slides with mounted specimens of sand. These were obtained by washing clay from the bowlder drift of Meeker county, Minn. In the specimens Professor Leidy recognized some well-preserved and characteristic foraminifera, of which two forms appeared identical with Sextularia globulosa and Rotalia globulosa, now living in the Atlantic Ocean. The fossils Mr. Thomas supposes to be derived from a soft yellow rock, cretaceous shale and lignite forming part of the drift. He also reports the finding of fragments of marine diatoms in the clay. Professor Heilprin suggested that the foraminifera referred to had probably been washed from underlying Silurian rocks.

Feb. 5. — A communication was read from Miss S. G. Foulke, describing a new species of rotifer under the name Apsilus bipera. The specimens were found in Fairmount Park; and, in common with all members of the genus, they possess, instead of rotatory organs, a membranous cup or net, which is used for the capture of food. The specific distinction of the form now described consists chiefly in the structure of the net, the presence of a true stomach in addition to the usual crop, and the presence of cilia inside the net. It was proposed to unite the forms Apsilus lentiformis Meczinchoff, Dictyophora vorax Leidy, Cupelopagus lucinedax Forbes, and the species now described, under one genus, Apsilus, in consequence of their strong points of resemblance. These are, briefly, the presence of two eye-spots, of a membranous crop instead of rotatory organs, of a mastax exactly alike in all, and the absence of a tail or foot-stalk.

Prof. H. Carvill Lewis announced the discovery of fossils in the triassic red shale from the neighborhood of Phoenixville, and gave a preliminary notice of them. They occurred in soft red rock at the southern entrance to the new tunnel, in strata dipping 10° N. 30° W., which would place the bed considerably below the strata of the old tunnel, perhaps a thousand feet, unless faults intervened. The specimens consist of some five distinct species of lamellibranch shells, a ganoid fish, some plants, and a doubtful fragment of a saurian bone. Among the shells are two species of Unio, somewhat resembling U. calceolus and U. lanceolatus of Lea. These are, of course, of fresh-water origin, and are found in single and double valves, and open. Three species of marine shells also occur in the collection; and the apparent commingling of fresh-water and marine species was referred to as an interesting fact. The shells, which in most instances lay parallel with the bedding, were frequently distorted by the movement of the shale. The Unios were regarded as probably the most ancient yet discovered, some specimens found in New Mexico being of later age. The coal-plants represented are fresh-water species, but reference was made to a triassic marine fucoid described by the speaker some years ago. The fish belongs to the lepidoganoids, and resembles the Catopteris gracilis of Redfield.

Engineers' club, Philadelphia.

Jan. 19. — Mr. Wilfred Lewis read a paper upon the resilience of steel, reviewing some of the means employed for the storage of energy, and showing the place occupied by steel among them. Among the means now employed, compressed air, hot water, and the storage battery were cited from an English writer as being about equal in value, and as giving out about 6,500 foot-pounds of work per pound of material used. Steel springs, according to the same writer, were said to yield about 18 foot-pounds per pound. In this connection, the project of using steel springs as a motor for street-cars was referred to as the most hopeless of all possible means of locomotion. To test the accuracy of this statement in regard to steel, several experiments were made by the writer upon tempered specimens, both for tension and flexure. Contrary to expectation, the highest results were shown by the flexure of a small spiral clock-spring weighing 2,040 grains, which gave out, when wound up, about 45 foot-pounds of energy; or, in other words, 154 foot-pounds per pound. The transverse strength of this steel, within the elastic limit, was found to be about 300,000 pounds per square inch, and its modulus of elasticity about 30,000,000. Such extraordinary strength, with such a low modulus, was so far beyond conjecture, that it seemed to give a new hope for the success of the project referred to; but, after making the necessary allowances for weight of car and efficiency of driving mechanism, it was found that not more than about 20 foot-pounds per pound of car would be available for locomotion. It was therefore improbable that such a car could ascend a hill over twenty feet high. It was also a matter of

doubt, whether larger springs could be made to show results which would even approach these figures; and on this account the experiments about to be tried might be looked for with some interest. —— Mr. H. C. Lüders exhibited specimen of rolled and annealed phosphor-bronze of maximum ductility, and consequently of minimum tensile strength, and submitted the following data of the test thereof: length, 2″; diameter, 0.57″; subjected to a strain of 13,620 pounds, equivalent to 53,400 pounds per square inch; elongation, 70.5 %; reduced area at point where fracture would occur, 0.3″; elastic limit, about 18,000 pounds per square inch. Hard-rolled rods, tested without turning off the surface, have shown a tenacity exceeding 90,000 pounds per square inch. —— Mr. Howard Murphy presented for Mr. Louis C. Madeira, jun., the Record of American and foreign shipping, containing an interesting set of drawings for the details of construction of iron ships. —— Mr. Percival Roberts, jun., gave some account of the results of experiments, now being conducted by Mr. James Christie at Pencoyd, upon the relative elasticity of iron and steel structural shapes.

NOTES AND NEWS.

WE noticed a fortnight ago the presentation of the Lyell medal of the Geological society of London to Professor Leidy; and we now learn that the council of the society at the same time awarded to Mr. Leo Lesquereux the sum of twenty pounds sterling from their Barlow Jameson fund, in recognition of the value of his services to geological science. The great extent and value of Mr. Lesquereux's contributions to our knowledge of the fossil flora of North America are well known, and will be still better appreciated when his volume on the tertiary plants, now completed, but not yet distributed, shall be issued.

— Any contributions that American biologists may feel disposed to make toward the Hermann Müller foundation, referred to in our last issue, can be sent direct to the treasurer of the committee, Wilhelm Thurmann, Lippstadt, Germany, or they will be receipted for and forwarded by Professor William Trelease, Madison, Wis.

— The death (March 2) is announced of Isaac Todhunter, whose name has been a terror to the average college-student of the present generation. He was born at Rye in 1820, and was senior wrangler in 1848. A large portion of his energy was devoted to the production of the invaluable mathematical text-books and treatises which are so well known.

— Capt. Bernard, in the course of a journey into the far interior of Algeria, twenty kilometres north of the Bou Saada River, found a singular flat-topped butte whose elongated rocky summit rises sixty-five feet vertically from the talus which crowns its sloping base. This place, called by the Algerians 'El Gueliaa,' forms a rocky table one hundred and seventy-five feet wide by six hundred feet long, reached by a stairway cut on the northern side. On this plateau has been erected a structure, still in a remarkable state of preservation, and, from the nature of its materials, apparently of Roman origin. On the east is a large rectangular stone building, containing eight or ten apartments opening upon an inner court. North of this building a vaulted cistern is dug in the rock: sixty feet to the west are two others, side by side, one vaulted over, and the second open to the sky. It is very difficult to say how these cisterns were filled, as there are no springs, or traces of wells, in the vicinity. It was evidently a post established for some special purpose. At Mesaad oasis a hillock thirty or thirty-five feet high bears the broken remains of a Roman gate. The Arabs have tunnelled or ditched the hillock for brick-clay; showing, that beneath the Roman remains now so long abandoned, and over the beds of chalk, salty earth, and clay, which form the mound, there are abundant remains of an earlier occupation, apparently for a considerable period, by a race whose stone weapons and tools, fragments of stone and ivory, and other rejectamenta, are their only memorial.

— The expedition charged by Russia with the task of exploring the ancient bed of the Oxus has concluded its work. The former path of the stream has been subjected to careful levelling from Khiva to the Caspian; proving that it is possible to turn the river into its old course only at the expense of a canal two hundred kilometres long, which is equivalent to a permanently adverse decision on its practicability.

— Signor F. P. Moreno, director of the anthropological museum of Buenos Ayres, was authorized in 1882 to undertake a journey into the interior of Bolivia for purposes of anthropological study. He now reports having visited the provinces of Cordoba, San Luis, and Mendoza as far as the slope of the Andes. During a year's travel he has studied the modern, as well as the traces of the former, inhabitants, and has exhumed in many places bones, weapons, inscriptions, and relics of burials, and has made plans and photographs of the remains of ancient villages. He believes he has obtained full material for a study of life in these regions before the Spanish conquest. He visited the whole extent of the so-called road of the Incas to the Uspallata Pass, when compelled to return by the advent of winter, and has pretty thoroughly explored the range of the same name.

— The material accumulated by the Krause brothers in Alaska, 1881–82, is being rapidly worked up. In the *Botanisches centralblatt* (Cassel, 1883, Nos. 41-43) Karl Müller publishes an account of the mosses of the Chukchi peninsula. He finds twenty-eight new out of seventy-five species collected, certainly a rather unusually large proportion. One of these, a cleistocarpous form allied to Voitia, is erected into a new genus by the name of Krauseella.

Dr. Hartlaub, in Cabanis's journal, enumerates the birds obtained at the head of Lynn Canal, near the mouth of the Chilkat River, S. E. Alaska. Lagopus leucurus, Certhia familiaris, Dendroica Townsendi, Sialia arctica, Chrysomitris pinus, Sphyropicus ruber, and Tinnunculus sparverius are noted as new to the region, though several of them may be only occa-

sional stragglers. The last mentioned has been observed on the Aleutian Islands.

In a late number of the *Deutsche geographische blätter*, Dr. Arthur Krause gives an interesting account of the houses of the T'linkit Indians, their methods of building, tools used, and modes of ornamentation. Iron was found at a very early date in the possession of the natives, but was without doubt procured by them from the Russian and Hudson Bay traders by a long but rapidly executed series of transfers from one band or tribe to another. In one year measles penetrated from British Columbia to Fort Yukon and beyond, and trade would take little longer.

Dr. Arzruni has reported on the minerals of the expedition in a paper read before the Gesellschaft für vaterländische kultur in Breslau. The rocks from widely separated portions of the territory indicated analogous geological structure, being chiefly of the oldest crystalline formations, — rocks belonging to the granite series, crystalline schists, and late tertiary volcanic ejections. Remarkable garnets were obtained from Fort Wrangell, and various gold ores from near Sitka.

— The Natural science association of Portland, Ore., has secured new quarters, and hopes soon to establish yearly courses of lectures. The annual address was given Feb. 6, by Prof. L. F. Henderson.

— Dr. D. G. Brinton, the well-known archeologist, has been elected professor of ethnology and archeology by the council of the Academy of natural sciences of Philadelphia, and is making arrangements for the delivery of a course of lectures on his specialty in connection with the department of instruction of the academy during the coming spring.

— Four scientific conventions are to be held in Washington in May, — that of the American medical association, the American surgical association, the American climatological association, and the American fish cultural association.

— The success of the borings for artesian wells at Denver, Col., seems to have encouraged the people of Montana to experiment in the same direction. A boring at Miles City, Montana Territory, on the Yellowstone River, struck flowing water at a depth of three hundred and forty-one feet. An analysis of the water proves it to contain more than sixty grains of carbonate of soda to the gallon. A second well has reached the depth of three hundred and twenty-one feet, without a flow of water. At Billings, nearly a hundred and fifty miles farther up the Yellowstone, a boring has been carried to a depth of nine hundred feet without success, but will be carried still farther down. At Helena, also, a well is being sunk; but work has been postponed until spring.

— Prof. W. Kitchen Parker gave the first of a course of nine lectures on mammalian descent, at the College of surgeons on Feb. 4. His remarks were of an introductory character, and were intended to aid the listener in comprehending the substance of the subsequent lectures. The subject of descent was viewed from an embryological and purely evolutional standpoint. The classification of the mammalia employed is that now generally in vogue among mammalogists, the class being divided into Prototheria, Metatheria, and Eutheria. It is to the consideration of the first and second of these sub-classes, and to the Ineducabilia among the Eutheria, that the majority of the lectures will be devoted. The lecturer expressed his belief in the former existence of a group of generalized forms, such as Huxley has described under the name of Hypotheria. Professor Parker's style is simple and pleasing, and, in the introductory lecture, highly poetical. His sentences are replete with biblical allusions, some of which border on the comical. He described the Metatheria, for example, as looking from the summit of their Pisgah toward the promised land of the Eutheria, into which they were never to enter.

— Mr. W. F. Denning was led to conclude, from certain markings discerned on the planet Mercury in the mornings of November, 1882, that its rotation-period is not accurately given in the text-books; the period of twenty-four hours derived from the observations of Schroeter and Harding, about the beginning of the present century, being apparently about one hour too short. His suspicion is now confirmed by a communication from Signor Schiaparelli, who has been very successful during the last two years in observing definite markings on Mercury, and who pronounces the planet's period of rotation, as usually given, 'very far from the truth.' His forthcoming memoir on Mercury is expected to give some very interesting details of the physical aspect of this planet. The necessarily unfavorable circumstances attending all observations of Mercury, make it not to be wondered at that little or nothing is known of its surface-phenomena; but Mr. Denning regards it as obvious that the markings are of a fairly distinct character, and likely to prove a fruitful subject for further investigation. He remarks that the general aspect of the disk, as seen in November, 1882, reminded him forcibly of Mars; and the definite nature of the spots may therefore be readily imagined. He thinks the dark spots and shadings may be regarded as fairly permanent, while the white spots are influenced by rapid variations.

— The following, from *Nature*, will interest our readers: —

On Tuesday afternoon [Feb. 5] at Oxford, convocation witnessed in the Sheldonian theatre the most exciting scene that has been enacted in the university since the opposition to Dean Stanley as select preacher. Last summer convocation passed by a small majority a vote of ten thousand pounds for a new physiological laboratory. The vote was opposed by the anti-vivisectionists, and by some on the ground of economy. A memorial got up by Mr. Nicholson against vivisection having produced no effect on the council, the opponents of Professor Burdon Sanderson determined to oppose the decree brought before convocation on Tuesday for empowering the sale of stocks for the ten thousand pounds voted last

June. The decree was supported by the dean of Christ church, Dr. Acland, and the warden of Keble, and was opposed by Professor Freeman and Mr. Nicholson. After a stormy debate, the vote was carried by a hundred and eighty-eight votes against a hundred and forty-seven. The result was received with enthusiasm, and Oxford is to be congratulated on it. To what shifts Dr. Sanderson's opponents were put may be seen from what the *Times* calls 'the most astonishing speech' of Mr. Freeman the historian, "who afforded a curious example of the confusion of thought into which even intelligent men may be led by an over-indulgence in sentiment. It would be as reasonable, said Mr. Freeman, for the historian to illustrate the festivities of Kenilworth by an actual bull-baiting, as for the physiologist to experiment upon living animals. Mr. Freeman, in his zeal to establish the scientific character of the historian, forgets the difference between description and discovery, and ignores the fact that the physiologist, at least under the existing law, makes his experiments, not for the instruction of pupils, but with a view to discover what is as yet unknown. A more curious article in the indictment against vivisection we have not met with since the celebrated letter in which Sir George Duckett told the royal commission that he had no evidence to give, but that he considered vivisection 'an abomination introduced from the continent, going hand in hand with atheism.'" The *Times*, in its leader on the subject, treats it sensibly and moderately. "All those who are open to argument have been long ago convinced that Science cannot proceed on her beneficent way without the aid of experiments, some of which must be painful; and those who are not open to argument, and those who believe, like some of the wiseacres whose opinion is on record, that 'medical science has arrived probably at its extreme limits,' are not likely to be convinced by any thing that can be said or by any facts that can be brought against them. Parliament, on the recommendation of one of the strongest royal commissions ever appointed, has legislated in the matter, and physiological experiment is now under limitations as severe as it is possible for it to be consistently with any kind of progress in discovery. Abuses are of the rarest occurrence. Men like Dr. Sanderson are not only humane, but they are conscious that public opinion is awake on the matter; and their discretion as to what should be done, and what should not, is absolutely to be trusted. It is to be hoped that the sensible action of convocation will not only encourage the Waynflete professor to proceed as his scientific conscience may guide him, but will convince the well-meaning but irrational opponents of scientific freedom that further action on their part would be not only vexatious, but unsuccessful."

— Professor Nehring has reported to the Berlin anthropological society the discovery, in a cave near the village of Holzon in Brunswick, of bones which show proofs of cannibal practices. It is the first evidence discovered, that a race of anthropophagi ever existed in Germany. The bones were not fully calcined, and had evidently been chopped to obtain the marrow. As a still greater proof of cannibalism, it was shown that the bones were thrown in a heap, as if cleared after a meal. Other objects of interest, such as rough bronze ornaments, were found in the cave; and, on excavating a lower stratum of the floor, bones of animals of the glacial period were found, showing the existence of the cave at that time. In the subsequent discussion, Professor Virchow raised some objections to the cannibal theory.

— A society with Dr. C. F. Millspaugh as president has been formed at Binghampton, N.Y., under the title of the Erosophian microscopical society. It has some forty or fifty members.

— *Papilio*, on its removal to Philadelphia, no longer appears as 'the organ of the New York entomological club;' but in other respects it does not differ noticeably, as the new editor, Mr. Aaron, has evidently endeavored to preserve the character of the journal, even to typographical details. As is fitting, considering its name, it is still 'devoted exclusively to Lepidoptera,' and renders the lovers of those insects good service.

— A memorial volume of the scientific papers of the late W. A. Forbes, at the time of his death prosector of the Zoölogical society of London, is to be published, through a committee consisting of Professors Flower and Bell, and Messrs. Johnston, Mivart, and Sclater, at the price of one guinea. Mr. Sclater will edit the volume, Mr. Johnston will add a biography, and Mr. F. Jeffrey Bell (5 Radnor Place, Gloucester Square, London) will act as secretary and treasurer.

— In his presidential address before the Biological society of Washington, on "Certain phases in the geological history of the North-American continent, biologically considered," Dr. C. A. White shows how important to a knowledge of the evolution of the continent is a study of terrestrial and fresh-water faunas and floras of geological times.

— Dr. C. B. Reichert, for many years director of the anatomical museum at Berlin, died in that city, Dec. 21, 1883.

— Prof. H. Carvill Lewis, A.M., recently appointed lecturer on geology and paleontology at Haverford college, gave his first lecture last week Wednesday, upon 'The foundation-stones of Pennsylvania.' This week's subject was 'The ancient life-history of the Chester valley;' and in following weeks 'The origin of the Pennsylvania mountains,' 'Volcanic action in Chester and Montgomery counties,' 'The geology of Haverford and its vicinity,' 'The glacial epoch in Pennsylvania,' will be treated. The lectures are open to the public.

— The seventh Saturday lecture in the National museum was on Feb. 16, by Prof. E. D. Cope, on the 'Origin of human physiognomy and character,' — a discourse the main features of which have already been published in the *American naturalist*. On Feb. 23 Mr. John Murdock, late of the signal-service party at the Oglaamie station, North Alaska, gave a very vivid account of 'Eskimo life at Point Barrow.'

GRANITE FALLS, A SCENE IN THE INNER GORGE OF KAIBAB DISTRICT, GRAND CAÑON OF THE COLORADO.

SCIENCE.

FRIDAY, MARCH 14, 1884.

COMMENT AND CRITICISM.

If one wishes to study man, it may be desirable to seek large cities, where men abound in great numbers and in almost infinite variety; but, if nature is to be questioned and cross-examined, it is wise to betake one's self to the fields, the woods, and the mountains, over which the artificial has not yet gained control. In the study of various problems in terrestrial physics, it is of the utmost importance to place the observing-stations so that they may fairly represent general conditions, and not be influenced by merely local disturbances; and it has long been customary to give such considerations proper weight in the selection of points at which various physical constants are to be determined. An article in the present issue, on the exposure of thermometers, furnishes evidence that it is quite possible for large cities to be fortunate in the possession of a climate which is largely artificial; that a meteorology which is based on observations taken under such artificial or peculiar conditions is likely, now and then, to go astray; and that in physics, as in politics, it is sometimes safe to await 'returns from the country.'

If the earth be represented by a globe sixteen inches in diameter, the largest city in the world will hardly be visible to the naked eye; and yet in most large cities there will be found to exist a set of meteorological conditions differing considerably from those of the surrounding country. It is not likely that difference exists alone in temperature, or that it is not noticeable, and worthy of serious attention, in other elements which go to make up 'the weather;' and it would appear desirable for working-meteorologists to agree upon some systematic plan of investigation which might result in the determination of the proper location and exposure of their instruments, that they may more truthfully exhibit the average condition of the area which they represent.

The close connection and interaction of religion, statescraft, and science in the modern world is illustrated in an interesting way in a recent number of the *Proceedings of the Royal society of London*. The British government, desiring to introduce cheese-making as an Indian industry, was met by the difficulty that the religious beliefs of a large portion of the population of India placed an absolute veto on the use by them of cheese, in the manufacture of which rennet obtained from the stomach of an animal had been employed. The leaves of a species of Pinguicula are used by the Laps to coagulate reindeer-milk; and the government circulated in India a request for information as to any Indian plant which was known to have a similar property. Surgeon-Major Aitchison called attention to Withania coagulans, a Himalayan and northern India plant, the seeds of which were said to coagulate milk. A quantity of this material was sent from Kew to Mr. Sheridan Lea of Cambridge for examination. He was able to extract from it a ferment identical with the rennet ferment of the gastric mucous membrane of animals, and capable of preservation in solution as a commercial article in a similar way. The ferment exists in the seeds in considerable quantity, and is readily and cheaply extracted from them.

Of the 'change in the unit of time' controversy, to which we alluded in a late issue, there seems as yet no likelihood of abatement. Originally begun by Mr. Stone, lately her Majesty's astronomer at the Cape of Good Hope, it was at once participated in by Sir George Airy, the late astronomer royal, by Professor Newcomb, and later by a number of continental astronomers. When the Royal astronomi-

cal society met last autumn, Mr. Christie, the present astronomer royal, declared the subject "pretty well thrashed out, and quite unsuitable for discussion at their meetings." Since that time, both sides have had important accessions; no less a person than Col. Tennant, of her Majesty's mint, Calcutta, taking essentially the same view with Mr. Stone, and Professors Cayley and Adams coming forward with the clearest of proof that no such deviations as those indicated by Mr. Stone exist.

At first blush, it will seem very improbable that an astronomer of Mr. Stone's well-earned reputation for acuteness should get muddled in a matter of fundamental astronomy involving only simple algebra; but when he finds himself unable to clarify, after a half-dozen astronomers more able than himself have been endeavoring for six months to convince him of his fallacy, it can scarcely be called rash heterodoxy to suggest that an error on the part of his opponents may be at least among the possibilities. Although he is now aware that it may appear useless to continue researches of which the fundamental principle is disputed by astronomers of note, his latest utterance is, "I have not seen at present any evidence which weakens in the slightest degree my confidence in the accuracy of my results." It is very difficult for the non-mathematical to recognize the possibility of a mathematical dispute, even when the terms involved are of slight importance; but no sort of excuse can appear for a difference regarding a supposed discrepancy of this magnitude, involving the early disruption of fundamental tables of the celestial motions. Unless, then, this matter admits of speedy and permanent decision, the one way or the other, with the entire agreement of all parties to the controversy, astronomy would appear to run the serious risk of forfeiting her claim to a place among the exact sciences.

ONE of the indications of the activity in chemical matters in Germany may be found in the great prosperity of the Berlin chemical society. This organization dates only from the year 1868, when it was started under the auspices of the Berlin chemists, headed by the genial Hofmann. In that year the volume containing the articles communicated to the society numbered only about two hundred and eighty pages. In a short time the society became a national instead of a local affair, fully deserving the name, '*Deutsche chemische gesellschaft*,' given to it at the outset. According to the last annual report, the number of members is now nearly three thousand; an increase of about two hundred having been made during the past year. The last annual volume published by the society numbers over three thousand pages. Of the members, eight hundred and forty-eight are foreigners; the largest number (one hundred and eighty-four) of these being English, while there are one hundred and forty-five Americans; and one hundred and forty-four Swiss, on the list. It will be seen that more than two-thirds, or about two thousand, of the members, are Germans.

It would lead too far to discuss fully the causes of the activity thus indicated. One of the most potent direct causes is, no doubt, the close bond of connection that has been established in Germany between pure chemistry and its industrial applications. While there is, perhaps, no country in which the maxim 'Science for the sake of science' is more frequently heard or more firmly believed in than in Germany, it is equally true that in this same country the most successful applications of the truths established by the votaries of pure chemistry have been made. Industries are there springing up every year, founded directly upon the most recent discoveries made in the university laboratories. Large numbers of thoroughly trained chemists are employed in the new factories. The value of science in carrying on industrial operations is fully recognized. It is certainly instructive to note that this state of things has been brought about by devotion to pure science. The much talked of 'practical man' who wants 'none of your theories' is not a common phenomenon in Germany.

THE notice in another column, of the pamphlet by Mr. Frank B. Scott, calls attention to a class of publications which belong to the idiosyncrasies of scientific writings. The law of variation among men involves the occasional occurrence of an extreme departure in any given direction from the normal average; and it is quite in accordance therewith that there should be from time to time a writer who seriously propounds startling views on a scientific subject about which he is ignorant. Such a person is one who is both very inexperienced and thoroughly unpractical, yet perhaps really intelligent. Something arrests his attention. He begins thinking about it, and finds a series of superficial or casual resemblances, which leads to a grand general conception. Startled and delighted, he eagerly hunts up some text-book: it contains no hint of the grand conception. The thought is then new. With feverish excitement, a few facts are patched together out of a fragmentary and too often inaccurate knowledge, and the idea is confirmed. The theory is then given to the world, condemned by the critics, laughed over as a choice bit by a few, and then forgotten according to its deserts. Fortunate is the author if he gains in experience what he does not secure in fame.

ATTENTION has recently been called to the bill for the establishment of 'national experiment-stations,' now pending before Congress, by a circular sent out by President S. A. Knapp of the Iowa agricultural college, who is the chairman of a committee appointed in January, 1883, by the U. S. department of agriculture, to have the matter in charge. The most interesting portion of the circular is, of course, the text of the bill. This provides for the establishment, at every agricultural college which possesses an improved farm, of a 'national experiment-station.' These stations are to be under the general control of the regents or trustees of the colleges where they are located; and the general character of the work to be done at each station is to be determined by the U. S. commissioner of agriculture, the president of the college, and the director or superintendent of the station. The sum of fifteen thousand dollars is to be appropriated to each such station, but only so much of this sum is to be paid over to the station as will cover expenditures actually incurred.

The objects aimed at in this bill appear to be twofold, — first, to promote the advance of a scientific knowledge of agriculture; and, second, to unify to a certain extent the work of investigation now carried on at scattered and independent centres. To the first of these objects it would seem that no one could take exception. If it be admitted to be within the province of the national government to aid at all the advancement of science, it would certainly seem that a branch of applied science which touches the every-day interests of fully half our people, and which deals with a calling which is one of the chief sources of our national wealth, might reasonably claim a portion of that bounty which is so freely extended to other sciences, especially since the experience of Europe, and of several states in this country, has abundantly demonstrated the great utility of such stations. Certainly such an expenditure of the public money is at least as legitimate as river and harbor appropriations or arrears of pensions acts.

As regards the second object of the bill, while it may be desirable, it is not so certain that it can be readily attained. It may be lamentable, but it certainly is a fact, that scientific men do not work well in harness, and are apt to entertain extreme ideas of the value of personal independence in their work. Much would depend upon the character of the commissioner of agriculture. No man fit for the position of director of an experiment-station would be likely to consent to conduct that station according to a plan laid out in Washington. On the other hand, if the commissioner were a man whose personal character and scientific attainments commanded respect, he would have an opportunity which, if judiciously used, could not fail to bring honor to him, and profit to the interests of agriculture.

Should the bill pass, it is not impossible that one of its benefits might be, that it would render more difficult the appointment to the responsible post of commissioner of agriculture of individuals such as some who have in the past held without filling that position.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Red sunsets and precipitation.

THE readers of the scientific journals have, no doubt, observed that the prevailing explanation for the red sunsets and colored sky during the past few months is that of chromatic diffusion of light by volcanic-ash particles. There are some apparent incongruities as pointed out by Mr. Proctor and others; but we believe that the established physical laws will permit a satisfactory solution of the phenomena, assuming volcanic matter as the cause.

The object of this letter is to notice what seems to the writer a probable connection between the conspicuous sunset colors and the excessive cloudiness and precipitation during the last month or six weeks. With regard to precipitation we must recognize Professor Aitken's discovery; viz., that clouds and all forms of precipitation occur by virtue of the solid particles of matter suspended in the atmosphere, serving as nuclei upon which the aqueous vapor is condensed. The supply of this solid matter in the aggregate is nearly uniform; but, if an excess occur from any cause, we should expect a larger precipitation for the same hygroscopic state of the atmosphere. This conclusion, we believe, has been verified during the past two months, in meteorological observations. It might be argued that the cloudiness and rain have not been evenly distributed, as would be expected if caused by the settling of the ash-particles; but in what has been said, no regard is taken of the various causes for an unequal distribution of the matter, and the common conditions of storms. We should expect weather-records to show the greater precipitation in regions where the sky colors have been most conspicuous. The writer, however, has no data for verifying this.

The above is advanced rather as a suggestion than as an exposition, in the hope that it may stimulate a more exhaustive study of this connection, if such there is. W. H. HOWARD.

Does Unio spin a byssus?

Attached to the female of a Unio which I collected, last August, from the middle fork of the Holston River, at Marion, Va., were stones, some of them more than an inch in diameter. So strongly were these attached that not only could they be lifted from the water by the attachment, but it took considerable force to separate them from the Unio. I had often seen Unio shells covered with gravel and mud firmly cemented by the Confervae that commonly grow upon the anterior portion of the valves exposed above the water; but these shells under consideration were unusually free from such growths. At the time, I removed the pebbles without giving attention to the phenomenon; but, recurring to it afterwards, I found, on examination, what appeared to be *the bases of byssi*, situated at about the middle of the anterior fourth of each valve.

Again: these were only found on females, all of which were gravid, having the eggs well developed. Is it a provision to prevent the strong current of this river from sweeping them into unsuitable spawning-grounds while depositing their eggs? Are these byssi (?) *seasonal*, or *permanent?* If byssi, how are they spun? E. P. LARKIN.

Retrograde metamorphosis of a strawberry-flower.

Mr. J. H. Foster of Orange county, Fla., sends a monstrous form of a strawberry-blossom, which is shown in the accompanying engraving. During the winter there were several hard frosts which blasted many of the strawberry-flowers in Florida. This injurious weather may have been the cause of the strange malformation. The engraving shows the flower-stalk,

a, raised from its reclining position. The calyx-lobes are at *b*, *b*, *b*, and within these is a circle of stamens. In place of the fleshy receptacle, so much relished by all when ripe, there is a small strawberry-plant, *c*, with its short stem, and a root, *d*, springing from near its base. This root, doubtless, penetrated the soil soon after it started out from the stem, and became a source of nourishment for the young plant. The base of the stem has many undeveloped pistils scattered over its surface, which plainly show that the plant is a transformed receptacle. The young leaves, when unfolded, are of the normal form, consisting of three wedge-shaped, coarsely serrated leaflets.

Flowers, and in fact all organs of plants, have been known to undergo strange changes of form. All gradations may be found, from one set of floral organs to another. This is seen between petals and stamens in almost every white water-lily, and between stamens and pistils in willow, apple, poppy, and other blossoms. Stamens are changed into, or become, petals in the familiar process of the 'doubling' of flowers. This tendency to retrograde is carried still farther when both the stamens and pistils become green, leafy expansions, and thus reveal their true nature. In many cases the floral axis is prolonged beyond one or more circles of floral organs, and the stem again assumes the ordinary leaf-bearing form. Such a metamorphosis sometimes takes place in an apple or pear blossom; and as a result, there may be a fully developed fruit, with a leafy branch extending beyond the blossom end (basin).

The metamorphosis which has taken place in the strawberry-flower shown in the engraving is in the line of our expectation: the strawberry-plant propagates itself readily and rapidly by slender branches sent off from the base of the parent-plant. Each one of these runners strikes root at its apex, and soon develops a tuft of leaves and an independent plant. In the case discovered by Mr. Foster, this strong tendency to increase by runners is carried out by a flower-stem with a frost-injured blossom lying upon the moist earth.

BYRON D. HALSTED.

The reproduction of Clathrulina elegans.

In *Science*, iii. 55, is published a *résumé* of Miss S. G. Foulke's remarks before the Philadelphia academy of natural sciences in reference to the reproductive methods of Clathrulina elegans; her statements being apparently confined chiefly to a process by quadruple subdivision of the body into uniflagellate organisms as observed by herself, with allusion to three additional processes as observed by others. In August, 1881, the writer repeatedly witnessed two forms of reproduction with this rhizopod, in some respects quite different from what was observed or mentioned by Miss Foulke.

The body of Clathrulina in no instance withdrew its rays before subdivision, but underwent transverse binary fission; each part, even after complete separation, retaining its pseudopodal rays fully extended. Soon after dividing, however, one part became perfectly smooth, having possessed up to this point a conspicuous pulsating vacuole, which now curiously contracted, and did not re-appear. The remaining half of the original body underwent no change except that caused by the protrusion of rays from the freshly divided surface.

The recently separated portion then slowly passed out of the capsule, forming, just before its escape, two vibratile flagella of unequal length. Its movements began immediately, being only moderately active, and continuing for less than two minutes, when it suddenly lifted itself upon the flagella-bearing end, and instantaneously collapsed into a shapeless mass studded with short blunt pseudopodia, which almost as quickly became filiform; and the zooid was an Actinophrys-like creature, with two flagella trembling at its front. The latter were soon lost among the rays, and the animal at once began to form the pedicle by a slow extrusion of the body-sarcode. The whole process consumed about three hours.

From the same gathering I was also fortunate enough to learn how Clathrulina produces the colonies occasionally met with. The process, up to the escape of the biflagellate zooid, even with the strange conduct of the contractile vesicle, was as just described. The longer of the flagella, however, terminated in a conspicuous bulb-like enlargement, which remained within, but was not attached to, the parent-shell. The vibrations of the short lash gave the zooid a rapid rotatory and oscillating movement, the anchoring bulb slipping freely from side to side of the opening in the lattice. Motion continued for perhaps five minutes. The obovate body then became rounded, the smooth surface roughened by irregular protrusions extending into filiform rays, until another flagellate Actinophrys-like creature appeared, loosely anchored to a Clathrulina lattice. It remained motionless on the extremity of the apparently rigid bulb-bearing lash, which I supposed would become the pedicle; but in a few moments an unusually thick pseudopodium was extruded, and attached by an expanded base to the capsule. On this the Actinophrys, with all its rays extended, was slowly lifted to the required distance above the parent; while the anchoring flagellum became more and more attenuated, the bulb less and less noticeable, until both finally disappeared.

It seems, then, that Clathrulina elegans has six reproductive methods, — "by self-division, by the instantaneous throwing-off of a small mass of sarcode, by the formation and liberation of minute germs," by the quadruple subdivision of the body into uniflagellate organisms, by the separation from the body of a free-swimming Heteromita-like zooid for the dissemination of the species, and by a similar body-fission whose resulting biflagellate organism is anchored to the parent-capsule for the formation of a colony.

Trenton, N. J.

Formation of anchor-ice.

On the 17th of January, this year, I had occasion to cross the River St. Lawrence in one of the small Indian ferryboats which ply between the Indian village of Caughnawaga, on the south shore, and Lachine, on the Island of Montreal. The current of the river at this point flows at the rate of four or five miles an hour, I think, and never freezes over. The day was quite stormy, the thermometer indicated about 12° or 15° F.; and the river was pretty thickly covered with cakes and masses of porous or very snowy ice. But the most peculiar phenomenon was the sudden and almost incessant rising of dark, muddy ice from the bottom of the river. The formation of this ice so far below the surface of the water is supposed to take place in very cold weather, when large masses of snow, descending the river, become saturated with water, and are carried by the current to the bottom, where they stick to the rocks and stones, clinging more firmly and becoming more compact as long as cold weather continues. At least, this is the theory that the Indians advanced. The ice may be seen six or eight feet under water, and often accumulates until it forms miniature islands. When it rises, it often lifts considerable quantities of small stones and gravel to the surface.

Another peculiar circumstance is, that this rising of the ice from the bed of the river always occurs a day or two before the approach of mild weather; and the Indians regard this phenomenon as an infallible presage of milder weather within forty-eight hours. The cause is most likely atmospheric, but I record the observation with the hope that it may be a hint to some one willing to make a further study of the subject.

J. G. J.

Chateauguay Basin, P. Q., Canada.

Manayunkia speciosa.

In this worm, described and figured by Leidy (*Proc. acad. nat. sc. Philad.*, 1883), the tentacular crown, or branchial organ, is the feature of special interest.

According to Leidy, the tentacles present in an adult are eighteen in number, besides two larger and longer tentacles situated dorsally, midway between the two lophophores. These larger tentacles are conspicuous by their bright green color, and are, in fact, external continuations of the blood-vessels extending lengthwise throughout the body. In shape these tentacles taper from base to apex, are convex on the outside, but concave on that side facing the centre of the tentacular crown; so that a transverse section would present the shape of a crescent. The two longitudinal edges thus formed are fringed with cilia. When closely watched, the green tentacles are seen to pulsate with a rhythmical motion, contracting and expanding laterally. The pulsation takes place in each tentacle alternately. At the moment of contraction the tentacle turns slightly on its axis outwards, and towards the end of the lophophore on that side, at the same time giving a backward jerk, returning to its former position at the moment of expansion. By force of the contraction the green blood filling the tentacles is forced downwards, out of the tentacle, and flows along the blood-vessel on that

side of the body. On the expanding of the tentacle the blood instantly returns, and suffuses it; and thus the process goes on. The contraction and expansion occur at regular intervals, together occupying the space of two seconds. It is in this way that the blood is purified and the circulation controlled. The above observations were made with a seven-eighths inch objective, the subject being placed in a zoöphyte-trough.

To ascertain how long the cilia upon the tentacles would continue their motion after separation from the worm, both lophophores of an adult were cut off above their own junction. At first the tentacles remained closed: but soon they expanded, the cilia displaying active motion; and presently the two separated lopophores began to move about in the zoöphyte-trough. This motion was produced by the action of the tentacles, which bent in all directions, their tips touching the glass, and was not a result of ciliary currents. In a few minutes one lophophore had *crawled* in this manner quite across the trough, while the other remained floating in the water near its first position. Sometimes the motion was produced by ciliary currents, the tentacles remaining motionless; but this was quite distinct from the *crawling* above noted.

During this time the decapitated worm had sunk to the bottom, and, though twisting and turning a good deal, did not attempt to protrude the mutilated support of the lophophores. Its body was so much contracted that the segments were not above one-third their usual size.

At the end of five hours the worm was apparently dead; numbers of infusoria had collected to prey upon it; and the surface of its body presented a roughened appearance, as though covered with tubercles. The lophophores were still in motion. At the end of the eighth hour the lophophores had ceased to move, and were paler and more transparent; but the ciliary action, though feeble and uncertain, still continued. The body of the worm was then covered with a thick fungoid growth, consisting of transparent, rod-like filaments, three-sixteenths of an inch in length, some of the filaments having a beaded appearance. All motion of the cilia upon the tentacles had now ceased, and these latter were also the prey of infusoria.

The above experiment showed that the independent motion of the cilia continued about twice as long as the mutilated worm gave evidence of vitality. Several individuals of Manayunkia were observed to be preyed upon while still alive by large monads, embedded in one or more segments, which were sometimes excavated to a considerable degree.

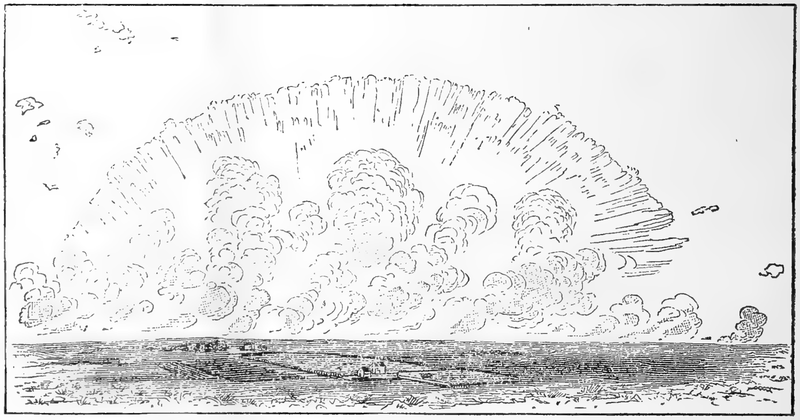
SARA GWENDOLEN FOULKE.

Appearance of the cyclone cloud at Rochester, Minn., 1883.

On Tuesday, Aug. 21, I left Minneapolis at three o'clock in the afternoon for Albert Lea, Io.

Late in the afternoon my attention was attracted to a remarkable storm-cloud that lay along the eastern horizon. As the sun grew low in the west, this cloud assumed most extraordinary proportions and colors; so much so, that it attracted almost universal attention. A strange, fan-like sheet of yellowish cloud, with broken but decided margin, rose above the centre of the storm like a great halo. It did not seem to stand in a vertical position, but projected above, toward the west, giving the effect of a huge funnel, viewed from below, on the exterior surface of which the descending sun cast shadows, and brought out a sort of radiate ribbed structure.

Beneath this was a great cluster of swelling cumulus 'thunder-heads,' whose bases were hidden by the horizon. Three of these, higher than the others, rose vertically from the centre of the mass; their magnificent fleece-like heads entering and apparently penetrating the yellow halo. These, especially the middle and largest one, glowed brilliantly in the strong sunlight, and cast long blue shadows down the inclined under-surface of the halo.



Encircling this brilliant mass were a number of enormous 'thunder-heads' of a most murky and forbidding appearance, that stood upright, like so many pillars of dense smoke. These upright clouds inclined a little to the east or south-east, indicating a movement in that direction.

There was a remarkable stability about the whole mass of clouds, and at sunset the effect was grand in the extreme. The sky about was clear, with the exception of isolated masses of cumulus-cloud.

I made a small pencil-sketch of the cloud-forms, with notes of color, and, since my return to Washington, have made a drawing in color.

I estimated that the cloud was from forty to fifty miles east of the railway, and, on studying the map carefully, became convinced that this was the cloud attending the great cyclone at Rochester. My attention was not called to the cloud until after five o'clock, at which time it was directly east of me, at Wilton. As the course of the cyclone was a little to the north of east, the movement was directly from me when the sketch was made.

The peculiar form of the halo, whether fan or funnel shaped, was doubtless, in a measure, the result of the movements of the storm-currents.

Geological survey, Washington.

Stones placed in pine-trees by birds.

About seventy-five miles south of the United States boundary, near this place, at an elevation of six thousand feet, is a stretch of table-lands covered with large pines (Pinus Jeffreysi?), broken by many ridges of giant granite bowlders, decomposing sufficiently to add materially to the soil. Broad, grassy meadows furnish food for cattle and deer.

My father and myself, in riding through this forest in July, 1883, noticed several pines with the bark bored into at varying distances from the base of the tree to the branches; and in about one-third of the holes were the acorns of the here common Quercus Emoryi, very tightly fitted, the holes containing the acorns apparently newly made. The remaining holes were weather-beaten; and in them were equally tightly fitted bits of the granite gravel, of size corresponding with the acorns in the other holes. In the Cuyamaca Mountains, of this county, a gentleman observed Colaptes auratus visit pines that contained similarly disposed acorns. The woodpecker tapped the acorns, breaking one now and then; the broken shells showing plain traces of having contained a worm, while the other acorns contained sound kernels. But what object could the birds have in substituting stones as shown above? Possibly they served as hiding-places for many insects which would otherwise have secured places inaccessible to the birds. C. R. ORCUTT.

San Diego, Cal., Feb. 16.

How a spider sometimes lifts heavy objects to its nest.

Last summer, while at Lynchburg, Va., I observed a spider — probably an Epeira — spinning a thread down from the upper section of a large fountain on the lawn of the Arlington hotel. He was some eight feet from the surface. I watched him descend to the water, where he captured a beetle that had unfortunately fallen into the large basin. The beetle must have been an inch long. Our Epeira made a turn of his line around his captive, and ascended all the way to his nest; immediately descending, he threw another loop around his prey, and again ascended to his nest, continuing this process for full ten minutes: to my surprise, while the spider was at his web, apparently overhauling and tightening the several threads that he had spun to and from the beetle, it left the water, and, evidently by elastic contraction of the threads, ascended full an inch from the surface. The spider spun down another lasso, and threw it round his victim, then retired and was busy with his lines, when the beetle again moved upwards. These operations were repeated, until, at the end of forty-five minutes, he had snugly secured his prey in his nest, at a distance of at least eight feet from the water, by this curious and interesting method.

Cambridge, March 3. E. P. LARKIN.

The use of the method of limits in mathematical teaching.

I notice in a recent number of *Science* a proposal to discuss the different methods of teaching the elements of the infinitesimal calculus, and, in connection with this, an allusion to Professors Rice and Johnson's 'New method of rates.'

I trust it is not out of place to suggest that the method in question seems to me very like the method given in Maclaurin's 'Fluxions,' which the author attributes, at least partially, to Newton; and that the present very general use of the method of limits is probably a case of 'the survival of the fittest:' for I have found in my experience as a teacher that those who are either too young or too slow to acquire at once the deeper conceptions of mathematics are often capable of doing very good work when the demonstrations are adapted to their comprehension.

The method of limits seems to me that which must be used with a class, if it is desired to give a sure foundation to as many as possible; the method of rates or fluxions requires rather more preparation of mind; and the infinitesimal method is best adapted to those who have mathematical genius.

The average engineer or architect is a person whose natural bent is towards construction and the use of tools. Such a person will, in all probability, require the infinitesimal calculus as a tool rather than as a recreation or a profession, and should therefore be trained by a slow and certain process — like the method of limits — in order that his real abilities may not be disguised by any slowness of comprehension in a matter which he can by patience acquire.

The weakness of mathematics as a general study in our institutions lies in the rapidity with which the successive steps are passed over; so that the slower pupils are left behind, and become discouraged. Old country schools do more solid work in average cases.

TRUMAN HENRY SAFFORD.

Williams college, March 1.

THE INTERNATIONAL BUREAU OF WEIGHTS AND MEASURES.[1]

THE annual report of operations for 1883 has just been received. It shows a steady advance towards the completion of the international standards. All the principal instruments and apparatus have now been procured, and are in position. The *comparateur géodésique*, for which a contract was made with the *Société Génevoise* in 1882, was to have been delivered by August of last year. Various events conspired to delay its complete delivery; but at the close of the report the entire apparatus was on its way, and was to be set up in the early part of January. All necessary masonry work was done in the spring of 1883.

Changes have been made in the method of heating the room of the Brunner comparator. Hitherto it has been done by regulating the temperature of water held between the double zinc walls in which the room is enclosed. It has been found, however, that, in addition to the difficulty and expense of maintaining a constant temperature of the water day and night, trouble was experienced from frequent leaks in the zinc walls, necessitating repairs, and stopping the observations: consequently the maintenance of temperature by the use of hot water has been discontinued; and for it has been substituted hot air, which so far has proved satisfactory, and which, it is hoped, will solve the problem of heating.

[1] Comité international des poids et mesures. Septième rapport aux gouvernements signataires de la convention du mètre sur l'exercice de 1883. Paris, 1884. 54 p. 4°. See also *Science*, No. 16.

Observations made in the upper vault, five metres under ground, show that the daily variation of temperature is insensible, and that the annual range is only a few degrees. As it is apparently water-tight, it will serve as a safe place of deposit for the standards. In the lower vault, ten metres under ground, the temperature is steady at 11° C. throughout the year. At present there is trouble from moisture. Steps are taking to overcome this difficulty; and, when they are complete, the chamber will be ready for the reception of the prototypes.

The examination of the universal comparator has been completed, and all values determined save the final errors of division of the two-metre scale. Certain auxiliary scales needed for this work were ordered, and have just been received.

Modifications are being made on the Brunner comparator to admit of comparisons of metres under water.

The report for 1882 showed that the balance for vacuum-weighings had been received; but certain defects of construction were found to exist, and it was returned to the makers to have them remedied. It was again received last autumn, and now appears to maintain a vacuum in a satisfactory manner. Its examination, and the determination of its instrumental constants, will be immediately begun.

The manufacture of the standard metres and kilograms by Johnson, Matthey, & Co., is progressing. Analyses of the alloy show it to fill all requisite conditions. Up to the present time the progress has necessarily been slow, as the important questions of alloy, refinement, and mechanical execution, had to be provided for. These matters have now been satisfactorily settled, and the delivery of the bars and ingots may be expected soon to begin.

In the report of the operations during 1882 was given an account of the copies of the *mètre des archives* and of the *kilogramme des archives*, which, on April 26, were confided to the care of the director of the bureau. Although rigorously compared, and the relation to the standards of the archives accurately determined, these were not adopted as international prototypes, but were deposited as witness-copies of these standards. The kilogram, K_{iii}, elaborately compared with the *kilogramme des archives* in 1882 and 1883, was found to be identical in value thereto; and on Oct. 3, 1883, it was formally adopted as the international prototype of the kilogram.

During the year, changes have taken place in the *personnel* of the international committee and the bureau. The Turkish member of the original committee having taken no part in its deliberations since its organization, and repeated attempts to ascertain his future intentions in the matter having failed, his place has formally been declared vacant. The vacancy as yet has not been filled. The resignation of Mr. Marek as a member of the international bureau took effect from March 1, 1883. Dr. Max Thiesen of Berlin was chosen as his successor, and is charged with matters relating to weighing.

The second volume of the *Travaux et mémoires* has appeared, and contains a number of important papers relating to comparisons and to determination of coefficients of expansion. The third volume is in press, and in great degree printed. It is expected to appear in a few months. The material for the fourth volume is in large degree prepared.

Although the comparison of the international standards has not yet begun, a number of national standards have been compared, and important physical investigations made.

Comparisons of much interest to Americans are those between the British platinum kilogram and a platinum-iridium and two brass avoirdupois pounds and the prototype kilogram, as through them our own weights are brought into more direct relation with the international standards. Also a steel metre belonging to the U. S. lake survey has been compared for length and coefficient of expansion.

Experiments with the Fizeau expansion apparatus have given a new and elaborate redetermination of the change, with temperature, of the index of refraction of atmospheric air; and the coefficients of expansion of many minerals have been determined. An elaborate redetermination of the wave-length of the sodium-ray is in progress.

Correspondence is in progress with Mexico with a view to the adoption, by that government, of the articles of the metric convention.

H. W. BLAIR.

A QUESTION OF EXPOSURE.

THE extraordinary depressions in temperature, which occurred in the month of January in many parts of the country, have attracted an unusual amount of attention to questions of thermometry. In some instances it has been observed that the areas of excessive cold were smaller than might have been anticipated, great differences often existing where there were no

geographical or topographical reasons for them. A comparison of reliable observations, made during this period, furnishes evidence of the great importance of considering the situation and exposure of thermometers.

In the state of Ohio, there were three distinct periods of great depression during the month; and at two of these the minimum temperatures were unprecedented in the history of the state. The important fact, however, to which it seems desirable to call attention, is that the records of the U. S. signal-service observers contain no account of these extraordinary cold-waves; and we should be ignorant of their existence, if obliged to depend for information upon these records alone. This fact can be attributed, in some degree, to the small number of regular signal-service stations in the state, but in a far greater degree, in the opinion of the writer, to the situation and exposure of the thermometers of that service.

The Ohio meteorological bureau has more than twenty observing-stations, pretty well distributed over the state. The observers are generally persons of more than ordinary intelligence, and many of them have had long experience in meteorological observations. The instruments which they use are of the best pattern, being similar, in fact, to those in use by the U. S. service; and all have been compared with the standards at Washington, through the kindness of the chief signal-officer, and their errors are in most cases very small.

The U. S. signal-service has four regular stations in Ohio, situated at Toledo, Cleveland, Columbus, and Cincinnati. A station at Sandusky has recently been re-established; but reports have not been received from that station, for the month of January, by the Ohio bureau.

The first cold-wave was most severe on the 5th, 6th, and 7th. On the 5th the mean minimum for the state, from the observations of the State service, was −16°; and from those of the U. S. service it was −12°. The lowest temperature recorded by the State service was −24.4°; and by the U.S. service it was −16.3°. On the 6th the mean minimum and the lowest temperature, as recorded by the State service, were −15.3° and −24.6° respectively, the corresponding numbers from the records of the U. S. service being −12.2° and −20.3°. On the 7th the difference was still more marked; the numbers being −11.6° and −19.6° for the State service, and −2° and −7° for the U. S. service.

The second great depression was of short duration, and was most severe on the 21st. On that day the mean minimum for the state, from the State-service observations, was −11.1°, while from those of the U. S. service it was +1.4°. The lowest temperature recorded by the State service was −31°, and by the U. S. service was −3.7°. These minima were recorded at the same place, Columbus; the distance between the stations being slightly less than three miles. It seems difficult to understand how two stations so near to each other could furnish results differing from each other so greatly.

The question appears to be purely one of situation and exposure. The U. S. signal-service thermometers are exposed in a box or case of the usual form, attached to the north side of a stone building in the centre of the city: those of the State service are exposed in a somewhat similar shelter, but in an open space on the campus of the Ohio state university, at a considerable distance from any building. The conditions on the night of the 20th and 21st were peculiarly favorable to the production of such a result as that given above. During the 20th the temperature was not very low; and in the evening and night the sky was clear, and there was scarcely any movement in the atmosphere. The rapid fall in temperature was unaccompanied by movement of masses of air; and, as a result, the air confined in the shelter of the U. S. service thermometers was not displaced; and, being in contact with a large building which lost its heat slowly, the fall in temperature was not great. Had there been a brisk wind, or even a breeze, the result would have been different. The minimum of −31°, recorded by the State service, cannot be questioned; as it was supported by numerous readings from 'private' instruments, equally reliable, in the immediate vicinity and in the neighborhood of the city. At Westerville, twelve miles distant, a minimum of −24° was recorded by one of the observers of the State service.

Nearly as great a difference was exhibited in the records of the 25th. For this 'dip,' which was the lowest of the three, the mean minimum for the whole state, as obtained from twenty-two stations of the State service, was −19.8°, while from the records of the U. S. service it was only −5.1°. The lowest temperature observed by the State service was −34°, while the lowest reported by the U. S. service was −15.1°.

These comparisons lead to some conclusions which are certainly not without importance in the study of climatology. In these instances it appears that the U. S. signal-service has failed to obtain the mean lowest temperature

by from 3° to 15°, and that it has missed the minimum on different days by 5°, 8°, 13°, 19°, and 27°.

Improper exposure of thermometers will account for a part of this discrepancy; and it is well known that the chief signal-officer has already recognized the importance of this point, circulars having been distributed, some months ago, to all volunteer observers, requesting detailed information concerning the manner and method of exposure. The location of the station appears to the writer to be of even greater importance. It is unfortunate that nearly all stations of the U.S. signal-service are in large cities, and often in the most densely built and populated portion of them. Concerning temperature, at least, it is not likely that such situations will give results of great value, even with the most careful attention to exposure.

From geographical and topographical considerations, the station at Columbus is more likely to fairly represent the state of Ohio than either of the others; but the above observations show that it may fall far short of doing it. Observations taken at Cincinnati represent little more than the conditions in that city, the topography of that region being such that the city might almost be said to have a climate of its own. One of the State-service stations is at Waverly, the latitude of which is very nearly the same as that of Cincinnati. On the 21st, Waverly reported a minimum of −14°, and Cincinnati, of +7.9°; and on the 25th, Waverly reported −27.2°, and Cincinnati, +3.7°. In Cleveland and Toledo the climate is modified greatly by the presence of Lake Erie. At Wauseon, thirty miles from Toledo, the minimum is reported on the 25th as −31.7°; and at Toledo it was −9°.

There are, doubtless, excellent reasons why these stations should be where they are, and also why it is generally desirable to locate stations in large cities; but there seems to be little doubt that for temperature measurements it would be well to put stations *near* rather than *in* large cities, and at sufficient distance from them to be free from purely local conditions.

The importance of the maintenance of state weather-services is not so generally appreciated as it deserves to be. It is impossible for the U.S. service, at least at present, to increase the number of its stations to the extent that would seem desirable and necessary in order to obtain the details of climatic conditions. The organization of state services is generously encouraged by the chief signal-officer; and if they become general, and are efficient, they may be of great service to the very competent corps of government meteorologists in their investigation of general problems in climatology.

T. C. MENDENHALL.

IRON FROM NORTH CAROLINA MOUNDS.

IN the Proceedings of the American antiquarian society, vol. ii. p. 349 (1883), Professor Putnam reviews the statements of the old writers respecting metal found in the western mounds. He comes to the conclusion that Mr. Atwater's iron-bladed sword or steel-bladed dagger is to be traced to that gentleman's lively imagination.

Although Professor Putnam may be correct in his conclusion, a discovery made in North Carolina by one of the assistants in the Bureau of ethnology, during the past season, would seem to render the statement made by Atwater in regard to finding the fragment of an iron sword-blade in an Ohio mound at least probable.

In order that the reader may understand the conditions under which the articles to be mentioned were found, it is necessary to give a description of the burial-place, which I do by copying the report of the assistant.

"This is not a mound, but a burial-pit, in the form of a triangle, the two longest sides each forty-eight feet, and the base, thirty-two feet, in which the bodies and articles were deposited, and then covered over, but not raised above the natural surface. The depth of the original excavation, the lines of which could be distinctly traced, varied from two and a half to three feet. A rude sketch of this triangle, showing the relative positions of the skeletons, is given in fig. 1.

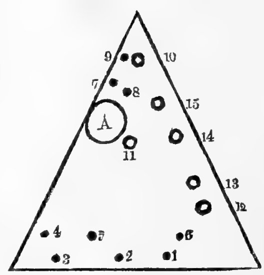

FIG. 1.

"Skeletons Nos. 1, 2, 3, 4, 5, 6, 7, 8, and 9 were lying horizontally on their backs, heads east and north-east. By No. 2 was a broken soapstone pipe; by No. 5 and also by No. 9, a small stone hatchet.

"Nos. 10, 11, 12, 13, 14, and 15 were buried in rude stone vaults built of cobblestones similar to those in fig. 2, which represents the arrangement of the bodies and vaults in a mound near by. (This mound was over a circular pit.) Nos. 10, 12, 13, and 15 were in a sitting-posture, and without any accom-

panying articles. Graves Nos. 11 and 14 contained each two bodies extended horizontally,—the lower ones, which were of smaller stature than the upper ones, face up, and with heavy flat stones on the extended arms and legs; the upper ones with the face down; no implements or ornaments with them.

inscribed shells were found. Scattered over and among these ten or more skeletons were found hatchets (polished axes and celts), rubbing and discoidal stones, copper arrow-points, mica, paint, black lead, etc."

This is sufficient to indicate the conditions under which the iron specimens were found.

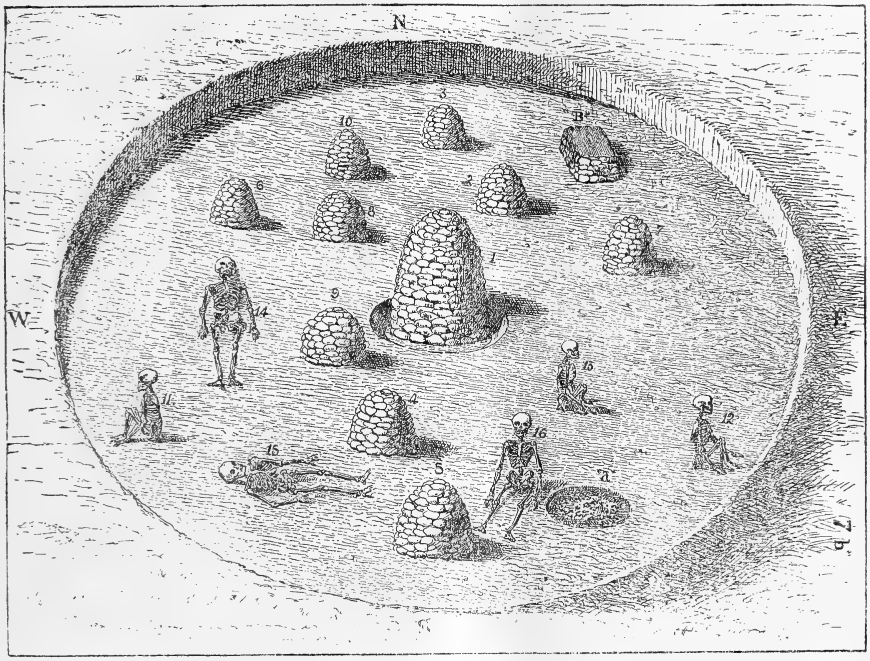

FIG. 2.

"On the north-west side of the triangle, at *A*, fig. 1, ten or more bodies were found which appeared to have been buried at one time; the old chief (?) with his head north-east, face down. Under his head was the larger sea-shell with hieroglyphics. Around his neck were the largest-sized beads. At or near each ear were the larger pieces of copper: there was also a piece of copper under his breast. His arms were extended, and his hands rested about one foot from each side of his head. Around each wrist was a bracelet composed of long, cylindrical, copper beads and shell beads alternated. *At his right hand were found the implements of iron.* Under his left hand was a sea-shell with hieroglyphics inscribed on the concave surface, and filled with beads of all sizes.

"Around and over him, with their heads resting near his, were placed nine or more bodies. Under the heads of two of these skeletons, resting within a foot of the chief's (?), similarly

It is proper to state that every article named was immediately forwarded to the bureau, and is now in the National museum. The celts and axes, which are chiefly of greenish sienite, are highly polished, and equal in finish to the finest hitherto discovered in this country. The pipes are well made, and mostly well polished. The engraved shells are fine, large specimens, the engraved design on each being of the same type as that shown in fig. 3, plate xxx., of Jones's Antiquities of the southern Indians.

The iron specimens alluded to are now before me, and are four in number, much corroded, but still showing the form. Two of them are flat pieces, of uniform thickness, not sharpened at the ends or edges, three to three and a half inches long, one to one and a half inches broad, and about a quarter of an inch thick. Another is five inches long, slightly tapering in width from one and an eighth to seven-eighths of an inch, both edges sharp, and is, without doubt, part of the blade of a long, slender, cutting or

thrusting weapon of some kind; as a sword, dagger, or large knife. The other specimen is part of some round, awl-shaped implement; and a small fragment of the bone handle in which it was fixed yet remains attached to it.

The bureau is also in possession of another rudely hammered, small iron chisel or celt, found under somewhat similar conditions in a mound in the same section.

It is evident, from what has been stated, that we cannot ascribe the presence of this metal to an intrusive burial. The people who dug the pit, deposited here their deceased chief, or man of authority, and placed around him, and those buried with him, the pipes, celts, axes, engraved shell-gorgets, and other implements and ornaments, undoubtedly placed here, also, the pieces of iron.

Whether the burials were comparatively modern or pre-Columbian, the evidence furnished by these fortunate finds compels us to conclude that the people who made these polished celts and axes, who carved these pipes, who made or at least used these copper implements, and engraved these shells with the figure of the mystic serpent, so strongly reminding us of Central-American figures, also had in possession these iron implements, and were mound-builders. That this burial-pit was made by the same people who erected the mounds of this region cannot be doubted.

CYRUS THOMAS.

PENNSYLVANIA ANTHRACITE.

SOME of the commonest articles used, either for manufacturing purposes or in the household, are frequently those about which we have the least definite information as to their composition or value. Near the point of production or manufacture, the consumer is apt to exhibit the most discriminating judgment in the selection of special brands or grades, on account of closer competition and a greater variety from which to make a selection. This is frequently done on the basis of a personal estimate, without substantial facts to warrant it. To no natural product does this apply with greater force, at the present time, than to the Pennsylvania anthracites, which are now depended upon by manufacturers and housekeepers, either as a necessary or luxuriant fuel, throughout portions of the entire western continent, and are used at points as distant as China and Japan.

Both the manufacturing and domestic consumers are beginning to realize the fact that their coal purchased this year does not seem to burn so freely, does not fire with so little trouble, and does not last so long, as that purchased during the last and previous years, or *vice versa*. Where coals of different sizes, or from different districts, are offered to the trade by the same or competing salesmen, the question suggests itself, what shall we buy?

Among housekeepers, who are the smallest and most numerous class of consumers, distinction is seldom recognized between these anthracites. By other consumers the coals are grouped into those, which, when burned, will produce either a white or a red ash, special qualities being arbitrarily attached to each. Others, again, know only of three varieties: 1°, those from the Wyoming and Lackawanna fields, or the coals shipped from the northernmost basins over the railroads running through north-eastern Pennsylvania direct to New York (notably, the Delaware, Lackawanna, and Western, Delaware and Hudson, and Erie railways); 2°, those shipped by the Lehigh valley railroad, and the Central railroad of New Jersey, down the Lehigh valley; and, 3°, those over the Philadelphia and Reading railroad down the Schuylkill valley. Still other distinctions are arbitrarily made, which it is not necessary to note. In special localities, where a favorite coal is largely used, the consumer will speak of one class, that composed of his favorite coal, which possibly comes from two or three collieries, with a total aggregate annual production of less than a million tons; and of a second class, that composed of the coals from all other collieries, represented by an annual production of over thirty million tons. I have noticed this particularly in sections of New England, where even an intelligent consumer will sometimes speak of Lykens valley coal and of all other Pennsylvania anthracites.

The pressing demand which has been made upon the Geological survey of Pennsylvania, for some answer as to the fuel-value of different coals, has led me to consider what is the composition of Pennsylvania anthracite, as a preliminary step in the investigation.

Various percentages of fixed carbon have been assigned by different authorities to a typical anthracite. That which has been most generally accepted has been about 94, with all the accidental impurities, such as those which are generally classified under ash and sulphur, eliminated. Professor Rogers (Final report of first survey, vol. ii. pp. 969, 970) gives analyses of fifteen specimens of hard, dry Pennsylvania anthracite, which show an average, of fixed carbon, 88.05; of volatile matter, 5.81; of

ash, 6.14. Eliminating the ash from these analyses, the percentages of the constituents of fuel are as follows: fixed carbon, 93.8; and volatile matter, 6.2. This result is identical with the composition assigned by Newberry to a typical anthracite (Johnson's cyclopaedia, vol. i. p. 993).

The range of fixed carbon in the analyses of these fifteen specimens was from 94 to 80; the specimen showing the maximum being obtained from near Pottsville, and that showing the minimum from near Pine Grove, both from the Southern field in Schuylkill county. The range in volatile matter in the fifteen analyses is from 1.40 to 9.53; the minimum amount being in the same Pottsville specimen, and the maximum in a specimen from Black Spring Gap. The range in ash was from 2.90 in a specimen from Tamaqua, to 12.28 in a Pine Grove specimen. These results are certainly misleading; for it has been a long-recognized fact, that the coals obtained in the Southern field do not contain the highest percentages of fixed carbon.

Taylor (Statistics of coal, 2d ed. p. 609) gives analyses of a number of Pennsylvania anthracites reported from various sources. Twelve specimens from the Panther-Creek basin, between Mauch Chunk and Tamaqua, showed the following: —

	Averages.	Maximum.	Minimum.
Carbon	89.21	92.60	86.00
Volatile matter	6.38	8.00	4.54
Ash	4.41	7.00	1.28

Six specimens from the Lehigh region gave —

	Averages.	Maximum.	Minimum.
Fixed carbon	89.00	92.30	85.34
Volatile matter	7.05	9.60	5.36
Ash	3.93	8.73	1.28

All of these analyses, particularly those given by Taylor, are constantly quoted in numerous descriptions of Pennsylvania anthracite found in technical publications, both at home and abroad. The foreign books and journals have been reporting the higher results; so that the opinion prevails, that the hard, dry anthracite mined in the state will range from 90 % to 94 % of fixed carbon in the market product. Such is, however, not the case, as recent analyses[1] made by the Geological survey show.

[1] Andrew S. McCreath, analyst.

The results which have been reported in the Rogers and Taylor tables referred to may be taken as those of analyses of mineralogical specimens, which were in most cases carefully selected, either from the mined coal or from special portions of the bed. In no case, as I believe, are the analyses a guaranty of the character of the coal which was being mined or shipped as fuel from the individual localities at the time that the samples were collected. Even the specimens which were collected in considerable quantity, and analyzed and tested for their evaporative capacity by Johnson for the government in 1842 were not, I consider, fair averages of the coal which could be commanded in the market from the different mines for which his results were reported.

As indications of the composition of mineralogical specimens, the chemical analyses reported by Rogers and Johnson are of little scientific value, without a minute description of the physical characteristics and geological associations of the coal for which they stand. This conclusion could be substantiated by a number of instances to which I might refer; notably, one where I requested an experienced mining-expert to collect duplicate specimens from a point in one of the Mammoth bed mines, which, when analyzed, showed, much to my surprise, the following results: —

	Water.	Volatile matter.	Fixed carbon.	Sulphur.	Ash.
1	2.590	3.883	86.233	0.851	6.443
2	2.440	3.998	80.301	0.649	12.612

These two analyses are worthless as indications of the fuel-value of the coal, because it would be unreasonable to suppose that either one or the other specimen, showing such a wide range of composition, could be taken as a fair average of the coal shipped from this mine. Nor are they of scientific value, without certain facts, connected with the occurrence of the coal at this special point, to suggest some reason why such wide differences should exist.

If the amount of combustible matter in a coal is any criterion of its fuel-value, an examination which has recently been made by the survey shows how ignorant we are as to the actual worth of the different coals which we burn, and how readily we may be deceived by the special characteristics of a coal which we may have noticed, and by which we may have judged of its heating-capacity.

In order to test the value to be attached to

the judgment of the trade in discriminating between different coals, I requested one of the largest miners and shippers of anthracite coal, who has for a great many years been connected with the mines over a wide area in the region, to name a number of coals, which, by most consumers, were credited with being of about equal value. Specimens of these coals were collected from one or two hundred tons, as they were ready to be shipped to market; the amount collected for each analysis, ranging in weight from one to two hundred pounds, which was then reduced by the ordinary methods now commonly used in sampling any mineral product for qualitative and quantitative tests. The number of specimens obtained in this way aggregated thirty-three. The analysis of each individual specimen is recorded in detail on p. xliv. of my 'First report of the progress of the anthracite survey,' issued by the state printer on the first of this month. For our present purpose it is not important to refer to the results in detail.

The table of averages which I have compiled shows the mean character of the coal obtained from the more important coal-beds in the Northern field in the vicinity of Wilkes Barre, in the Eastern middle (Lehigh) field in the vicinity of Hazleton, in the Western middle field in the vicinity of Shenandoah, and in the Southern field on the property of the Lehigh coal and navigation company, between Mauch Chunk and Tamaqua. These results are shown in the following table: —

No. of specimens.	Name of coal-bed.	Name of coal-field.	Chemical analysis.						Specific gravity.	Percentage of constituents of fuel.		
			Water.	Volatile matter.	Fixed carbon.	Sulphur.	Ash.	Total.		Fixed carbon.	Volatile combustible matter.	Fuel ratio, $\frac{C.}{V.H. - C.}$
3	Wharton . . .	Eastern middle .	3.713	3.080	86.404	.585	6.218	100	1.620	96.56	3.44	28.07
5	Mammoth . . .	Eastern middle .	4.119	3.084	86.379	.496	5.922	100	1.617	96.55	3.45	27.99
2	Primrose . . .	Western middle .	3.541	3.716	81.590	.499	10.654	100	1.654	95.64	4.36	21.93
5	Mammoth . . .	Western middle .	3.163	3.717	81.143	.899	11.078	100	1.657	95.62	4.38	21.83
2	Primrose? (F) .	Southern	3.008	4.125	87.982	.506	4.379	100	1.584	95.52	4.48	21.32
2	Buck-Mountain .	Western middle .	3.042	3.949	82.662	.462	9.885	100	1.667	95.44	4.56	20.93
1	Seven-foot . . .	Western middle .	3.410	3.978	80.868	.512	11.232	100	1.651	95.31	4.69	20.32
7	Mammoth . . .	Southern	3.087	4.275	83.813	.641	8.184	100	1.631	95.15	4.85	19.62
3	Mammoth . . .	Northern	3.421	4.381	83.268	.727	8.203	100	1.575	95.00	5.00	19.00

These analyses are arranged in the order of the percentage of fixed carbon in the fuel constituents.

A comparison of these results with those already referred to, as given by Taylor for the Panther-Creek basin, shows wide differences. The two Primrose and seven Mammoth specimens reported in the table for the Southern field came from the Panther-Creek basin; the average of the two Primrose coals indicating 1.29%, and the average of the seven Mammoth specimens 5.4%, less fixed carbon than Taylor's average; the minimum fixed carbon in the survey's analyses being 78 as against 86 in Taylor's table, and the survey's maximum being 88 against 92.6.

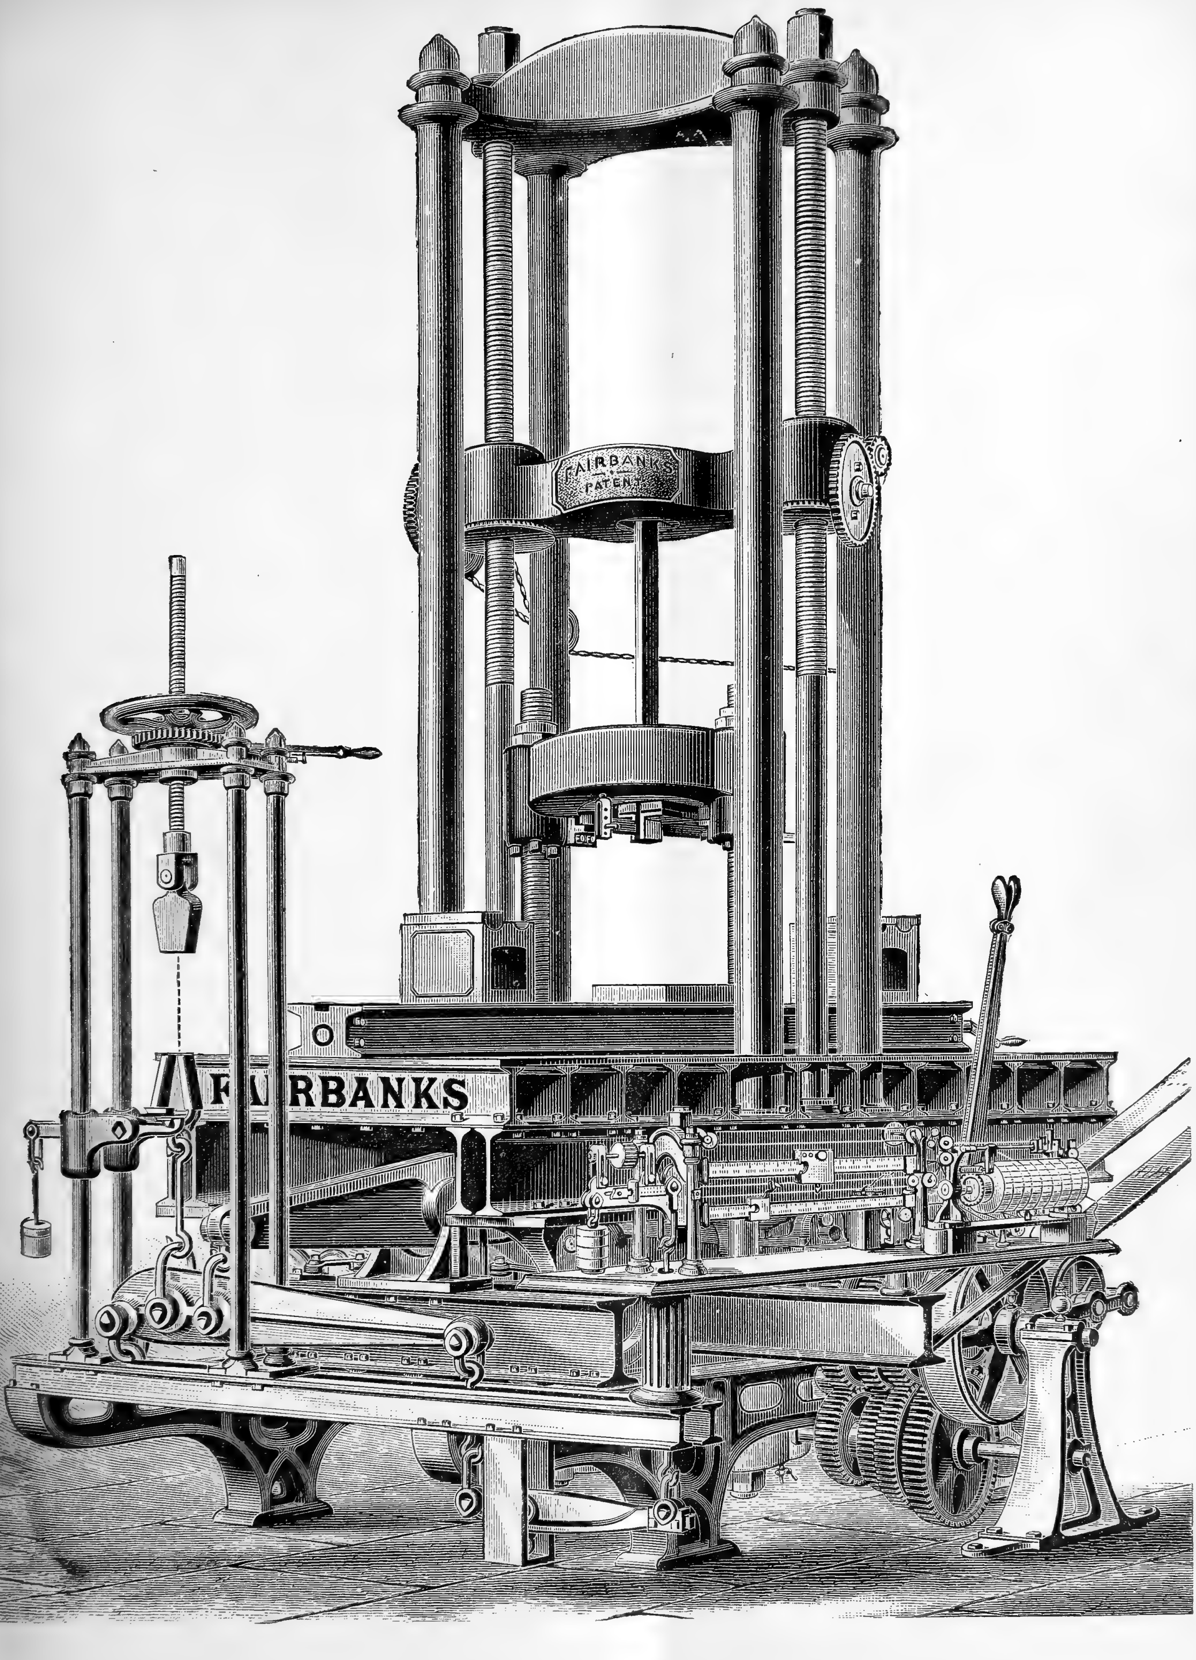
These results evidently prove, 1°, that the specimens which were collected in the past for analysis were not sampled with sufficient care; for with the improvements which have been made in breaker machinery, and the greater care exercised in the preparation of coal for market, we might reasonably expect to find the higher percentages in the more recent analyses: and, 2°, the necessity of changing the basis upon which Pennsylvania anthracite has been rated in the past.

CHARLES A. ASHBURNER.

IMPROVEMENTS IN TESTING-MACHINES.

SOME philosopher has remarked that the prosperity of a nation is directly in proportion to the success of its people as constructors. According to this maxim, America occupies a very high place in the list of nations. With our almost inexhaustible ore-beds, and fertility in inventing new processes of mining and working metal, the necessity of becoming better acquainted with the properties of American building-materials is daily growing more apparent; and at present no question is exciting more attention among our constructors than that of the strength of materials.

About two years ago Messrs. Fairbanks & Co. conceived the idea of locating in New York a bureau so arranged that engineers and all interested could be afforded an opportunity



FAIRBANKS
PATENT

to make experiments and tests on any material, and to give to America a laboratory that should speedily become to our country what the laboratory of Kirkaldy is to England.

Fig. 1 shows the machine now employed in their department of tests and experiments. The machine stands on two cast-iron legs, supported by any suitable foundation. On these legs there rests a framework of wrought-iron I-beams, so constructed as to give the entire structure an exceedingly solid and firm basis. This framework supports a system of levers arranged in a manner similar to that of an ordinary scale, only proportioned so as to withstand the severe stresses and shocks. These levers support a secondary framework, also constructed of I-beams, and carrying four columns. On the tops of these columns stands a heavy casting, from which are suspended two side-screws, carrying the top crosshead, to which one end of the specimen to be examined may be attached. These screws are simply used as a rapid and convenient means of adjustability, so that longer or shorter specimens can be tested. This system — namely, the adjusting-screws and top crosshead — is supported upon the framework of I-beams forming the platform. Beneath the top crosshead is a second crosshead, also supported on two screws, which are placed inside the adjusting-screws. These screws extend downward through the platform, and are attached to two worm-gears firmly secured to the under side of the bottom framework. The worm-gears may be rotated in either direction, at the pleasure of the operator, by means of the belt and gears at the right hand. The worm-gears and screws form the straining-mechanism, capable of applying any stress up to two hundred thousand pounds. Great care is taken in the construction, so that no part of this mechanism whatsoever shall touch, or in any other way come in contact with, the platform, save solely and simply through the specimen to be tested: consequently all the stress produced by the crosshead on the platform must necessarily pass through the specimen; and only this amount, and no more, can be estimated on the weighing-beam.

A part of the scale system may be seen in the front of the cut; the end of one of the large levers extending under the platform, and two smaller ones carrying the stress from the end of this lever to the beam. Over the larger one of these levers are four small columns supporting a handle and lever. This apparatus is a testing-machine in miniature. The full power of the machine may be used, having a capacity of two hundred thousand pounds, reading to ten pounds, and accommodating specimens up to ten feet in length; or by means of the lever a force of ten thousand pounds may be exerted, reading to half-pounds, and accommodating specimens up to five feet in length.

The platform of the machine occupies considerable space, being some ten feet long by six feet in width. As this platform is supported on the scale, any weight which is placed on it must be felt by the beam; and, in order to test the machine, all that is necessary is to pile on the platform a series of standard test-weights.

Fig. 2 is a transverse section. Here the legs are shown supporting the beams in the same way as in the previous drawing. The lower crosshead screws, *k k*, carry the crosshead *C*, while the screws *h*, carrying the upper head, are in front of the columns *j j*. At the left may be seen the driving-apparatus for furnishing the power to the lower crosshead, the belt l^3 being arranged to slide to and fro on a tight and loose pulley. The tight pulley conveys the motion of the belt to the top driving-shaft. On this shaft there is a set of three gears, arranged in a manner very similar to the back gears of an ordinary lathe, by means of which three different speeds may be communicated to the main driving-shaft, *l*. Just to the right of these three gears may be seen a set of reversing-gears, so arranged, that, by throwing a lever to and fro, the crosshead may be run either up or down, at the will of the operator. On the driving-shaft, *l*, are placed two worms, cut, respectively, right-handed and left-handed. These match in the corresponding worm-gears which are placed at the bottom of the screws *k* and *k*. The main screws are cut right and left handed, so as to turn in opposite directions, neutralizing all the frictional stresses of the crosshead, and preventing any tendency to twist.

Perhaps the action of the machine can be well understood by supposing a test-piece in tension. The piece is secured in the top crosshead, *B*, by wedges; the other end, secured to the lower crosshead, *C*, thereby forming the only connection between the platform and the driving-mechanism. As fast as the screws are turned, stress is exerted on the specimen, which is communicated to the platform, and weighed by means of the beam at the left hand.

The results of tests are so largely dependent upon the skill of the operator, that very naturally much hesitation has been felt in accepting them as conclusive. It has been the aim,

in the design of the present machine, that as far as possible the machine should do its own work, thereby eliminating from the result all personal equation; and, supposing the machine of the machine coincide with the axis of the specimen. In making experiments on wrought iron and steel, and upon other materials which are more or less of a ductile character, this

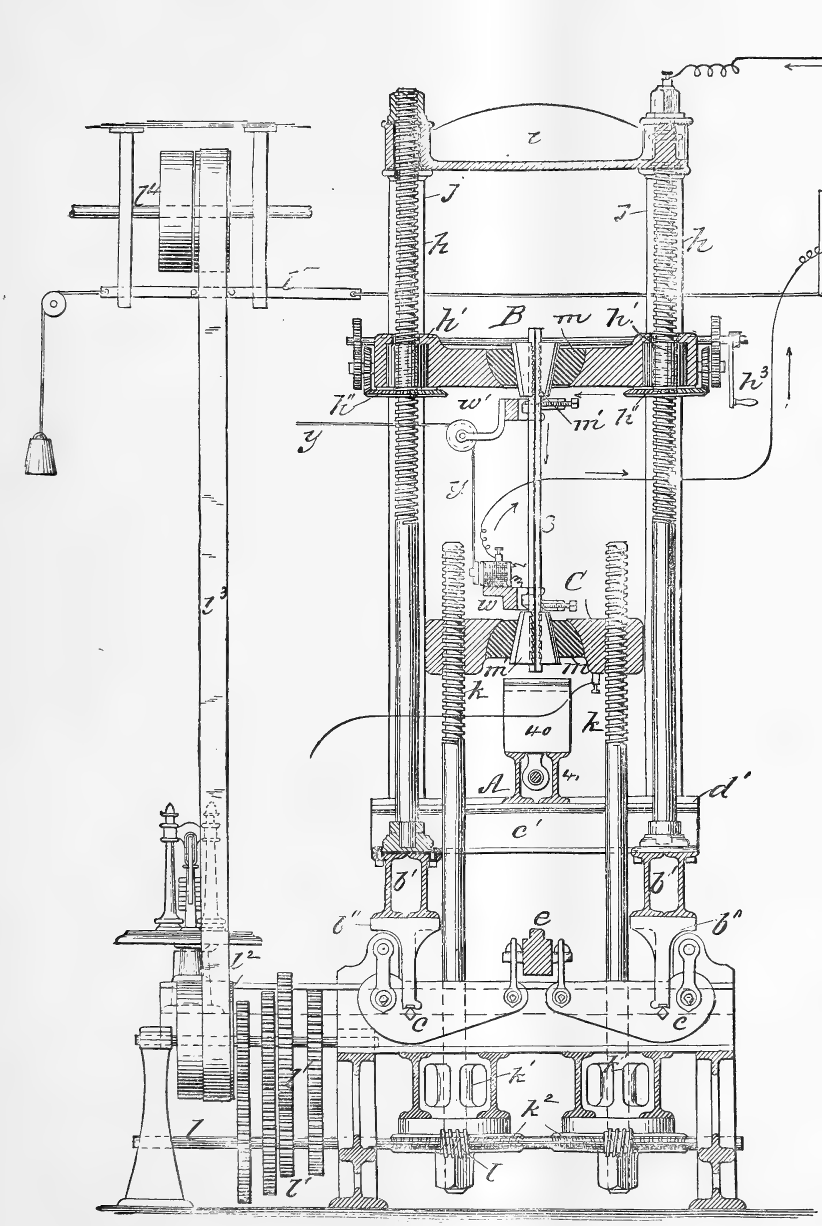


FIG. 2.

to be once correct, all subsequent records should be correct mechanically. One of the greatest obstacles to making accurate tests has been the feasibility of making the axis of stress objection is not a serious one, as it introduces but a slight error in the results. In experiments on cast-iron, cast-steel, or materials of a brittle character, the slightest cross-strain

vitiates the results, introducing stresses into the test-piece which produce an effect not to be calculated upon.

By referring to fig. 2, a device for enabling the machine to automatically centre the test-piece may be understood. The top and the bottom crossheads have in their centres a large spherical concavity. This concavity contains a segment of a sphere in which the wedges for griping the test-piece are placed. The spherical segment is made of steel turned and polished, and the concavity is lined with the best anti-friction metal. Any eccentric stress swings the segments in their sockets, and causes the axis of stress in the machine to coincide with the axis of the test-piece. The spherical segments weigh about two hundred pounds. They are, however, carefully supported on India-rubber springs, so as to eliminate as far as possible the weight of the segment from the friction in its socket. But supposing, under the most unfavorable circumstances, the whole weight of the segment does come on the joint, the coefficient of friction is not over two per cent: consequently a maximum cross-strain of four pounds on the test-piece will cause the segment to swing, and to adjust itself to the axis of stress through the piece. As this weight of four pounds is less than half the least reading of the poise, it may be assumed to produce no sensible effect on the piece to be examined.

The most of the testing-machines now in use require a careful preparation of the test-piece previous to an examination. If, for example, it is wished to ascertain the strength of an I-beam or of a channel, it is necessary to send the shape to the machine-shop, and plane a piece of one or two inches in area. This requires much time and expense. The specimen is then sent to the testing-machine and broken; and what is obtained? Simply the result of a piece cut from the shape, which may or may not give a fair knowledge of the actual strength of the member in question. What is wanted at the present time is not the strength of a carefully prepared test-piece, broken under special circumstances, but of the actual bar just as it comes from the rolls in the mill itself. The spherical segments in the crossheads of the Fairbanks testing-machine have four sides inclined at an angle of about twelve degrees to the axis of the machine. Two of these sides are curved, and two are straight. By using a number of wedges with backs correspondingly curved or straight, any piece, of whatsoever section, may be completely surrounded by the wedges, and griped on all sides; so that a channel, an angle, and I-beam, a T or a star, or, indeed, any of the shapes now rolled in the mills, may be placed in the machine and broken in full size.

Much time and labor have been spent to accomplish the power of autographically recording, at each instant of time during the experiment, the amount of stress, and the effect produced thereby on the specimen. To the best of the author's knowledge, Professor Thurston of the Stevens institute was the first to originate the idea of making a testing-machine in such a manner as to record graphically. In 1876, at the Centennial exhibition, Professor Thurston exhibited a machine designed to make tests in torsion and to record the action thereof. As a matter of history, it may be stated, that, while engaged in examining material for the East River bridge in 1877, the author designed and built the first testing-machine to autographically record results of the experiments in other stresses than that of torsion. While this machine, being the first of its kind, was necessarily crude and imperfect, it gave for some years very satisfactory results, and is still in use by the Bridge company. While the present machine is essentially different from the one just mentioned, the principles employed are the same as those devised for the East River bridge.

Referring to fig. 2, it will be seen that the battery *G* is attached to the top of the adjusting-screws *hh*. These screws are carefully insulated from the rest of the machine. As soon as the test-piece is placed in the top crosshead, it becomes thereby connected with the battery. On the lower end of the specimen may be seen a small clamp, carrying an electro-magnet. One end of the wire of this magnet is in connection with the specimen, while the other end of the wire is joined to a little binding-screw on top, to which the other pole of the battery is attached; so that the current actuating this magnet flows through the test-piece under examination. It will also be seen that the magnetic clutch, *m*, for holding the driving-belt on the tight pulley, is also included in this part of the battery-circuit. When the rupture of the test-piece occurs, the current is broken, the magnetic clutch is released, the belt slides by means of the counterpoise weight to the loose pulley, and the testing-machine stops. On the top of the specimen nearest to the upper crosshead is attached a second clamp, carrying a small sheave or pulley. Around this pulley, parallel to the specimen, and attached to the armature of the lower clamp magnet, passes a flexible steel tape, *y*, that, after passing alongside the specimen, runs

down to a pencil or stylographic pen that is carried on a sliding-track placed over a metal cylinder carrying a sheet of cross-section paper. It is obvious, that, as fast as the specimen elongates under the action of the stress, the pencil is drawn along the ways of the cylinder parallel to its axis.

Figs. 3 and 4 show the beam and registering-cylinder. In fig. 3 it will be seen that the beam consists of a single bar, sustained on a stand at one end, and enclosed in a guard at the other, while on this beam there rests a semicircular brass box forming a poise. Along the top of the beam, there is cut an exceedingly fine rack; and the motion of the poise is obtained by a pinion placed inside of the box and gearing into this rack. At the end of the beam may be seen the mercury-cups for making an electrical connection as the beam rises and falls. The operation of this piece of apparatus is substantially as follows. The clock-work motor contained in the poise, for driving it to and fro on the beam, is connected with the mercury-cups by means of some brass strips placed in the rear of the beam. These strips are connected with two electro-magnets on the inside of the poise: consequently, when the beam either rises or falls, one or the other of the magnets is excited, the corresponding train of clock-work is thrown into action, and the poise rolls to and fro until a balance is re-established. This motion of the poise to and fro on the beam is exceedingly simple, the knotty part of the problem being to correlate the motion of the poise with the motion of the cylinder exactly, so that, in a given travel of the poise along the beam, the cylinder may move a corresponding quantity. Of course, the ratio between the two movements is simply a matter of proportioning so as to accommodate the ordinary cross-section sheet to the circumference of the cylinder; but an exact and constant ratio is a very important point. Inside of the poise are two large wheels, about eight inches in diameter. The wheel placed in front is graduated with a series of numbers. The pinion carrying the poise along the beam is an inch in circumference, and consequently a single revolution of the pinion carries the poise one inch along the beam. The front wheel is secured directly to the pinion-shaft, so that there can be no back-lash between the two; and, being eight inches in diameter, one revolution of the pinion causes this dial-wheel to travel twenty-five inches of circumference. A motion of one inch along the beam corresponds to a weight of four thousand pounds. The dial-wheel being eight inches in diameter, and subdivided into four hundred parts, each of these parts corresponds to ten thousand pounds. The rear wheel of the poise is constructed in precisely the same manner as the front wheel, excepting that the marks on the dial are replaced by little strips of India-rubber, so that the wheel presents a series of teeth alternately made of India-rubber and of brass. On this wheel, there presses a brass commutator-strip, so arranged as to include the cylinder in its

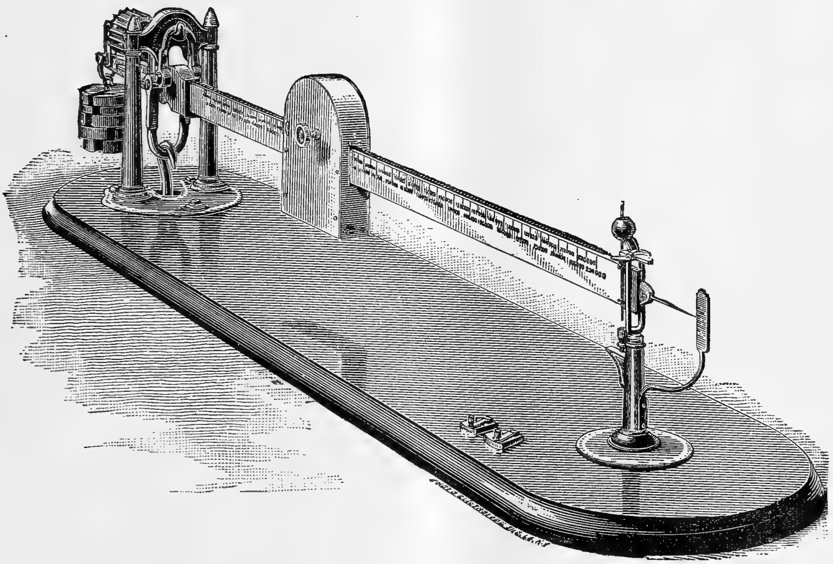

FIG. 3.

electric circuit. As soon as the poise commences to move along the beam, this wheel, with its insulated spaces, commences to turn under its commutator-strip; and with every passage of a tooth under the strip a current passes into the cylinder. Inside of the cylinder are two toothed wheels, mounted on the central shaft, and capable of being ratcheted round by means of a little lever arm and pawl, operated by a magnet placed directly under each of the wheels. locked up in a way to be absolutely exterior to any control on the part of the operator.

An old proverb has said that 'the proof of the pudding is in the eating.' In fig. 5 may be seen a half-dozen curves corresponding to as many test-pieces. The vertical scale gives the stresses, while the horizontal scale gives the normal stretches, of the pieces under examination. The two steel curves bear to each other a strong resemblance. Each commences

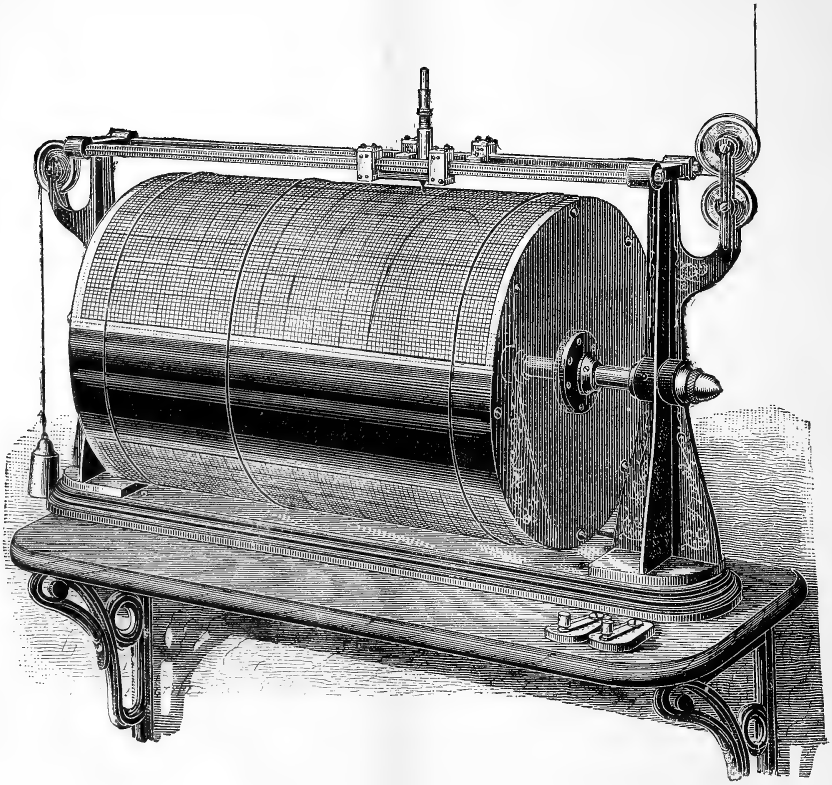

FIG. 4.

One of these wheels is intended to drive the cylinder in one direction, and the other in a contrary. One electro-magnet is connected with the mercury on the bottom of the beam, and the other in the mercury-cup on the top. As a consequence, as soon as the beam makes connection with either cup, the poise commences to travel: the corresponding electro-magnet acts, and rotates the cylinder in one way or the other. The cylinder might be placed in New York, and the registering-cylinder in Cincinnati, and the two work absolutely in harmony with each other: so, should it ever be deemed expedient, the cylinder may be enclosed or with a line slightly inclined to the axis of stress at a constant tangent. As soon as the elastic limit is reached, a sudden point of inflection occurs. Very soon, however, there is a second point of inflection, and the curve takes on a parabolic form. The steel curves, as well as that given by the specimen of Ulster iron, may be taken to be typical forms obtained from the material which is nearly homogeneous. The lines are quite true, and without any special irregularities, until the maximum stress is reached, shortly before the specimen breaks. The stress then commences to decrease, owing to the rapid reduction of area of the piece;

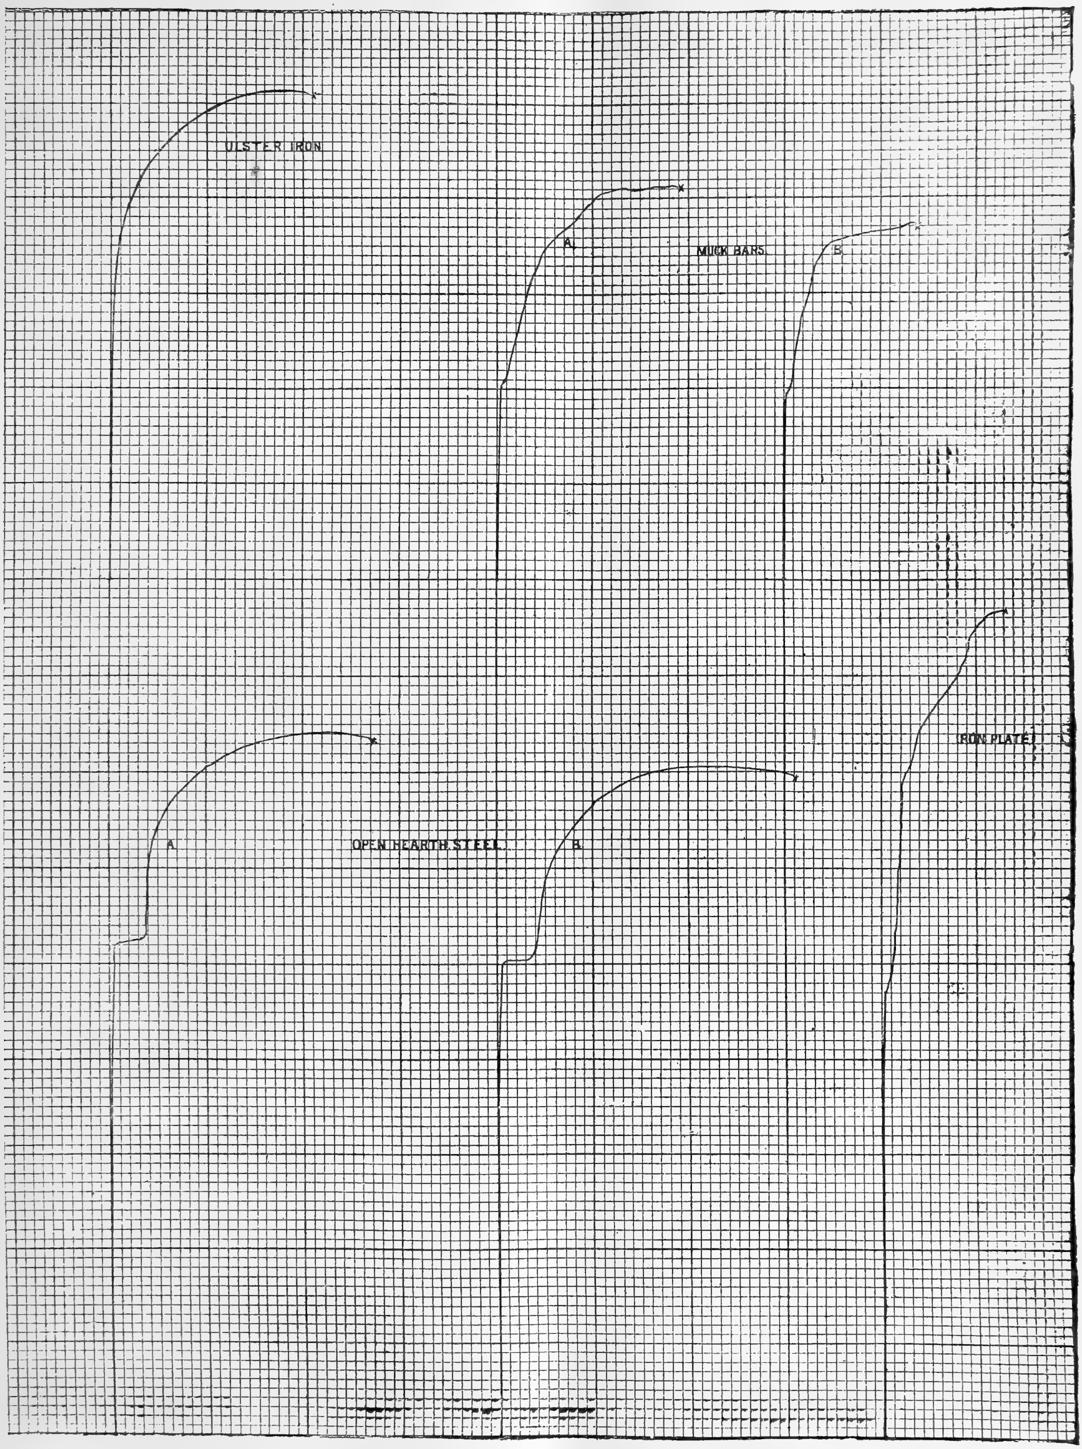

FIG. 5.—AUTOGRAPHIC RECORD ON FAIRBANKS TESTING-MACHINE.
Vertical scale, 10,000 lbs. to the inch; horizontal scale, normal stretch.

and with the reduction of the stress, the curve drops, until very shortly the specimen is ruptured, and the apparatus comes to a standstill. The other three curves are those given by a piece of boiler-plate and of a specimen of muck-bar, and are very good examples of the value of the autographic method. As is well known, both boiler-plate and muck-bar are decidedly non-homogeneous; and as a result we have curves here that are exceedingly irregular, especially after passing the elastic limit. While they bear a general resemblance to the previous ones, they are full of points of inflection, turning and twisting about, and giving one an idea that the specimen consisted of a bundle of threads or fibres which gradually parted under the action of the stress, giving any thing but a constant and uniform action.

In conclusion, a word as to the practical accuracy of the lever testing-machine may not be out of place. The machine under consideration has been subjected to severe use for nearly two years, during which time its sensitiveness, even when loaded, has not risen so high as the least reading on the poise. From this, and from long practice in similar scale-work, it may be safely stated that the testing-machine, with proper care, may have an exceedingly long life. The attainment of absolute accuracy in any department of investigation, would, if it were possible, be an extremely desirable result; yet even our best experiments are simply close approximations to the truth, and it will be granted that it is desirable to make all of our improvements commensurate towards an absolute standard of accuracy. It is of no importance to carry the weighing-power of the testing-machine beyond the possibility of the measurement of the bar. For example: supposing the tests most frequently made are those of bars having about a square inch of cross-section. In a piece of iron an error of a thousandth of a square inch of cross-section corresponds to a possible inaccuracy, in the stress produced on the bar, of fifty pounds; while the corresponding quantity in a steel bar corresponds to about seventy to ninety pounds. There are very few lathes in the country in which it is possible to turn a bar so exactly that it shall be perfectly round, and that there shall be no variation from one end to the other of more than a thousandth of a square inch. There are few men that are capable of manipulating any lathe to produce such a result; and there are still fewer gauges that are capable of measuring even a perfect bar so as to exclude the possibility of an error as great as a thousandth of a square inch. Now, if it be impossible to measure our bars to within an error of fifty to a hundred pounds in the testing-machine, is it of any importance to refine the machine beyond this reading? In the lever system of testing-machines it is perfectly possible to obtain a machine which will uniformly and constantly give readings which shall not have a greater variation than from five to twenty pounds; and, if our bars can only be measured to fifty or a hundred pounds, would it not be wiser to spend money in refining the gauges rather than in refining the machine? Again: when the consideration of the tests on the full-sized members occurs, or bars direct from the rolls, carrying with them the scale, and other imperfections from the mill, the possibility of measuring to a thousandth of a square inch becomes absurd, and two or three hundredths is the nearest approximation that can be made. In making a test of an ordinary I-bar, of, say, five or six inches of cross-section, it is certain that the bar has any thing but an absolutely uniform section from end to end; and how long, may it be asked, would it take to measure that bar from end to end, so that the least cross-section could be obtained for the record? And again: in actual experience it has been frequently found, that, having obtained what is supposed to be the least cross-section, the test-piece may break in a totally different place. It will be conceded that practical engineers care very little for test-records beyond the hundredth's place of figures; and what the country wants at the present time, is not so much testing-machines constructed with a theoretical refinement of accuracy, as a large number of practical machines, so that one may be located in every iron-works in the country, and means to carry on the experiments and to obtain from these machines a practical knowledge of what America's constructive materials really are. A. V. ABBOTT.

NEW METHOD OF MOUNTING REFLECTORS.[1]

IT is well known to all who have given attention to this subject, that the optical performance of great reflecting-telescopes has not been proportional to their size, and that the mechanical difficulties of keeping a large reflector in proper figure in different positions have been apparently insurmountable. A plan of supporting a large mirror, devised by Mr. Henry, has been adopted in Paris, which it is hoped may obviate this difficulty. It consists, in principle, in supporting the mirror upon a

[1] Extracted from a report to the secretary of the navy on improvements in astronomical instruments.

second surface, ground to fit it with accuracy when the mirror is in proper shape. If the mirror rested directly in contact with this second surface, no advantage would be gained, since the backing itself would bend as readily as the mirror. Therefore between the two is inserted a thin stratum of some elastic substance. Mr. Henry has found a fine sheet of flannel to give the best results. The effect of the sheet is to diminish the flexure of the mirror by a fraction depending on its stiffness and on the elasticity of the flannel. Theoretically it may be considered imperfect, because, in order to act, some stiffness is required in the mirror itself. A perfectly flexible mirror would bend just as much with the flannel as without it. But the flexure of the mirror can, it appears to me, be reduced to quite a small fraction of its amount. Moreover, I see no insuperable objection to the superposition of two systems of the kind; the mirror resting upon a stiff disk, which is itself supported upon a second one. This plan has been entirely successful in the cases in which it has been applied. Mirrors up to twelve inches in length show not the slightest flexure when moved into all practical positions. Unfortunately it has not yet been tried with reflectors of a larger size.

SIMON NEWCOMB.

AFTER-IMAGES.

THAT one cannot well contribute to a subject unless he knows something of its literature is illustrated afresh in a painstaking article by Mr. Sydney Hodges, in the October number of the *Nineteenth century*, on 'After-images.' Mr. Hodges has discovered for himself the fact that the after-images of bright objects are in general colored, and that they change color as they gradually fade away in the dark field of vision when the eyes have been covered. He has very carefully observed the phenomena in his own case; and he comes to the conclusion, that, in all cases of such after-images, "the color of the image is produced, not by the tint of the object we look at, but by the amount of light thrown on the retina, either by the greater or less intensity of light in the object itself, or by the amount of time during which one looks at it." This remarkable result is, however, reached by experiments that cannot prove it: for in all of them the conditions are too complex; namely, in all the important cases, our experimenter observed the bright object for a comparatively long time before covering the eyes. The common theory of these phenomena, however, assumes, that, after such a continued observation, the causes of the colors in the after-image are decidedly complex; and their complexity may be such as to render a complete explanation of the phenomena wholly impossible. Therefore the only simple way to begin observing the phenomena is to get instantaneously produced after-images, and to observe the order of colors in them as they disappear: for the common theory is substantially, that the separate nervous elements, whatever they are, that respond to the different wave-lengths, or that produce, when excited, the three primary color-sensations, recover from the after-effects of excitement with different degrees of rapidity, and again, if continuously excited, yield to exhaustion with various degrees of speed; so that the color of the after-image at each instant, since it must depend on the mixture of the different after-effects in the different elements, must vary as these elements return, each at its own rate, to the condition of rest, and must so depend, not only on the rates of recovery of each element, but also upon the degree of exhaustion that each element has undergone during the time of stimulus. Hence the simplest case would be the one where the degree of previous excitement was as nearly as possible equal for the different elements, — a case which would be realized best through momentary stimulus. But if the stimulus is continued ten or twenty seconds, then the after-image will be further affected by the rates at which the different elements have tended to get exhausted; and if these rates are themselves quite different, as is likely, then the after-image will be determined in its successive colors, not only by the different rates of subsidence of excitement in the elements, but by the different degrees of previous exhaustion: and all this may possibly so complicate things as to make the phenomena of the after-image seem wholly out of relation to the color of the original object. And thus any such uniformity as our author notices will be of little worth, unless we know just the conditions of time and illumination, and unless we observe the results with very many persons; and even then the facts may turn out to be too complex for us to explain, so that no light will be thrown by them on the theory of after-images.

All this Mr. Hodges could have found stated or implied in many places. The phenomena have been much observed and discussed. Helmholtz gives the older literature in § 23 of his Physiological optics, and himself declares that it is impossible, by reason of the complexity of the phenomena of fatigue, to give a complete explanation of these phases. Wundt, in the *Physiologische psychologie*, while not agreeing as to the theory with Helmholtz, still holds to an explanation somewhat analogous; and he considers, that, to avoid confusion, one must clearly separate the cases of instantaneous stimulation from the more complex ones, in which, as he implies, fatigue and other causes may affect the phenomena (*Op. cit.*, bd. i., p. 438, of 2d ed.). But of such separation our author is ignorant, and confuses all the phenomena in one mass together; so that observations that might easily have been made really valuable for the theory cannot well be used in their present shape at all, and can only raise in the casual reader's mind a false hope that a law has been found, when, in fact, as it is stated, the supposed law of our author is false, and is at once contradicted by the observation,

added by himself in a footnote, that the "solar spectrum does produce the complementary colors in the after-image." For if the so confidently proclaimed law did not turn out true for saturated colors, the simplest of all perceptions of color, why did not our author suspect that he was on dangerous ground? As for the rest of his article, it is really no contribution to science, but contains an effort to refute the doctrine of fatigue in favor of some quite unintelligible explanation of after-pictures, and to edify the reader by general reflections.

We are far from being fully persuaded of the truth of the common theory, and have nothing ourselves to add to the discussion of the subject, save the present note of warning to solitary observers of mental phenomena. Let us all observe, by all means, and independently; but let us know what other people have said, or at least what the greatest men have said. Mr. Hodges is actually capable of believing and saying, at the outset of his article, such words as these: "I should add, that brief references to after-images with closed eyes may be found in Helmholtz's great work on Physiological optics, in Dr. Foster's Text-book of physiology, and in a few other works; but the fact that neither of them contains any detailed experiments (?) such as I am about to describe, induces me to hope," etc. And this Mr. Hodges could write, presumably with Helmholtz's book, § 23 and all, before him. What he is about to describe we have indicated. He looked at a window, and then covered his eyes; afterwards he tried the sun, colored cards, etc.; then he asked two or three people to try similar experiments; and then he wrote his article. And now who shall say that every intelligent man understands how to use even the best-known and best-arranged books? And why should the pages of the *Nineteenth century* be thus occupied? JOSIAH ROYCE.

LAKES OF THE GREAT BASIN.

As the geological observations given in a recent paper by Prof. E. D. Cope[1] relate to a region somewhat familiar to me, I venture to offer the following comments.

Under the heading of 'Preliminary observations' it is stated that the geologists of the Fortieth-parallel survey have shown that Lake Bonneville existed during tertiary time. It must be known to every one, however, who has read vol. i. of the reports of the survey mentioned, that this lake is there classed as quaternary: it has been so regarded by all geologists who have made any considerable study of the surface geology of Utah. Lake Lahontan is supposed, with good reason, to have been contemporaneous with Lake Bonneville, and therefore also of quaternary age. Recent observations tend to prove that the last great rise of these lakes was later than the greatest extension of the Sierra-Nevada glaciers, and perhaps synchronous with the Champlain epoch of the Atlantic coast.

[1] On the fishes of the recent and pliocene lakes of the western part of the Great Basin, and of the Idaho pliocene lake (*Proc. acad. nat. sc. Philad.*, June, 1883).

Lake Bonneville was not named by the geologists of the Fortieth-parallel survey, as stated by Professor Cope, but was first so designated by Mr. Gilbert.[1]

The list of lakes given as now existing in the Lahontan basin should also include Honey Lake, California, as the valley in which it occurs formed a bay of the old lake with over three hundred feet of water. A map, showing the outline of Lake Lahontan as recently determined, will appear in the third annual report of the U. S. geological survey.

The prediction "that it will be shown that a third lake existed in Oregon, north of the supposed northern boundary of Lake Lahontan," has proved correct only in part. A geological reconnoissance conducted by myself in this region in the spring of 1882 has shown that the Great Basin, north of the hydrographic rim of Lake Lahontan, was divided during quaternary time into not less than ten independent hydrographic areas, each of which held a lake of small size, as compared with Bonneville and Lahontan.

The statement that "the lakes of the Great Basin in Nevada and Oregon diminish in alkalinity as we approach the Sierra Nevada Mountains," meets with a notable exception in Moro Lake, California, which lies at the immediate base of the highest portion of the mountains, but is yet, according to an analysis of its water made for me by Dr. F. W. Taylor, far more alkaline than any of the lakes of the Lahontan basin, excepting the soda-ponds at Ragtown, Nev.

Professor Cope also says, that "the lakes most remote from the mountains are not inhabited by fish, their only animal population being crustacea and the larvae of insects." That this conclusion is too broad is illustrated by the life of Humboldt Lake, which is inhabited by both fish and mollusks, and also that of Ruby and Franklin lakes, situated still farther eastward, which abound in molluscan life. That the freshness of lakes, and consequently their inhabitability by fishes and mollusks, do not depend on their relation to mountains, or even on the existence of an outlet, can be shown by numerous examples in the Great Basin. The only explanation of the apparent anomaly of an enclosed lake of comparative freshness (with less than one per cent of saline matter in solution) in the nearly desiccated basin of a far larger lake, which never overflowed, has been suggested by Mr. Gilbert.[2] His hypothesis is, that such lakes owe their freshness to complete desiccation and the burial of the precipitated salts beneath plaza deposits. When water re-occupies such a basin, the imprisoned salts may not be redissolved. It is evident that this process might take place in any part of an arid region like the Great Basin, whether it be near or remote from mountain ranges.

The locality mentioned on p. 137 as having furnished fossil remains is included within the still distinct beach-lines of an ancient lake which once filled the Christmas Lake and Silver Lake valleys. The shells collected at this locality by myself have been

[1] Wheeler survey, vol. iii. pp. 88, 89.
[2] Second ann. rep. of U. S. geol. surv., p. 177.

examined by Mr. R. Ellsworth Call, who reports the following species: Aphaerium dentalum Haldeman, Pisidium ultramontanum Prime, Helisoma trivolvis Say, Granulus vermicularis Gould, Limnophysa bulimoides Lea, Carnifex Newberryi Lea, Valvata virens Tryon.

The mingling of the blackened and mineralized bones of horses, camels, elephants, edentates, etc., with the shells enumerated above, presents a puzzling association of extinct tertiary(?) mammals with quantities of shells of living species, which we had hoped Professor Cope's studies would elucidate.

The presence of 'worked flints,' mingled with the fossil bones, is a matter of but little significance; as the bones occur on the surface, and might have had arrow-heads, etc., scattered among them at a very recent date. There is no evidence that the fossil animals, and the people who chipped the flints, were contemporaneous.

The valley of the Warner Lakes is referred to as a 'fractured anticlinal.' Again, the same expression is used in describing Silver Lake. We believe, however, that geologists familiar with the progress of exploration in the Far West during the past ten years would class these basins as monoclinal valleys, of the Great Basin type.[1] The Warner valley has a profound fault along both the eastern and western borders, and is enclosed to a great extent by lofty fault-scarps.

The Abert Lake basin also owes its formation to displacements. The lake occurs at the base of a great fault-scarp, forming a cliff two thousand feet high, and covers the depressed edge of a thrown block.

In the passage relating to Abert Lake (p. 138), the reader is left in doubt as to whether the lake, or the Chewaucan River, abounds in trout. Later, however, three species of fish are credited to Abert Lake. My own experience has been, that trout are abundant in the river, and absent from the lake; although they perhaps could exist in the latter in the immediate vicinity of the mouth of the Chewaucan River (frontiersmen who are familiar with the lake say that it is uninhabited by fish). During my own examination I found its waters swarming with 'brine shrimps' and the larvae of insects, but never saw a trace of piscine life. Its waters are strongly alkaline, and utterly unfit for culinary purposes. In its physical properties the water of Abert Lake resembles the brines of Sumner Lake (Oregon), Moro Lake (California), and the soda-ponds (near Ragtown, Nev.), all of which are too strongly alkaline to be inhabited by fishes. It is not evident on what authority Professor Cope ascribes a fish fauna to this lake, as on p. 138 it is stated distinctly that he did not get a near view of it.

From a study of the geographical distribution of the fishes in the lakes of the Great Basin, Professor Cope has found that the larger fishes inhabiting the lakes in northern Nevada and south-eastern Oregon are different from those of the lakes of the Bonneville basin. This is an interesting determination; as the former basins were mostly without outlets during the quaternary, while the latter became tributary to the Columbia.

The effect of alkalinity on the growth of fishes has been noted by Professor Cope to some extent, and is evidently a study that might lead to interesting geological conclusions. The comparison of the faunas of Pyramid and Tahoe lakes would perhaps show the effect of salinity and alkalinity on the species of fishes which probably inhabit both lakes. Pyramid Lake, it will be remembered, is supplied almost wholly by the Truckee River, the outlet of Lake Tahoe.

Before concluding that "all the species of Pyramid Lake are peculiar to it, excepting Catostomus tahoensis," it would be desirable to compare its fishes with those of Walker Lake. As these two lakes are quite similar in chemical composition, and both occur in the Lahontan basin, it seems probable that their abundant faunas would be found nearly identical. One species of trout, at least, seems to the writer, from superficial examination, to be common to the two.

The second part of Professor Cope's paper is devoted to the description of the fossil fauna of 'Idaho Lake.' This lake existed in eastern Oregon and western and southern Idaho during pliocene time. No body of water represents it at present; and the fish-remains found in its sediments differ from those of the Oregon basin, both recent and fossil. The extent of this ancient lake is not known. Its sediments are named the 'Idaho formation,' but no typical exposure is described or in any way indicated. Even the locality at which the fossil bones were collected is, for some unstated reason, withheld. This method is to be regretted; as Professor Cope does not stand alone in making geological divisions on purely paleontological grounds, without attempting to describe or locate the formations named. If this practice is persisted in, it can only lead to confusion.

Of the twenty-two species of fossil fishes described, eight are new. Besides these, the sediments of the Idaho Lake have furnished three species of crawfish which were reported by Professor Cope some years since. The mollusks, it appears, have already been described by F. B. Meek. Both the vertebrate and invertebrate fossils of the formation determine it to be lacustrine and fresh.

Although we have ventured to take exception to a number of statements in the paper under review, yet we welcome it as adding materially to our knowledge in a field that had previously been but little studied.

ISRAEL C. RUSSELL.

Washington, D.C.

THE DEFINITION OF MEAN SOLAR TIME.[1]

THE proper definition of mean solar time appears to me a very simple matter, and to have nothing arbitrary about it. The mean sun is merely an imaginary body which is supposed to move uniformly

[1] Paper by Prof. J. C. Adams of Cambridge, at the December meeting of the Royal astronomical society. From *The observatory*, February.

in the equator at such a rate that the difference between its right ascension at any time, and that of the true sun, consists entirely of periodic terms. This difference is called the equation of time, which, therefore, by its very nature, cannot contain any term increasing indefinitely with the time. Mean noon at any place is determined by the transit of this imaginary body over the meridian of the place, just as apparent noon is determined by the transit of the true sun.

Thus mean time is defined with reference to a natural phenomenon; viz., the transit of the real sun over a given meridian: and we cannot have one length of a mean solar day according to Bessel, and another length according to LeVerrier, any more than we can have different lengths of the apparent solar day.

A mean solar day, according to Mr. Stone's theory, is something totally different from that above defined. It has no reference to the average length of the apparent solar day, but is purely artificial or conventional in character. Practically, Mr. Stone's mean solar day is the time during which the mean *longitude* of the sun increases by some definite amount. Bessel gives one determination of this amount, and LeVerrier a different one: hence Mr. Stone is obliged to employ two mean solar days, which are of different lengths, according as Bessel's or LeVerrier's mean motion of the sun is used. On this principle, every fresh investigator of the sun's motion would require a mean solar day peculiar to himself. We are tempted to ask, What was the meaning of the mean solar day before Bessel's time?

The origin of Mr. Stone's misapprehension on this point seems to be the following. In the ordinary practice of an observatory it is usual and convenient to deduce the mean solar time from the sidereal time supposed to be known, instead of finding it by direct observation of the sun. In order that this conversion of sidereal into mean solar time, however, may be correctly performed, it is necessary to employ the correct mean longitude of the sun at the given instant. Any error in the assumed mean longitude will produce an equivalent error in the mean time deduced; and, if the sun's mean motion be incorrectly assumed, the error of time thus produced will gradually accumulate.

Thus the error of mean solar time as deduced from sidereal time by means of Bessel's formula, which amounted in the year 1864 to a little more than half a second, has increased to a little more than six-tenths of a second at the present time. The increase of the error of mean solar time in nineteen years is in reality rather less than eight-hundredths of a second, whereas Mr. Stone's theory makes it amount to twenty-seven seconds! In fact, the error, according to Mr. Stone's theory, is about three hundred and sixty-five times as great as it should be. The reason is, that mean time is measured, *not* by the sun's mean motion in *longitude*, as Mr. Stone's theory supposes, but by its mean motion in *hour-angle*, which is about three hundred and sixty-five times as great; so that the error in time produced by a small error in the mean motion in longitude is only about $\frac{1}{365}$ of that which would be produced if the error in time bore the same proportion to the time that the error in the mean motion in longitude bears to this mean motion itself.

If n denote the sun's mean motion in longitude in a mean solar day, then the ratio of the length of a mean solar to that of a sidereal day is

$$360° + n : 360°.$$

And if $n + d\,n$ denote a slightly different determination of the mean motion in longitude, this ratio will be altered to

$$360° + n + d\,n : 360°.$$

Hence the measure of the sidereal interval corresponding to any given number of mean solar days will be altered in the ratio of

$$360° + n + d\,n : 360° + n,$$

or

$$1 + \frac{dn}{360° + n} : 1;$$

that is, since 360° is nearly equal to $365\,n$, the sidereal measure of the interval will be altered nearly in the ratio of

$$1 + \frac{1\,dn}{366\,n} : 1$$

instead of in the ratio of

$$1 + \frac{dn}{n} : 1,$$

as it should be by Mr. Stone's theory.

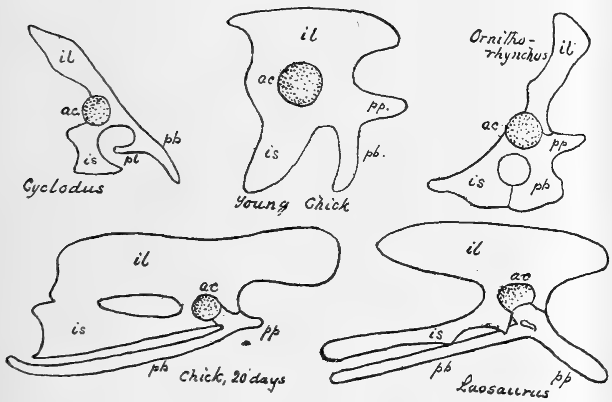
In conclusion, we will test Mr. Stone's theory of mean solar time by supposing an extreme case. Let us imagine that the sun had *no motion* in longitude, but, like a fixed star, retained a constant position in the heavens. On this supposition, mean solar time would be just as intelligible as it is at present, and it is evident that the mean solar day and the sidereal day would become identical with each other; but what would become of mean solar time according to Mr. Stone's idea of it?

MORPHOLOGY OF THE PELVIS AND LEG.

MISS ALICE JOHNSON, at the suggestion of the late F. M. Balfour, has investigated the development of the pelvic girdle and hind-limb of the chick (*Quart. journ. micr. sc.*, xxiii. 399). On the fourth day of incubation the limb is merely a local exaggeration of the Wolffian ridge, consisting, like it, of a mass of rounded mesoblastic cells crowded together. The first trace of the skeletal parts appears on the fifth day; the mesoblastic tissue of the axis of the limb becoming more condensed, and, by the seventh day, converted into recognizable cartilage. Ossification begins very late. The entire skeletal *anlage* of the girdle and limb is at first continuous, making a T, of which the stem represents the limb, and the cross the girdle running dorsoventrally. The pelvic *anlage* soon expands, above the centrally placed acetabular region, into a broad plate, the ileum; below, and in front, into the narrow pubis. A little later the pectineal process grows out in front from the upper part

of the pubis, and the ischium appears behind as a downward expansion below the acetabulum. The further change consists chiefly in the expansion of the ileum, and in the growth of the pubis and ischium; which last two become inclined backward, and acquire a considerable posterior prolongation. During these changes the pelvis passes through a stage which is permanent in Apteryx. The division of the primitive anlage into the skeletal parts is produced by the known histological changes at the joints. The author thinks that Hofmann's 'epipubis' (*Nederl. arch. zool.*, iii.) is the true pubis, and his 'pubis' in reptiles a process of the ischium. She also corrects some errors of Bunge.

These observations throw much light on the homologies of the pubis, of which the pectineal process is a branch, so that the pubis is biramous. A comparison of the bird with mammals (in which the pectineal process is often reduced, and sometimes absent) and dinosaurs at once determines the homologies of the pubis in these forms. In reptiles the pubis has also two branches,—the main body of the pubis; and the



Explanation.—*il*, ileum; *ac*, acetabulum; *is*, ischium; *pb*, pubis; *pl*, processus lateralis; *pp*, pectineal process.

posterior ramus lateralis, which may be wanting, however, as is the case with crocodiles. After discussion of the subject, the writer concludes, we think rightly, that the so-called pubis of reptiles is homologous with the pectineal process, and the lateral ramus homologous with the pubis of higher forms. The homologies are given in the following table, and differ, it will be seen, very widely from those current:—

Reptiles.	Dinosaurs.	Embryo bird.	Birds.	Mammals.
1. Pubis.	Pubis (Marsh).	Anterior branch of pubis.	Pectineal process.	Pectineal process.
2. Processus lateralis.	Postpubis (Marsh).	Posterior branch.	Pubis.	Pubis.

Miss Johnson also investigated the development of the limb. Her observations agree in almost every detail with Baur's (*Morphol. jahrb.*, viii.): we therefore note merely the presence of five metacarpals, and the failure to find a separate origin for the intermedium; but, in opposition to Morse, she is inclined to concur with Baur in describing the ascending process of the astragalus as an outgrowth from the tibiale. Morse's conclusion may be due to his having studied different birds (aquatic species). It is a pleasure to praise this excellent paper.

C. S. Minot.

RECENT WORK ON BRACHIOPODS.

The important though rather fragmentary observations of Kovalevski on the development of the brachiopods have long remained sealed in their original Russian from western naturalists, who have only had access to more or less incomplete synopses of the original. MM. Oehlert and Deniker have prepared for the latest volume of the *Archives de zoologie expérimentale* a careful analysis of the paper in question, illustrated by rough but sufficiently clear figures reproduced from the original. The result is a paper of some twenty pages, which may be obtained separately, and will have a value for all biologists, whatever their position as to the author's theories.

In a note on Terebratula (Centronella) Guerangeri, M. Oehlert signalizes the existence of two or three forms of this genus in the Devonian of Europe. He discusses the relations of Centronella, Leptocoelia, and Renssellaeria, and concludes that they probably represent an arrested development, which would, if carried out, bring them into relations with Waldheimia, and that they should be referred to the same sub-family. The absence of punctation in the test is referred to metamorphism, as in C. Guerangeri all stages were discovered, from impunctate to completely punctate.

The same author, in the *Bulletin de la société géologique de France*, discusses the Devonian Chonetes of western France, where four species are found in the grauwacke and calcaire beds, but are absent in the grits. One of the species, C. tenuicostata, is new, and all are figured; while the characteristics of the genus are thoroughly reviewed.

In the same publication the author describes two new species of Acroculia from the lower Devonian of Mayenne, reviews the genus, and shows that the prior name of Platyceras Conrad, being doubly preoccupied in insects, must give way to Acroculia.

Lingula Norwoodi, from the Cincinnati limestone, is redescribed and figured by U. P. James in the *Cincinnati journal of natural history.*

Glottidia pyramidata Stimpson has been found by Hemphill in South Florida, considerably extending its range, and leading to the suspicion that G. antillarum Reeve, described from the West Indies, may be identical with it.

W. H. Dall.

THE AMERICAN INSTITUTE OF MINING-ENGINEERS.

THE winter meeting was held at Cincinnati, Feb. 19–22, and was not so numerously attended as usual by reason of the flood in the Ohio, which had so interfered with railroad travel during the preceding week as to keep many at home who had expected to be present.

At the first session, on the evening of Tuesday, Feb. 19, the institute was cordially welcomed to Cincinnati by representatives of the city authorities, of the citizens, of the university, of the Ohio mechanics' institute, and of other organizations.

Mr. Robert W. Hunt of Troy, N.Y., president of the institute, returned thanks in behalf of his fellow-members. The remainder of the evening was occupied by Mr. Arthur V. Abbott of New-York City, who delivered a lecture on physical tests of metals, in which he gave a lucid description of the Fairbanks automatic testing-machine at New York. Diagrams of the various parts of the machine were thrown upon the screen, including representations of the novel contrivances employed for the automatic registration of stresses and strains, as well as some of the autographic sheets, which showed how the ultimate tensile strength of short bars differs from that of longer ones of the same material and same cross-section. The machine has a capacity of two hundred thousand pounds for either kind of stress, — tension, compression, torsion, etc. (see p. 312).

The session of Feb. 20 was opened with a paper by Mr. Magnus Troilius of the Midvale steel-works, Philadelphia, describing and advocating the bromide process for determining the sulphur in steel; and this was followed by a supplementary paper, by the same author, giving tables for facilitating the heat-calculations of furnace-gases containing CO_2, CO, CH_4, H, and N.

The next paper, by Mr. George C. Stone of Newark, N.J., was on further determinations of manganese in spiegel, being a continuation of a paper presented at the Troy meeting, in which the results of many analyses of spiegel by different chemists were tabulated, and the comparative value of the chemical processes employed was discussed.

The next paper read was by Dr. T. Sterry Hunt of Montreal, on the apatite deposits of Canada, their distribution, richness, and value, the amount at present annually exported, the economic conditions for mining it, etc.

Mr. Nelson W. Perry of Cincinnati exhibited specimens of a new mineral discovered by him near Ramos, San Luis Potosi, Mex., for which he proposed the name ramosite. Its hardness is nine in the scale, being next to the diamond; its color, black; its specific gravity, 3.83. Mr. Perry also exhibited crystals of topaz found in Mexico, some of which were as much as an inch in diameter, occurring in the unusual matrix, trachyte.

After a paper by Mr. Frank Firmstone of Easton, Penn., on incrustations in pig-iron, a report was made by Dr. Thomas Egleston of the Columbia school of mines, New York, on the bill now pending before Congress to re-establish a commission for testing the strength and other properties of iron, steel, and other materials of construction. He earnestly disclaimed any intention of interfering in any manner with the use of the Emory testing-machine at Watertown (built by the last commission), or of having it removed to any other locality, and urged that all legitimate influence be brought to bear to have the bill passed.

In an elaborate paper by Mr. S. Stoltz of Pittsburg, Penn., on coal-washing, elevating and conveying machinery, the plant employed by him in handling soft coal was explained in detail by the aid of numerous diagrams.

Professor Lord, of the Ohio state university, Columbus, gave the results of analyses of certain Ohio clays.

A paper by Mr. Joseph H. Harris of Philadelphia, on the benefit fund of the Lehigh coal and navigation company, gave a *résumé* of this and various other forms of life and accident insurance for the benefit of miners, and compared the usefulness of the different plans which have been adopted in Pennsylvania; it being a matter of extreme difficulty and delicacy to arrange a plan which works well, in face of the strained relations often existing between the miners and their employers.

The session of Feb. 21 was opened with a lecture by Dr. A. A. Springer of Cincinnati, on torsion, illustrated by diagrams. He was followed by Prof. William L. Dudley of Cincinnati, who explained somewhat minutely the new process of electroplating with iridium, and exhibited specimens of articles so plated.

A paper by Mr. Pedro G. Salom of Thurlow, Penn., giving the results of the analyses and tests of steel used in the U. S. cruisers now building at Chester, Penn., was, by reason of the important and remarkable results obtained, made the special order for the next meeting of the institute.

The officers elected at this meeting were: —

President, James C. Bayless, New-York City; vice-presidents, Eckley B. Coxe (Dufton, Penn.), Thomas Egleston (New York), Edwin C. Pechlur (Cleveland); managers, Edward S. Cook (Pottstown, Penn.), Frank Firmstone (Easton, Penn.), C. W. Maynard (New York); treasurer, T. D. Rand, Philadelphia; secretary, Rossiter W. Raymond, New York; scrutineers, S. T. Williams, J. T. Lewis.

The annual report of the secretary showed a total membership of 1,341, which was largely increased at this meeting.

The meeting was a success, not only in a professional and scientific way, but socially as well. The institute invited its Cincinnati friends to dinner at the Grand Hotel on Wednesday evening; Mr. and Mrs. T. B. Aldrich entertained the institute, at their residence on Mount Auburn, on Thursday evening; the Southern railway provided an excursion to the high bridge over the Kentucky River, with special train of Pullman cars, and lunch, on Friday; and the institute was invited to attend the opera festival to hear Nilsson on Friday evening.

GEOLOGY OF THE GRAND CAÑON.

Tertiary history of the Grand Cañon district. By CLARENCE E. DUTTON. (Monographs U.S. geological survey, ii.) Washington, *Government printing-office*, 1882. 264 p., 42 pl. 4°. Atlas, 23 sh. f°.

THIS work is the second in numerical order, though the first in date of publication, of the monographs of the U. S. geological survey. It is not a geological report in the generally accepted sense of the term, but deals strictly with the physical problems displayed by the Grand Cañon district, and, as its title indicates, principally with that part of its history embraced in the tertiary period, of which the distinguishing feature in this region is denudation on a stupendous scale.

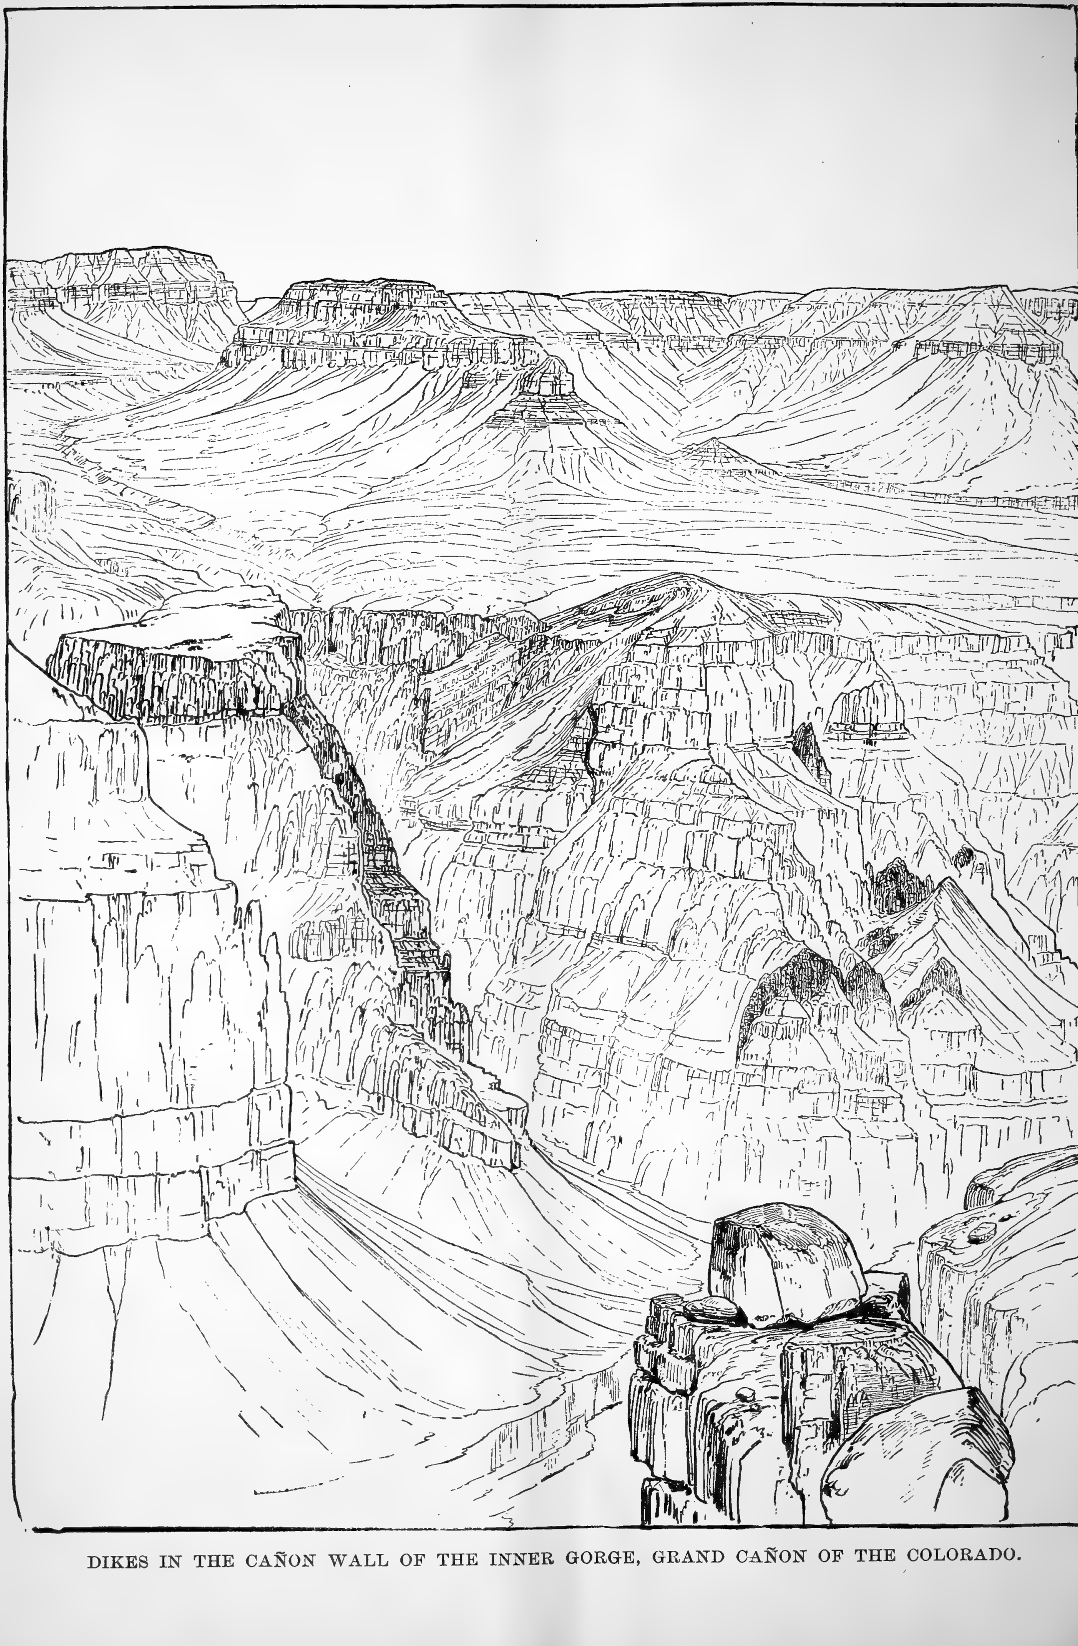
The first geological exploration of the Grand Cañon of the Colorado is due to Major Powell; and for several years his name was closely associated with the progress of discovery in this field. Finding himself, however, unable to continue the work, it was delegated to Capt. Dutton, who had already become familiar with some parts of the district; and the present monograph is the best possible evidence that Major Powell has found no unworthy successor in his investigations.

Capt. Dutton writes as one in love with his subject; and it would indeed be surprising if any geologist who has had the privilege of studying this region were otherwise than enthusiastic in regard to it. A large part of the western territory is such that the geologist who runs may read; that even from the windows of the railway more facts may be gleaned in a day's journey than could be certainly arrived at by months of study in a wooded country, or one mantled by the northern drift. In addition to these advantages, common to vast tracts, the Grand Cañon presents the most striking river-section in America, and perhaps in the world. In such a field a more complete knowledge of the problem is possible, and a closer and more logical method in its treatment admissible, than elsewhere, — circumstances fully taken advantage of in the present report.

The high plateaus of southern Utah descend to the south in a succession of gigantic terraces, composed in succession of the eocene, cretaceous, triassic, and Permian formations, till the summit of the carboniferous is eventually reached. This forms a wide platform, with some approach to regularity of surface, but drops at length in an escarpment of great cliffs to the desert and sierra regions of the farther south and west. The terrace country has a width of from thirty to forty miles, with a length of about one hundred, and forms, as it were, a giant stairway, leading down from the high plateaus, with an elevation of over ten thousand feet, to the carboniferous platform, five thousand feet or more lower. The whole rock series has a preponderant northward dip of an extremely regular character, which seldom exceeds two degrees, and is generally less than one degree, in amount. The carboniferous surface presents a corresponding light slope from south to north; and the strata are traversed by a series of faults and congenetic monoclinal flexures, running in north and south courses, but showing a convexity toward the west. These define the several minor plateaus which diversify the surface; but the region, as a whole, is characterized by the proximate horizontality and undisturbed condition of its rocks, and is in marked contrast to the turmoil of flexed beds found in the adjacent sierra country. Across the carboniferous platform, in a general south-westward course, the great cañon has been cut, — a vast chasm, with a total length of about two hundred miles, a depth of from five thousand to six thousand feet, and a width of from five to twelve miles.

The history of the cañon district, from the later paleozoic to the present day, is naturally divided into two widely contrasted periods; the first extending from early carboniferous time into the eocene, having been one of steady, conformable deposition, bed succeeding bed, till a thickness of about fourteen thousand feet was accumulated. To this succeeded a period of continuous erosion, during which an average thickness of ten thousand feet of the strata was removed from a large part of the surface.

Though rather heterogeneous in character as compared among themselves, the beds of the Grand Cañon region in general closely resemble those representing the same horizons in other parts of the west. The archaean and other basal rocks, not throwing any light in the physical problem proposed in the monograph, are merely mentioned. The carboniferous, broadly viewed, may be characterized as chiefly limestone; and the conditions of a somewhat deep sea at the time of its formation are implied. The Permian and triassic are mainly represented by sandstones, which frequently display cross-bedding, and denote that the water at the time of their deposition was continuously shallow. In the cretaceous, argillaceous and marly rocks become more abundant; and the occurrence of coals and carbonaceous layers throughout, shows that portions of the region became land-surfaces from time to time.



DIKES IN THE CAÑON WALL OF THE INNER GORGE, GRAND CAÑON OF THE COLORADO.

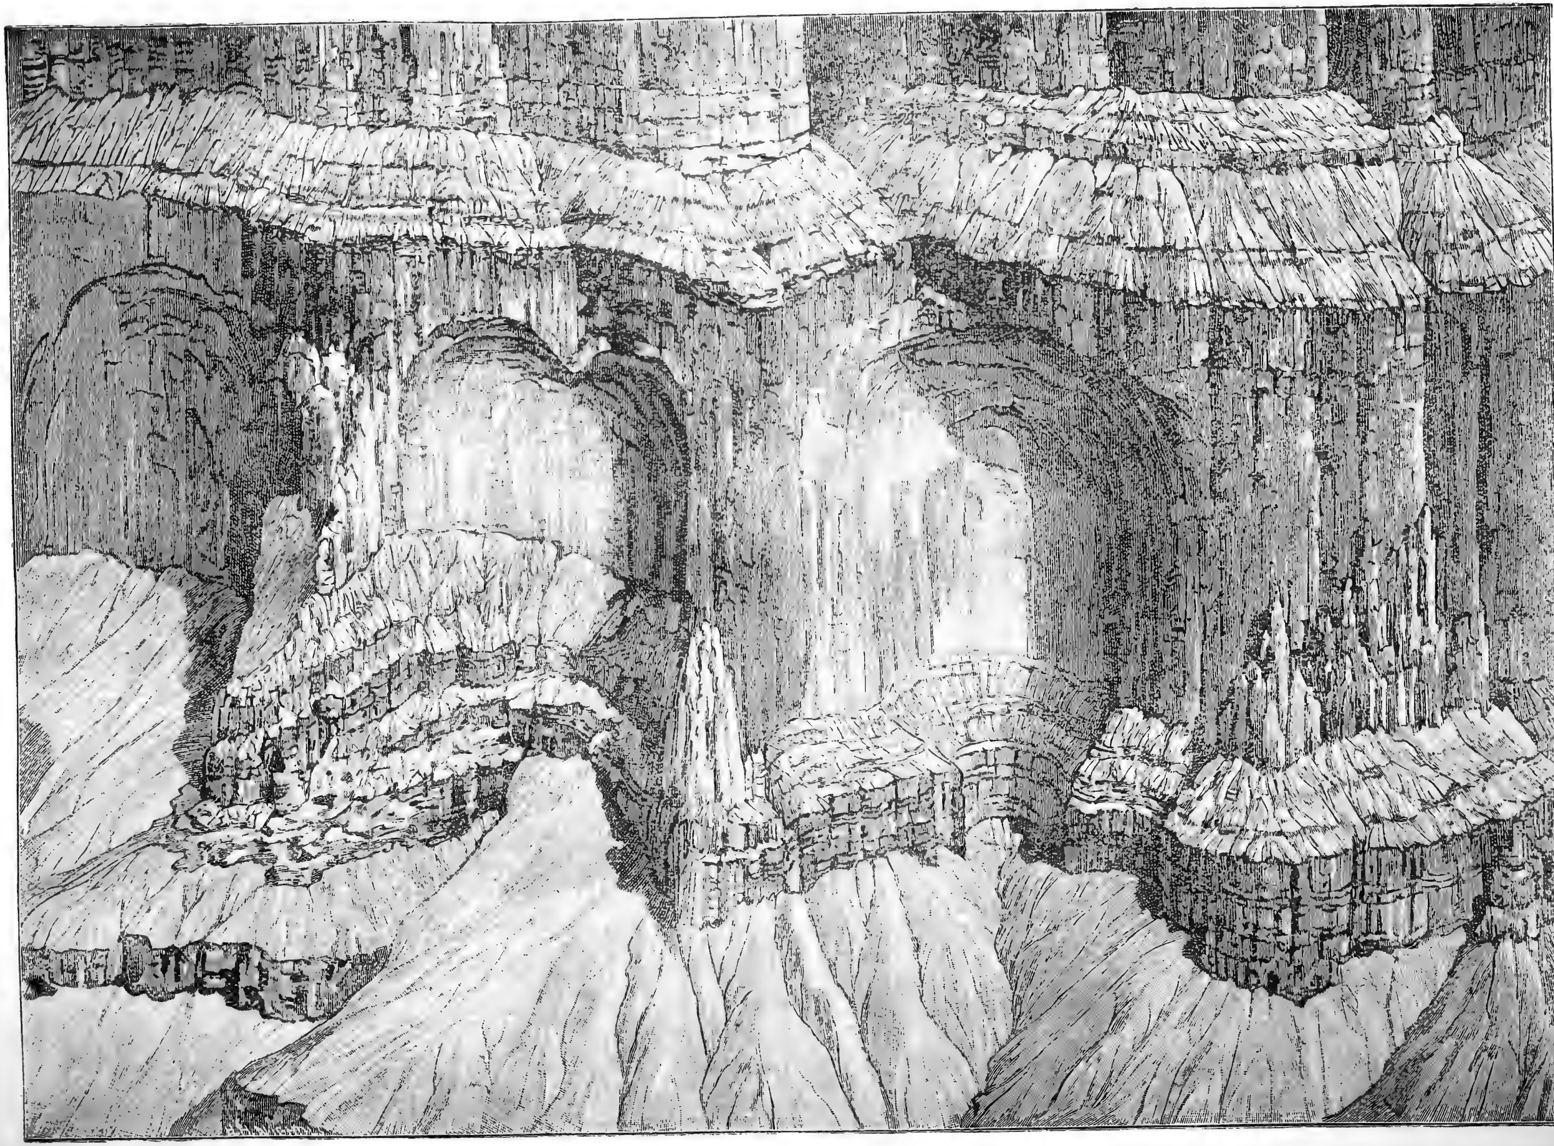
This period closed amid important disturbances; as, in neighboring districts, the succeeding beds are occasionally found to rest directly on the Jura-trias, or basset edges of the cretaceous. As a result of these movements, a great eocene lake was formed, which appears to have been not far above the sea-level, and to have outflowed southward. The change from salt to fresh water conditions is quite sudden. During the eocene period this lake gradually shrank back, and finally disappeared to the north, near the base of the Uinta Mountains, where alone the later eocene deposits are found.

The author finds a little difficulty in explaining the great horizontal similarity in character of the materials laid down during the later periods in a wide expanse of water so persistently shallow. It is suggested, however, that the very shallowness of the sea or lake may, by insuring a constant sectional area, have resulted in maintaining the velocity, and consequent transporting-power, of any currents which existed. The continuance of shallow-water conditions also proves that the profound subsidence required by the volume of the sediments was not acquired suddenly, but that the two increased *pari passu*.

With the eocene the immensely prolonged period of subsidence came to an end, and elevation — shown to have been somewhat spasmodic — and consequent erosion began. It is found by reducing the faults and flexures of the region, and taking into consideration the thickness of the beds, that at this time the carboniferous must have lain over considerable areas, at a depth of from ten thousand to twelve thousand feet below the level of the sea; and it is interesting to remark in passing, that no great degree of alteration appears to have resulted from this deep burial in the earth's crust. The present altitudes of the plateaus mark the difference between the amount of the succeeding uplift and that of denudation; and it is shown that the total movement in elevation has been in different places from twelve thousand to eighteen thousand feet.

The 'great erosion,' as Capt. Dutton names the second period of the history, began at the time of the drainage of the eocene lake, of which there is good reason to believe the Colorado still marks the position of the deepest portion. The immutable permanence in position of the channels of the Colorado and its main tributaries, and the fact that they have been able thus to maintain their original courses in opposition to the superimposed northward dip of the beds, is one of the most striking facts brought out in the study of this district, being, in fact, that which has been most influential in impressing it with its peculiar features. In the latter part of the eocene, and in the miocene, great progress was doubtless made in the removal of the mesozoic strata. The process of elevation continued, and rapid corrasion by numerous streams made steady progress; the Colorado, at this time, probably flowing in a cañon walled by these mesozoic formations, the escarpments of which have now retreated to the terrace district, fifty miles or more to the northward. Through all this lapse of time we are, however, without any very precise data as to the progress of the erosion; and it is not till a date approximately referred to the close of the miocene that any measure of the waste accomplished can be arrived at. The elevation of the district was then for a time arrested; and the streams reached what the author, following Major Powell, calls a 'base level of erosion,' in which, with the production of a uniform light gradient, the wear of their channels clased, and denudation acted only in reducing the probably rough and irregular features of the neighboring country to an approximate level. The Permian strata apparently at this time constituted the actual surface.

About the time at which the Colorado began to cut into the carboniferous rocks, a climatic change occurred, which resulted in producing very arid conditions, and dried up the smaller streams to their sources. This, from what is elsewhere known of the western tertiary, is presumed, with great probability, to be synchronous with the close of the miocene and beginning of the pliocene. Nearly contemporaneous with these events was an uplift of two thousand to three thousand feet, and the outpouring of the earlier basalts, which, forming protective cappings, have preserved portions of the Permian surface above alluded to. The great faults, also, about this epoch first betray their existence; though it is by no means certain that all were then formed, and the evidence is clear that their throw subsequently continued to increase gradually. Corrasion, or the wear by the rivers of these beds, now again became active, but only in the case of the larger streams, which, by reason of their origin in high, well-watered uplands beyond the cañon district, had been enabled to survive. A base level was soon again reached: and the Colorado remained during the greater part of the pliocene at the level of what Capt. Dutton calls the esplanade, or wide upper valley of the present cañon; which valley continued to increase laterally, but not in depth, till the



NICHES OR PANELS (OVER 600 FEET HIGH) IN THE RED WALL LIMESTONE, GRAND CAÑON OF THE COLORADO.

final paroxysm of upheaval set in, producing a further rise of from three thousand to four thousand feet. The faults, which are strictly correlated with the varying uplifts of the several minor plateaus, again increased their displacement; and at the same time, or shortly afterward, the volcanic forces resumed their activity, producing cones of eruption which still display their characteristic form. These, and the lavas erupted from them, afford evidence, that, though the cañon had at the time a considerable depth, the greater part of its excavation still remained to be affected by that last great effort of corrasive action which has only lately come to an end.

It is believed that the elevation of the plateau region has now ceased, and that the rivers have again nearly reached a base level of erosion. Some, at least, of the faults cut the older basalts; but no evidence has been found, where the newer lavas cross them, of any renewed movement. The glacial period passed over this region without leaving any traces of ice-action, manifesting its occurrence merely as a pluvial episode, very brief in comparison with the stages of the great erosion, but of which some effects may nevertheless be traced.

Such is a very brief and necessarily imperfect outline of the train of reasoning in which the author follows out the exceptional processes which have acted in the Grand Cañon district, and eventuated in producing its present remarkable features. Very few of the conclusions arrived at are open to any question; and, though it has been for so short a time known to science, it may be considered as one of the most fully thought out of geological problems. Among the collateral facts illustrated in this region are several, which, from their apparently anomalous character, are of special interest to the student of dynamical geology. Such is the want of coincidence between the great faults and points of volcanic eruption, the bending-*down* of the strata along the dropped sides of the faults, the connection of the latter with the peculiar monoclinal flexures, the not uncommon reversal in direction of throw in the opposite ends of a single fault, and the remarkable observation that the general light dip of the strata is increased notably at the bases of the terraces. The last-named circumstance the author is disposed to connect, though doubtfully, with the theory of plastic equilibrium in the earth's crust, — a theory which we believe few geologists will be ready to follow so far.

A notice of this monograph would be incomplete without special reference to the accompanying atlas, containing geological maps and panoramic views of the district. The latter, together with a number of illustrations in the volume itself, are from the pencil of Mr. W. H. Holmes, and convey a better idea of the proportions and intricacy of the physical features than could be accomplished by any word-painting, however elaborate.

If the character of the critic must be maintained in reviewing this work, which in its main features demands our praise alone, it may be suggested that the 'effusive' style adopted in some of the chapters is scarcely in keeping with the incomparable dignity of the subject, and is not likely to appeal to the specialists for whom this class of publication is intended.

THE BACILLUS OF BERIBERI.

Etiologia e genesis do beriberi. Pelo Dr. J. B. de Lacerda. Rio de Janeiro, *Faro & Lino*, 1884. 68 p., illustr. 8°.

This pamphlet gives the results of a medico-biological study, carried on in the physiological laboratory of the National museum of Rio de Janeiro, on a very obscure disease, which, introduced many years ago in Brazil from India, carries off annually a large number of victims, particularly in the northern provinces of the empire.

Employing the method of Pasteur, and introducing blood of beriberi patients in meat-solution, Dr. Lacerda obtained in numerous experiments a microphyte similar in form to the bacillus of carbuncle. This organism, which reproduces itself by segmentation and by spores, was also found in the fresh urine and blood of beriberi patients, the spores being at times extremely abundant in the blood. On making subcutaneous injections of the liquid in which the organisms were cultivated, in rabbits and guinea-pigs, these animals were found to succumb in periods of from five to twenty days, some of them presenting a true paralysis of the posterior members; others, a notable weakening of these members, with difficulty of locomotion, and loss of cutaneous sensibility. Death in many cases was caused by asphyxia, the paralysis having extended to the anterior members. The cultivated blood of these animals reproduced the same microphytes that had been obtained from the blood of beriberi patients. The microscopic examination of the spinal medulla and of the muscles revealed the presence of the microphyte and of its spores, their abundance in the medulla being especially remarkable.

From these facts the author draws the logical conclusion, that beriberi is a parasitic disease, and that the parasites attack particularly the blood, muscles, and medulla. In seeking the origin of the parasite, it was found that similar organisms were found at times in rice-grains. The characteristics of the grains of rice attacked by the parasite are given; and the hypothesis is advanced, that rice is often the vehicle of the microphyte by which it enters the human system, which appears to be in accord with the fact that rice is a principal article of food in the regions subject to the disease.

Contaminated grains of rice, subjected to the same cultivation as the blood of beriberi patients, produced organisms entirely identical in appearance. Injections of the liquid of the rice-culture in guinea-pigs produced death in thirteen, seventeen, and twenty days, with paralytic phenomena, and death by asphyxia; and the microscopic examination of the spinal medulla and muscles showed the presence of the same organisms found in animals inoculated with the blood-culture of beriberi. The author proposes to continue his investigation of the suspected relation between a rice diet and beriberi.

BIOLOGICAL THEORIES OF AN ARTIST.

Morphology. Estimates of intelligence. Vital chemistry. By FRANK B. SCOTT, artist. Buffalo, *Bigelow pr.*, 1883. 16 p. 8°.

THE author says in his preface, "If we fail in proving the truth of what we advance, our labor will not be lost: we may lead the way to further discoveries. Columbus was mistaken in his seeking another way to India, but his mistake led to the discovery of a new continent." In science great continents of knowledge never have been discovered by ignorant adventurers: we therefore do not believe that Mr. Scott will achieve the important success he dreams of, although he is mistaken in perhaps half his statements. We are acquainted with no other publication, purporting to be scientific, which contains so many amusing errors and entertaining hypotheses in so few pages. We need only give the following extracts in our justification. "Without oxygen, hydrogen, nitrogen, and carbon, we have no knowledge of life. . . . There are other elements subordinate to these. There is also some other element not subordinate. . . . Perhaps this fifth element was the *quint*-essence of the ancients. Huxley, in his 'Biology,' calls it electricity." Will the author kindly refer us to authority on the quintessence of life of the ancients; also to the page of Huxley? He further states that the blood at one moment is red with oxygen; the next, black with carbon. We have no doubt that sufficient carbon might blacken the blood, but we are surprised to learn that the mixture occurs regularly during life. The whole pamphlet resembles these samples.

THE ILLINOIS GEOLOGICAL REPORT.

Geological survey of Illinois. A. H. WORTHEN, director. Vol. vii., Geology and paleontology. Springfield, *State*, 1883. 4+373 p., 31 pl. 8°.

THE first two volumes of this series of reports appeared in 1866; and the others have followed at intervals since then, the seventh having appeared during the past year. The leading feature of these reports is paleontology, in connection with which the names of some of the ablest American paleontologists appear.

In his preface to the present volume, Mr. Worthen says, that to complete the paleontology of the state upon the plan originally contemplated will require two volumes more, with from forty to fifty plates of illustrations each, but that this cannot be done until authorized by special legislative act. It is not improbable, therefore, that the present volume will be the last of the series.

Mr. Worthen's chapter, of fifty-one pages, on economic geology, treats mainly of local sections in different parts of the state, principally of coal-measure strata. He announces the discovery of 'coal-oil' in the town of Litchfield, — a dense lubricating-oil, mingled with salt water, which he thinks comes from the base of the coal-measure conglomerate, or one of the upper Chester sandstones.

Four borings have reached the oil at a depth of nearly seven hundred feet, each boring yielding about two barrels of crude oil per day. He also reports the discovery of brine in Perry county. Six borings have been made, each flowing sixteen gallons a minute, from which an aggregate of thirty-five hundred barrels of salt is made annually.

The work on the fossil fishes by Orestes St. John and Mr. Worthen is a very important one, embracing two hundred and eight pages and twenty-six plates. It treats of those characteristic carboniferous families, the Cochliodontidae and Psammodontidae, and also of Ichthyodorulites. The important works on similar fossil fishes, which were published in previous volumes, are well known; and yet the material now published is unexpectedly comprehensive as regards the variety of forms

embraced in the two families just named. The authors describe and figure fifty-six new species of the Cochliodontidae, together with eight species previously published. They embrace, in all, fourteen genera, six of which are new; namely, Vaticinodus, Stenopterodus, Chitonodus, Deltodopsis, Orthopleurodus, and Taenodus. The last is a hitherto unpublished name, proposed by de Koninck. Of the Psammodontidae, thirteen species (eleven new) are described and figured; eleven of them being referred to Psammodus, and two to Copodus. Eleven genera are recognized among the Ichthyodorulites, one of which, Eunemacanthus, they propose as new. Of these genera, they describe and figure twenty-two species, only two of which have before been published. The specific and generic descriptions are full and clear, and Mr. St. John has made good use of his large experience in their discussion.

Pages 269–322 and four plates are devoted to descriptions and figures of fifty-five species of crinoids, together with a few carboniferous shells. Descriptions of all these except one of the shells were published by Mr. Worthen, without illustrations, in 1882, in Bulletin No. 1 of the Illinois state museum of natural history.

On pp. 323–326 he describes eight species of carboniferous mollusca without illustrations.

Pages 327–338 and one plate are occupied by Worthen and S. A. Miller's descriptions and illustrations of nine forms of echinoderms. Their material for this study was imperfect, and yet they have proposed five new genera; namely, Compsaster, Cholaster, Tremaster, Hybochinus, and Echinodiscus. The latter they refer to the Agelacrinidae, together with Archaeocidaris.

Pages 341–357 are occupied by Mr. Charles A. Wachsmuth. He figures and redescribes, in this volume, two echinoderms which he had previously described in the bulletin of the Illinois state museum of natural history. Following this, he gives an important discussion of certain blastoids, with a description of a new genus, namely, Heteroschisma.

The text of the volume closes with descriptions of three new species of blastoids by Prof. W. H. Barris. They are, however, without illustrations, except one woodcut. Professor Barris refers one of these species to Pentremites Say, and the other two to Elaeacrinus Roemer. He rejects the generic name Nucleocrinus Conrad, because of the erroneous description which Conrad gave of it. Nucleocrinus is, without doubt, identical with Elaeacrinus; but unfortunately Conrad's type specimen, which is still extant, shows plainly that he mistook its base for its summit. Diagnoses are seldom perfect, and it is difficult to determine how much of error we ought to overlook in the retention of imperfectly defined genera.

The letterpress and binding of this book are creditable; but the illustrations are not up to that standard of excellence which was attained in the previous volumes, and which the present state of art demands. Still, they serve well for the identification of the objects which they are intended to illustrate. The make-up of the book has one inexcusable deficiency, which was, no doubt, due to an oversight, since the other volumes are free from this defect. We refer to the absence of any table of contents, or any reference in the index to the different authors, or the titles of their subjects. This does not detract from the merit of the work, however, which is, as a whole, very great; and the people of Illinois may well be proud of what has been accomplished by their geological survey, even if it should now be suspended.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Work in the District of Columbia. — It is intended to map about three hundred square miles of the region about Washington, including the District of Columbia and adjacent country on the north, east, and west, extending to a distance of about ten miles from the district boundaries in those directions. This map will be used for the delineation of the geological features of the district and adjacent country, the investigation of which has been carried on for some time by Mr. W. H. McGee. The topographic work done so far consists mainly of the compilation and transferrence of material furnished by the Coast and geodetic survey in the form of original unpublished sheets upon a scale of 1–15,000, with contours twenty feet apart vertically, and covering the greater part of the area required for the immediate use of the geologist. Mr. S. H. Bodfish has been assigned to the topographic work, and will utilize all work previously done in the area above indicated by the coast-survey and the commissioners of the district.

Springs of Florida. — Prof. L. C. Johnson, while working in Florida during January, gave some attention to the springs and wells in the vicinity of

Jacksonville. He says that within five miles of Jacksonville is a remarkable spring, known as the Moncrief spring, the waters of which seem to be identical with those of the excavation at the city water-works and of many of the springs of this portion of the state. They differ from those of the southern and western portions in being more decidedly chalybeate. In temperature they are decidedly similar. All those near Jacksonville have temperatures of 72° F., and are said to be almost invariable, summer and winter. The extreme range is two degrees; that is, from 72° to 74°. The deep wells, the shallow ones, and also several lake-like springs, all register 72° F. Some are in superficial strata, reaching a depth of only fifteen or twenty feet; others are from thirty to forty feet deep in clay and rock; and some artesian wells penetrate to two hundred feet.

Chemical division. — During January and February Prof. F. W. Clarke and Dr. T. H. Chatard have been busy in the analyses of mineral waters. Among them, Professor Clarke has examined water from the Helena hot-springs of Helena, Montana Territory, which is an alkaline saline water, and water from the warm springs of Livingston, Montana, which is a calcic sulphur-water. Both are thermal, and these are probably the first analyses ever made of them. Dr. Thomas Chatard has also finished some analyses of Damourite from the well-known topaz locality at Stoneham, Me.

At New Haven, Messrs. Barus and Hallock, during January, were engaged in experiments to determine the exact boiling-point of zinc.

The north wind of California. — Mr. Gilbert Thompson, while engaged in topographical researches in the Cascade-range section of California, has been incidentally collecting information concerning what is generally observed as the 'north wind of California,' as it was first observed in that state, and supposed to be local. The name, however, should not be so restricted, as it should be extended to the Pacific slope of the United States and possibly of North America. The characteristics of this wind have been more particularly described by Dr. J. H. C. Bonté, of the University of California, than by any one else. To describe them briefly, they are included under the head of excessive drying-qualities. These are marked both in summer and in winter. In the former, vegetation sometimes appears as though it were burnt, and the effect upon both animals and men is striking. Men who have recently arrived in the country, and are robust, are not so sensitive to the wind as residents; and it has therefore been said that the imagination has a great deal to do with it, but this is a mistake. It matters not whether the wind is hot or cold, it produces a feeling of great depression and nervous irritability, lassitude, and restlessness. Some call it the 'poison wind,' and others the 'crazy wind.' The effects produced are similar to those of the 'Puna wind' of Peru, and the 'Hammattan' of Africa. It blows at no regular interval, nor for any known definite periods. There is some local authority, however, for the opinion that some multiple of three has been observed by some of its recurrences. The wind is really vicious only once in eight or ten years; and it undoubtedly has a powerful and favorable effect in drying up the wet soil, and neutralizing the effects of the rank vegetation, in the Sacramento valley after the rainy seasons. Mr. Thompson has, so far, traced its course and width to latitude 42°; and such information as he possesses to date seems to indicate that the wind moves down along the east base of the Cascade range, and thence through the Sacramento and San Joaquin valleys of California. There are numerous theories as to its origin, and the reasons why it produces such marked and peculiar effects.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Academy of natural sciences, Philadelphia.

Feb. 12. — Dr. N. Roe Bradner exhibited an inscribed stone found inside a skull taken from one of the ancient mounds at Newark, O., in 1865. An exploration of the region had been undertaken in consequence of the finding of stones bearing markings somewhat resembling Hebrew letters, in the hope of finding other specimens of a like character. The exploration was supposed to have been entirely unproductive of such objects, until Dr. Bradner had found the engraved stone now exhibited in a skull which had been given to him. The specimen is of a dark reddish material, of a rounded wedge shape, and bears on its surface a number of characters, the significance of which had not been determined, but which resemble the markings on the specimens before discovered. —— Rev. H. C. McCook described the nests of a new species of spider recently received from Mr. W. G. Wright of San Bernardino, Cal., for which he proposed the name Segestria canites. The cocoons hang in strings from the limbs of trees extending over a pathway. They are placed one above the other to the number of eight, and are united by a netting of white silk, covered with the leaves of the neighboring plants. They are kept in place over the path by lines which extend to either side, sometimes to a distance of five feet. Along one side of the suspended nests is a tube, which is inhabited by the mature spiders. As the weaving of nests over pathways leads to their being frequently torn away by passing animals, it had been suggested that the case was an illustration of a weakening of the instinct of preservation. It may, however, be rather a means adopted for the distribution of the species; the spiderlings being doubtless carried to remote points by the animals which tear away the nests. —— Mr. Edward Potts reported that he had examined the fore-bay at Fairmount water-works, from

which the water had been temporarily withdrawn, with a view to discover the winter condition of the fresh-water sponges and other inhabitants of that locality. Where the surface could be reached, it was found to be covered with a mud-colored incrustation of considerable thickness, which proved to be composed almost wholly of the statoblasts and spicules of the sponge Meyenia Leidyi. Some few fragments of Meyenia fluviatilis and Spongilla fragilis were seen, but the first named was clearly the prevailing species. A disused sluice-way was covered with a dry incrustation of the same material. While considering the effect of the presence of so large a sponge-growth at the inlet to the supply-pumps, Mr. Potts stated that Meyenia Leidyi was conspicuous among the known North-American sponges by its great relative density, and the small proportion of its sarcode or flesh. Its decay, therefore, at the termination of its period of summer growth, would be a slighter cause of pollution to the water-supply than that of any other species. He was, moreover, inclined to believe that decay was not the normal or necessary result of the close of each season's growth. The fragile branches of some species inhabiting exposed situations may, of course, be broken off and destroyed while the sarcode still covers them; but in the sessile portions, and in all when sufficiently protected, the cells of the sarcode at the period of full maturity, forsaking their places along the line of the skeleton framework, gather together by simultaneous amoeboid movement into dense groups, where they are soon covered by a tough chitinous coat, which, in turn, generally becomes surrounded by a crust of minute granular cells, and armor-plated by a series of protective spicules. These groups are now recognized as the statoblasts, gemmules, or winter eggs of the sponge. They are eggs only in appearance, being in reality the resting-spores or protected germs which conserve the life of the individual through the cold of winter. This life-history indicates rather a condensation than a decay of substance as winter approaches, and leaves little or no reason to regard such organisms as a source of water-pollution.

Feb. 19. — Mr. Thomas Meehan exhibited twigs of the plant used by the Piutes and other western tribes of Indians for making baskets. They proved, on examination, to belong to Apocynum cannabinum, the species used by the eastern Indians for a like purpose. —— Mr. Meehan called attention to sections of trees from Schuylkill county, Penn., illustrating remarkably slow growth. A black oak, Quercus tinctoria, in a little over two inches from the centre, had an average of thirty-six circles to an inch; one of hemlock spruce, fifty-one circles to an inch; and one of the common chestnut, twenty-four circles to an inch. Though only four inches in diameter, the oak stem was seventy-six years old; the hemlock, four inches in diameter, was one hundred and four years old; and the chestnut had grown only four and a half inches in diameter in sixty years. He believed two hundred years to be the full average duration of most of the trees of the eastern United States. —— The same speaker, referring to the supposed parasitic nature of the snow-plant Sarcodes sanguinea, of the Rocky Mountains, stated that he had carefully examined a specimen growing at an elevation in the Yosemite Valley, and found it to be existing independently, no connection being traceable with either living or dead roots. No trace of vegetation was found in the soil which was carefully washed away, but a huge mass of coralline fleshy matter, out of which the inflorescence arose. The origin of this fleshy mass was yet an unsolved mystery. From analogy with the behavior of other plants, he was inclined to believe that there was some parasitic attachment in the early life of the plant, and that it stored up in this coralline mass enough nutrition in one season to support the inflorescence, after which the connection was severed. —— Mr. Meehan also exhibited the dried leaves and fruit of Halesia diptera, H. tetraptera, and of a remarkable departure raised from the last-named species some years ago. This appeared in a bed of seedlings, all raised from seed gathered from one tree growing in a garden in Germantown. It attracted attention, when one year old, by the leaves bearing a resemblance to those of an apple-tree. The original tree had leaves narrowly lanceolate and acuminate, rather thin, pale green on the upper surface, and with no particularly prominent veins. The plant in question had broadly ovate leaves, scarcely pointed, very dark green, rugose on the upper surface, and strongly veined and hirsute below. The flowers, when they appeared, were open cup-shaped, instead of being drawn into a narrow tube at the base, as in the parent plant; and the pistil was wholly enclosed, and not exserted. For several years the plant was sterile; and many good botanists, whose attention was called to it, regarded the plant as a hybrid, and the sterility as a proof thereof. It was of no avail to point out that there was no other species from which the parent could have obtained pollen within many miles, nor to show that hybrids were not necessarily sterile. This season, however, the plant produced fruit. It is very small, not much over a quarter of an inch in diameter, and the four equal wings are comparatively large and of a strongly coriaceous character. The fruit which had been cut open was found to have perfect seeds. If the plant, with these leaves, flowers, and fruit, had been found in a state of nature, the botanists would surely have considered it the representative of a distinct species, if not of a new genus. While the suggestion of hybridity might be reasonably excluded, change of surroundings could not be advanced as the cause of the variation, for the environment was precisely the same for the sport, the seedlings which grew without change, and the parent stock. —— Professor Angelo Heilprin stated that among a small number of carboniferous fossils obtained from the border of Wise county, Tex., and submitted to him for examination by Mr. G. Howard Parker, a form occurs which can unhesitatingly be referred to the genus Ammonites. Only a fragment of a single individual is to be found; and this, unfortunately, has lost the shell, so that no external ornamentation, if any such existed, can now be discerned. This is the first Ammonites that has been detected in any Amer-

ican formation below the mesozoic series. The association with it of characteristic paleozoic forms of life, such as Zaphrentis, Phillipsia, Bellerophon, Conularia, Chonetes, and Productus, leaves no doubt as to its position; and hence we must conclude that here, as well as in India, where Waagen first announced the occurrence of true carboniferous ammonitic forms, the distribution of this highly characteristic group of organisms was not so rigidly defined by the mesozoic line as geologists had been led to conclude. That pre-mesozoic Ammonites will be discovered elsewhere besides in India and Texas, there is no reason to doubt; indeed, no assumption could be more illogical than the contrary: and therefore the present discovery is in no way specially surprising, and only interesting rather than important. Special interest, however, attaches to this form; as through it, and the individuals or fragments that have been found in the Tejon (tertiary) rocks of California, we have established in this country the extreme range of the group which it represents. The name Ammonites Parkeri was proposed for the species.

Philosophical society, Washington.

Feb. 2. — Prof. C. V. Riley presented a review of recent progress in economic entomology; describing especially the development of insecticide methods and apparatus, and closing his remarks with a plea for applied science. —— Dr. Swan M. Burnett discussed the question, why the eyes of animals shine in the dark, giving a short digest of the subject, and describing experiments of his own. He concluded that the phenomenon was caused by reflection from the retina of the eye. It is seen best when the observer is on the line connecting the shining eye with a source of light, and ceases when his station departs from that line by a certain amount. The limiting angle (measured at the reflecting eye) is relatively great in the case of eyes which are hypermetropic. Professor William Harkness pointed out that the limiting angle is likewise affected by the magnitude of the bright image on the retina. —— Mr. A. B. Johnson spoke on eccentricities of ocean-currents as illustrated by the voyages of lost buoys. At various times buoys have been torn from their moorings in the waters of the United States, and carried to sea; and eleven of these have been afterward found at distant points, and identified by means of letters cast in their constituent plates. One was found on the west coast of Ireland; a second, at Pendeen Cove, England; two others, just east of Teneriffe; a fifth, near Turk's Island; and a sixth and seventh, near Bermuda. The remainder were found in the open Atlantic, in the following positions: latitude 42° 22′, longitude 26° 38′; latitude 29° 46′, longitude 77° 38′; latitude 30° 30′, longitude 28° 40′; latitude 24° 11′, longitude 32° 43′. Admiral Jenkins cited another instance of a U. S. buoy stranding on the coast of Ireland. In the discussion which ensued, the opinion was expressed by Dr. William H. Dall and others, that the buoys found near Teneriffe had made a northward *détour*, and that those picked up near Bermuda and Turk's Island might have continued on the same course, and afterwards turned west, completing the circuit of the Sargossa Sea; but it was thought more probable that the latter had followed the southward coastwise current inside the Gulf Stream.

Feb. 16. — Prof. F. W. Clarke spoke on the periodic law of chemical elements, giving the history of the discovery of the law and of its verification by the subsequent discovery of elements indicated by it, and even specifically predicted. He exhibited an enlarged copy of Meyer's atomic-volume curve drawn with the latest values for atomic weights and specific gravities, and presented a similar curve illustrating the connection between atomic weight and melting-point. Each curve presents a series of maxima and minima, the maxima of one corresponding to the minima of the other. The regularities of these curves indicate that the elements originated by some method of evolution, and that a feature of transmutation of one element into another is not impossible. —— Mr. Henry A. Hazen read a paper on the sun-glows, which has since been printed in the March number of the *American journal of science.* The first appearance of the phenomenon was at Mauritius, Aug. 28, 1883; and it was next seen at Maranham, Brazil, Aug. 30. It then appeared at irregular intervals on either side of the equator, until Nov. 26 and 27, when it seemed to burst out over the whole world. After describing the nature of the phenomena, and stating the principal theories which had been advanced to account for them, he proceeded to advocate the vapor theory as follows: *a.* The glows are precisely like the ordinary sunset phenomena, which are known to be caused by the presence of aqueous vapor; *b.* The abundance of the material so uniformly distributed accords with the universality of the glows; *c.* The fact that faint stars and clusters could be easily seen indicates that nothing more opaque than water-vapor or frost-particles could be in suspension; *d.* Frost-particles might be repelled to a great height above the earth, and might be kept there by some form of electrical action; *e.* The fact of the spectroscope giving no indication of an abundance of moisture does not militate against this theory, because it has been shown that ice-crystals or frost-particles do not affect the spectrum in a rainband spectroscope. To the volcanic-ash theory he opposed the following objections: 1°. On this theory there must have been sufficient material ejected from Krakatoa, on Aug. 26 and 27, to cover more than a hundred and thirty-five million square miles of the earth's surface; 2°. There must have been currents of nearly equal force, moving *in opposite directions* from the volcano; 3°. The upper currents must have had a sufficient velocity to carry the ashes twelve thousand miles in a hundred and fifty hours (about eighty miles per hour) toward the west, while meteorology indicates no such velocities, and in general shows the upper current to be always toward the east; 4°. The ashes must have been mechanically distributed over the whole earth by air-currents; 5°. The phenomenon has been markedly intermittent; 6°. Volcanic ashes

are more or less opaque, while the phenomena attendant upon the glows indicate no such opacity. The cosmic-dust theory incurs many of the same objections, besides being inherently improbable. In the ensuing discussion Prof. E. B. Elliott argued that the phenomena were electrical; and Prof. H. M. Paul sustained the volcanic-ash theory, pointing out that Mr. Hazen's conclusion as to the simultaneousness of the first appearance of the phenomenon at remote points depended on a special interpretation of imperfections of the record, depending on cloudiness, and claiming the equal privilege of interpreting them in another way.

Ottawa field-naturalists' club, Canada.

Feb. 28. — Dr. George M. Dawson read a paper on the occurrence of phosphate deposits. After showing that phosphatic materials were essential to the life both of plants and animals, he pointed out that the natural cycle of the rotation of these substances was interrupted by the action of man, and that large quantities of matter which should return to the soil were withdrawn from it and taken elsewhere. The cropping of the soil impoverishes it, and prevents it from yielding as abundantly as formerly, unless the loss is compensated by the application of phosphatic fertilizers. The grain exported from the port of Montreal in a single year has been estimated to contain 2,574 tons of phosphoric acid, which implies the total exhaustion, in as far as phosphates are concerned, of 75,000 acres of good land, to renew which would necessitate the application of some 6,000 tons of apatite. It is easily seen that there must always be, under the present condition of affairs, an extensive demand for phosphatic materials; and it becomes necessary to inquire where specially concentrated natural sources of supply may be found. The occurrence of such deposits was traced from the guano, which accumulates in exceptionally dry climates, on islands frequented by immense numbers of sea-birds, and such recent deposits as the 'mussel muds' of Prince Edward Island, through the so-called coprolite beds of England, Carolina, and elsewhere, to the more concentrated and metamorphosed deposits found in the older rocks of Canada and Norway. The main facts in regard to the mode of occurrence of apatite deposits in the Laurentian rocks of Canada were explained, and the great economic importance of such accumulations was considered. —— Mr. Fraser Torrance who, as a mining-engineer, has had large experience with the deposits found in the vicinity of Ottawa, gave a very interesting description of the character of some of the deposits, and of the difficulties met with in working them, owing to the irregular manner of the deposition of the mineral; which cannot be considered as occurring either in veins or in beds, but as passing from one to the other without any regularity of transition. The methods in which the present surface-workings are conducted are such as to throw most serious difficulties in the way of any future mining of the lower deposits. The imperfect manner in which apatite has hitherto been manufactured in Canada was described; and it was stated that it was highly probable that much of the mineral which was mined in Canada and exported to Great Britain returned, either in the raw or manufactured condition, to the United States. —— Mr. F. D. Adams reported the detection by him, in minerals received from Arnprior, of a specimen of rock identical with that in which apatite occurs in Norway, and which had previously been known only from Norway and Finland.

Boston society of natural history.

March 5. — Prof. A. Hyatt read a paper on the larval theory of the origin of cellular tissue. He reviewed the history of investigation among sponges; concluding, that, though true metazoa, they possessed characteristics which showed them to be derived from protozoa. The parallel between the development of the cell and egg in the tissue is strictly parallel with the evolution of nucleated from unnucleated forms in protozoa. Recent investigations have removed all objections to the homology of the egg or any cell with the adult of the nucleated protozoon; and the principal mode of reproduction by division is the same in all these forms. The egg builds up tissue by division after being fertilized by the male or spermatozoon, just as the protozoon builds up colonies after fertilization. Spontaneous division of a cell which undergoes encystment takes place, and the spermatozoa which result from this are true larval monads. These resemble the monads derived from division of the encysted bodies of protozoa in their forms and in their activity. They differ in being able to fertilize the female or ovum at once, instead of being obliged to grow up to maturity before arriving at this stage. Thus all cells may be regarded as larval protozoa, and eggs and spermatocysts as encysted larval forms, the spermatozoa being equivalent also to larval forms which have inherited the tendencies of the mature forms in the protozoa at the earliest stages. Thus the origin of the tissues in the metazoa is in exact accord with the law of concentration and acceleration in heredity. The cells are larval, which, in accordance with this law, have inherited the characteristics and tendencies of their adult ancestors in their earliest stages. The three layers can be accounted for as larval characteristics inherited from colonies of Infusoria flagellata, which had two forms (protective and feeding zoons), and then three (protective, feeding, and supporting), these corresponding to ectoderm, endoderm, and mesoderm. —— Dr. M. E. Wadsworth read a paper on the structure of the earth's interior, which he held to be a molten or semi-fluid mass, which will gradually cool and solidify.

NOTES AND NEWS.

THE National academy of sciences will hold its next annual session at the National museum, Washington, commencing April 15, at eleven A.M. An election of five new members will be held. This will not make good the vacancies of the past year; for, of the ninety-eight members on the roll a year ago, six have since died, — Professors Alexander and Guyot

of Princeton, Gens. Humphreys and Warren of the Corps of engineers, Dr. LeConte of Philadelphia, and Professor Lawrence Smith of Louisville. Dr. Engelmann, whose death we recently announced, was an honorary member, and, like all the others excepting Gen. Warren and Professor Smith, a foundation member. Only eighteen of the fifty foundation members of 1863 now remain. We shall soon print memoirs and portraits of Dr. Engelmann and Gen. Humphreys.

— Another effect of the great eruption of Mount Krakatoa has been recently noticed. It was followed by a series of barometric waves which seem to have spread almost over the entire world. Professor Förster of Berlin says, The great eruption in the Straits of Sunda, which happened on the morning of Aug. 27, gave rise to an atmospheric wave which showed itself for five or six days in the records of the self-registering barometers in all parts of the world. In the barometric markings which are registered by the Commission of weights and measures in Berlin, in order to have a permanent record of the minuter variations, these effects of the volcanic eruption appear with striking clearness.

The first atmospheric wave from this source appeared in Berlin about ten hours after the catastrophe. Supposing it to have taken the shortest course from its origin to Berlin, this time would indicate a speed of somewhat more than a thousand kilometres per hour, agreeing very closely with the velocity of sound. This result is in complete accord with barometric records in other parts of the world. About sixteen hours afterward a second and entirely similar barometric wave appeared, which, however, is to be considered as the arrival of the same wave by the longer circuit over America and Europe. In fact, if we take the difference of the two courses, — the one from the Straits of Sunda to Berlin over the East Indies, and the other over America, — we shall find that to the above velocity of propagation corresponds the delay of sixteen hours in the arrival of the wave by the American route. It thus appears that the entire wave completed the circuit of the earth in a time which must have amounted to thirty-six hours. In fact, thirty-six hours later there did appear in Berlin, in a direction from the East Indies, another perceptible wave corresponding closely to the first one, but somewhat diminished in strength. The corresponding return from America took place in a period of some thirty-four or thirty-five hours. This is brought into agreement with the other period by the consideration that the atmosphere in general has a motion from west to east. A third wave was recognized after an interval of thirty-seven hours from this time. The diminishing strength of the waves prevented the returns of the single waves from being accurately followed, but small variations of an unusual kind are seen in the record until the 4th of September. We can therefore be satisfied that the atmospheric waves caused by the volcanic eruption were powerful enough to make the entire circuit of the earth three or four times, and that in the beginning the variations of pressure amounted to one five-hundredth of the entire atmospheric pressure. We are thus obliged to recognize the operation of force through which the heated gases and masses of volcanic dust might be carried into very high regions of the atmosphere.

Mr. Baillaud of Toulouse has communicated to the French Academy of science similar observations of the phenomena, from which he concludes the velocity to have been 349 metres per second. This, also, is very nearly the velocity of sound. From the intervals between the waves, he finds that the waves made the circuit of the earth at the average rate of 324 metres per second.

The most important conclusion to be drawn from these extraordinary observations is, that a mass of air or gas of which no one had before formed a conception must have been ejected by the volcano.

— The entomologists of Washington and Baltimore have decided to form an entomological society. A preliminary meeting was held at the house of Dr. C. V. Riley on the evening of Feb. 29, at which Rev. J. G. Morris of Baltimore presided, and Mr. B. P. Mann acted as secretary. A committee was appointed to draw up the necessary regulations, and to call a future meeting for organization.

— A vineyard proprietor near Nimes, having had several complaints made to him about his wines, requested M. Barthélemy, of the Faculty of sciences at Toulouse, to analyze them for him. In some of them a rather large proportion of arsenic was found, larger than the trace sometimes found in red wines. The wine from one barrel tested contained no arsenic at all, and in this instance the cask containing the wine was a new one: it had not been previously used. The other barrels had been cleaned, after use, with 'drogue,' which, in point of fact, is diluted sulphuric acid; and the sulphuric acid of the central districts of France has of late years contained so much arsenic, that M. Barthélemy has sometimes used it to obtain a supply of that material.

— Mr. Winter Blyth has recently been employed to analyze imported canned fruits (apricots, tomatoes, etc.) in order to ascertain the amount of contamination by metal in them. In twenty-three samples the amounts found, calculated as stannous hydrate, ranged from 1.9 grains to 14.3 grains per pound, the mean amount being 5.2 grains. The juice and fruit in some instances had a metallic taste. Several of the tins showed signs of corrosion. The *Journal of the Society of arts* says, "The little that is known of the action of stannous hydrate may be summed up in a few lines. Doses of about .174 gram per kilogram of body-weight cause, in guinea-pigs, death with signs of intestinal irritation; but with doses smaller than .17 to .2 gram the effects are uncertain, and the animals generally recover. Hence, supposing a man to be affected in the same proportion, he would have to take from three to four drams, or consume at a meal ten pounds of the most contaminate of Mr. Winter Blyth's tinned fruits. But it is not a question of immediate deadliness: it is rather one for inquiry as to the action of small repeated doses continued for a long time.

— As long ago as 1868, René de Semallé made the statement before the Paris geographical society, that, granting the general diminution of the Indians of the United States from year to year, the decrease has been arrested in the case of the Iroquois and other partially civilized tribes; and that there will arrive a time when the general decline will reach its lowest point, and will be followed by an increase, normal and continuous. The total disappearance of a tribe is something very rare. At Nablous we find the Samaritans still protesting toward the temple of Jerusalem, destroyed eighteen hundred years ago. In the struggle for existence, before re-adjustments are made, the weak begin to decline before the strong; but, after the bloody struggle is over, each party to the conflict finds itself undergoing modifications which are the conditions of survival. In using the figures of the census reports and of the Indian-office report, M. Semallé falls into the error, pointed out by Mr. Simonin, of supposing that the Indians have increased by birth simply because there seems to be the addition of several thousands in the census. The truth is, there are many causes of fluctuation; such as crossing the border, and moving from place to place. The truth remains, however, that the Indians are slowly increasing.

— Dr. Delaunay is the author of a paper in the memoirs of the Société d'ethnographie, upon the inferiority of precocious races. The term 'precocity,' as applied by biologists to individuals, explains a similar phenomenon as applied to societies. Claude Bernard tells us that the force of development is greatest in the inferior animals, and that this precocity is an evidence of inferiority, and excludes longevity. The inferior races of men mature most rapidly. An Eskimo, African, Arab, or Cochin-China child of one year is farther advanced in body and mind than a white child of the same age. The young Japanese at Paris excel the French boys up to the sixteenth year; and then there is an arrest of development. M. Delaunay makes the same assertion respecting puberty, cranial sutures, the different centuries of history, sex, the various periods of the same life, strength of constitutions, and different parts of the same body. The inferior races, by virtue of their precocity, became civilized before the superior races, and then suffered an arrest of development, became extinct or fossilized. The races and the civilizations of China, Egypt, etc., have evolved just as the individual Chinaman or Egyptian has evolved. On the contrary, the higher modern societies have developed slowly, just as develop the men who compose them. We may go farther, says M. Delaunay, and affirm, that, as the members of the body develop with different degrees of rapidity, so do the various groups or classes of the same society. The author combats the idea that our modern civilizations are the children and heirs of the older ones, from which they sprang, and without which they would not now exist. Speaking of the French, he affirms that they did not descend from the Aryans; that their language is not Aryan; that their domestic animals did not come from Asia; that their civilization is Celtic, not Greek and Roman. Finally, the civilization of Europe has been retarded by influences from Asia. Not to speak of cholera, plague, and other maladies, two-thirds of our intellectual lives are spent in perpetuating the errors and exploded fancies of Asiatic, Greek, and Roman thinkers and myth-makers.

— François Lenormant, who recently died at the early age of forty-six, was a most enthusiastic student of antiquity. A man endowed with great power of work, and interested in all archeological research, he was in recent years more specially concerned with the early Asiatic civilizations. The study of the cuneiform inscriptions had for him special charms. The most interesting use which he has made of these researches is to be found in his book, *Les origines de l'histoire*. Here he finds in the literature of the cuneiform inscriptions abundant material for comparison with the early traditions of the Jews and of other nations, as to creation, the deluge, and a whole circle of primitive beliefs. One of the latest fruits of his pen is a translation of the book of Genesis, in which, by the use of different kinds of type, he distinguishes the portions which he supposes to have come from different authors. Though a good Catholic, M. Lenormant did not allow his religion to interfere with his science, nor his science with his religion. Himself a religious spirit, he claimed for investigation the fullest freedom, and denied the propriety of dividing science into a Christian and a non-Christian faction.

— Mr. T. Lewis writes as follows in *At home*: —

There is, as may naturally be supposed, no important break in the chain of mounds stretching along the Mississippi valley from its lower regions to Minnesota; for they are very numerous along the river-bluffs up to the mouth of the St. Croix. They are then met with at intervals on the plateaus and headlands of the Mississippi as far north as Little Falls. In like manner they occupy the River St. Croix from its mouth to Yellow River, if not beyond that point. They are also found in abundance on the lower Minnesota River, and continue up that stream to Big Stone Lake, thence along that lake and Lake Traverse, and down the valley of the Red River to beyond Winnipeg in Manitoba. About the geographical centre of Minnesota, and in the westward region adjacent, aboriginal earthworks are often discovered; there being some particularly noticeable ones in Otter Tail county. In the north-eastern quarter of the state, with one or two slight exceptions, we have no authentic account of the existence of any artificial mounds. There are also many mounds around Lake Minnetonka and along Crow River: indeed, there are more or less on nearly every small stream and lake in central and southern Minnesota. The largest one known in the state is situated on the lower end of Dayton's Bluff in St. Paul, its former height being eighteen feet. Another very handsome mound is located in the village of White Bear, near the lake shore: it is conical in form, and thirteen feet high. Occasionally elongated mounds and embankments have been met with that have been termed 'forts;' but definite surveys and much critical examination are required before it

will be safe to adopt the term as expressive of their true character and use.

This indicates how poorly represented is the state of Minnesota in mounds of any kind. The variety and contents give as little satisfaction as the distribution. Mr. Lewis well says, that the "task of thoroughly examining artificial earthworks by excavation is so onerous, and the prospect of finding any thing of material value to pay for it so slight, there being scarcely any thing but the knowledge acquired to compensate the labor, that few persons care to undertake such work for so poor a return."

— The Dorpat Naturforscher-gesellschaft has received by bequest A. Schrenk's collection of Mollusca, which has been named by Mr. S. Clessin, and arranged by Dr. Max Braun. A hundred and eight species of land and fresh-water shells are known to occur in the Baltic provinces, and of these the Dorpat collection now contains eighty-eight.

— Dr. M. Braun has continued his faunal exploration of the Finland Bay, and in connection therewith has studied the physical characteristics of the water. The temperature diminishes, and the amount of salt increases, with the depth; but the water is so shallow that in severe storms the whole is stirred, mixing the colder and salter water of the bottom with the top layers. The water thus varies greatly, and this fact must have a great influence upon the life in the bay. The observations are being continued by Commander H. von Roth, and, when completed, are to be carefully worked up.

— Zoölogists and microscopists will welcome the two instalments, just appeared, of Bütschli's learned and thorough treatise on the Protozoa, which is to form vol. i. of the new revision of Bronn's classical 'Thierreich.' Parts xx.–xxv., just received, are entirely devoted to the Flagellata. This work is important not only from its intrinsic value, but also because it is the first comprehensive scientific work on the Protozoa ever published, and must, as such, be very efficient in spreading fuller and more correct knowledge concerning this much misunderstood group of animals. The utter lack of conciseness is the worst, and, at the same time, a serious and inexcusable, defect of this invaluable volume.

— In the *American journal of science and arts*, vol. xxiii., 2d series, p. 276, a letter from Rev. George Jones, U.S.N., to Professor Silliman, written at Quito, Ecuador, Dec. 13, 1856, describes a fall of ashes from Cotopaxi, which was thirty miles distant, in which a purple sky was noted. The paragraph in which the mention is made runs as follows: "Yesterday morning we noticed that at the south the sky had an unusual appearance, being of a purple color for about 90° along the horizon, and so up to about 45° in height, the edge of this being mixed up with patches of white. About 12 o'clock ashes began to fall, first in small quantities; but by 8 o'clock the fall had got to be so considerable as to powder the clothes quickly, on our going out: and people coming into a house would look as we do at home when coming in from a snow-storm."

— The Amherst college scientific association, organized in 1883, has for an object the promotion of scientific knowledge among its members. It consists of the heads of the scientific departments of the faculty as honorary members, and of active members chosen by the association, at the close of the year, from the members of the junior class recommended by the faculty. At present the membership is limited to twelve. Meetings are held weekly, and consist either of an address by some member of the faculty upon scientific subjects, or a paper read by one of the members, followed by questions and discussions. During the present year the society has listened to President Seelye, on science; Dr. Hitchcock, on social science; Professors Todd, on mountain observatories; Emerson, on the state of geology one hundred years ago; Tyler, on the biblical idea of nature; and Pond, on student-life in Germany. Some of the papers read thus far, by members of the association, are on the relation of chemistry to civilization, the Iatro age of chemistry, eggs, alchemy, the phlogistic theory, the condensation of gases, state of ornithology a hundred years ago, the nebular hypothesis, and proofs of the antiquity of man in the eastern United States.

— M. J. Deniker has prepared for the *Revue d'ethnographie* a sketch of the Ghiliaks, who live about the mouth of the Amoor River, based chiefly on the elaborate works of Schrenk and Seeland, published in St. Petersburg, the former in 1881, the latter in 1882. The Ghiliaks are mentioned for the first time by Witsen (1707); but they have been visited by Russian travellers since, although several distinguished ethnographers have confounded them with the Ainos, Tunguses, etc. The word 'Ghiliak' is a Russian corruption of the Tunguse word 'Kilé.' The people call themselves Niback. Their country is quite restricted. Their villages are sparsely scattered along the valley of the lower Amoor to the Okhotsk Sea. The Oltchas, a Tunguse tribe, adjoin them on the south: the Samagheres, of the same stock, are on the west. Besides the valley and the mouth of the Amoor, the Ghiliaks people the neighboring shore of the Okhotsk Sea. Beyond the Tatar Straits, they are found all along the northern part of Saghalin, the southern part being peopled by the Ainos. According to Schrenk, they form, together with Yukagirs, Ainos, Kamtchadals, Koriaks, Chukchis, and Eskimo (extant), and Ostyaks (disappearing), and Omoks, Anaules, Kottes, etc. (disappeared), the family of Palaeasiatics, who have been pushed back by the later invading Mongoloids. The average height is 1.62 m. for males, 1.50 m. for females. They are dolichocephalic (76.5). M. Deniker gives detailed descriptions of their measurements, physiognomy, maladies, and character; their food, meals, habitations, housekeeping, clothing, occupations (both of men and women), arms, and transportation; their marriages, polygamy, cremation, religion, myths, and language. A singular custom exists of betrothing children at five or six years of age, in which case the father of the husband adopts the girl, and keeps her until the marriage takes place. After the death of a husband, the wife marries the husband's brother, although she

may decline if she please. The Ghiliaks burn their dead; while the Oltchas and Orotches suspend theirs from the trees, or bury them. Their superstitions and religious practices are very interesting, especially the *fête* of the bear, which takes place in January, and lasts fifteen days.

— Mr. J. G. Vassar has given an additional ten thousand dollars to Vassar college for the better support of the chemical and physical departments of the Vassar brothers' laboratory.

— A prize of five thousand pounds was offered by the Indian government for the best machine for the treatment of rhea fibre. In 1869 a Mr. Greig of Edinburgh made a machine for this purpose; but it did not fulfil the conditions laid down, so the full prize was not awarded. Another competition took place, but was unsuccessful. Some rhea fibre experimented on in 1852 by Dr. Forbes Royle was in strength, as compared with St. Petersburg hemp, in the ratio of 280 to 160, while the wild rhea from Assam was as high as 343. Rhea has the widest range of possible applications of any fibre, as shown by an exhaustive report on the preparation and use of rhea fibre by Dr. Forbes Watson. Last year, however, says the *Engineer*, witnessed the solution of the question of decortication in the green state in a satisfactory manner by Mr. A. Favier's process. This process consists in subjecting the plant to the action of steam for a period varying from ten to twenty-five minutes, according to the length of time the plant had been cut. After steaming, the fibre and its adjuncts were easily stripped from the wood. Mr. Favier's process greatly simplified the commercial production of the fibre up to a certain point; but it still stopped short of what was required, in that it delivered the fibre in ribands, with its cementitious matter and outer skin attached. Various methods of removing this were tried without success, until a year ago the whole case was submitted to the distinguished French chemist, Professor Frémy, member of the Institute of France. Professor Frémy carefully investigated the nature of the various substances, and found that the vasculose and pectose were soluble in an alkali under certain conditions, and that the cellulose was insoluble. He therefore dissolves out the cutose, vasculose, and pectose by a very simple process, obtaining the fibre clean, and free from all extraneous adherent matter, ready for the spinner.

— An account and hysometric chart are published by Alfred Grandidier of the district of Madagascar, occupied by the so-called Hovas, whose stout resistance to the French has recently attracted much attention. The country is very different from one's preconceived ideas of a tropical island. The word 'Hova,' it seems, refers only to the middle class of the nation, properly called 'Antai-merina,' or 'Merinas,' in contradistinction to the other two classes of nobles and slaves. The superior intelligence and discipline of the Merina race have enabled them to conquer, during the present century, most of the tribes which inhabit that immense island. The district which they specially inhabit is called 'Imerina.' It is a mountainous country, completely destitute of trees and shrubs, and often uncultivated. The higher parts are hardly inhabited, but the valleys and lowlands sustain a dense population. The hills, which are composed of masses of granite and dense red clay, are not fertile; but the smallest valleys, when their situation permits, are transformed into rice-fields by the intelligent and industrious natives. West of the capital, there is a large plain twenty miles square, once a lake or marsh, but now one huge rice-field, which presents a beautiful appearance in the wet season, with little hamlets or large houses rising out of it here and there like islands. Other vegetables and fruits of a sub-tropical character are cultivated with moderate success on the hillsides. In the southern part is an assemblage of peaks reaching to eight or nine thousand feet above the sea. From the highest of these the entire district is visible, and appears like a sea of barren mountains destitute of shrubs or trees, and with numerous detached rocks amid coarse grasses not suitable for cattle, and only useful for fuel. Only the rich can afford to send for fagots to a limited strip of woodland which borders the district on the east. Even the dry grass used by the people for cooking becomes very dear in the rainy season; a single fire, perhaps, costing twelve cents. The population of the district reaches a million, and of Antananarivo, the capital, one hundred thousand. The villages are usually built on the summits of hills, and surrounded by a ditch. They contain for the most part but a few dwellings of inexpensive character, and are near the cultivated rice-lands of their owners, which are very valuable, in some places worth eight thousand dollars an acre. The houses are of an oriental character, commonly with one door and one window opening westward to avoid the raw south-east winds. The houses are arranged quite irregularly, and generally are not very clean. The roads are mere footpaths, and, notwithstanding the multiplicity of water-courses, bridges are very rare.

The people are somewhat smaller than those of other Malagasy tribes, but full of energy and intelligence, and in spite of faults peculiar to barbarism, from which they are only just emerging, exhibit industry, economy, and relative sobriety. In these qualities the other tribes cannot be compared with them. They have large families, though the Merina women are said to become sterile if they leave the mountains for the coast. Manufactures have made but little progress, and are chiefly due to white instruction. The rainy season commences toward the end of November, and lasts until March; but there are few severe storms, except during the period from Dec. 15 to Feb. 25.

— In a paper in the Bulletin of the Moscow society of naturalists upon periodic oceanic oscillations, Trautschold attacks the problem of oceanic alterations of level, and their relations to geological phenomena. His conclusions, based upon a careful study of the past and present physiography of eastern and central Europe and western Asia, are to the effect that many of the phenomena of sedimentation and

deposition attributed by geologists to a subsidence of the crust, are, in fact, due to periodic oscillations, or upheavals of the oceanic surface, producing thereby inundations of the land-masses; and that such is the nature of much of the newer sedimentations, e.g., Jurassic of Russia. The position here maintained, a revival of the views of many of the older geologists, is anticipated by Professor Edouard Suess, who, in his 'Antlitz der erde' (Prague, 1883), clearly indicates the necessity of invoking the assistance of periodic oceanic fluctuations of level to account for the existence of much that has been heretofore attributed to terrestrial subsidence.

— The seventh Saturday lecture in the National museum was on Feb. 16, by Prof. E. D. Cope, on the 'Origin of human physiognomy and character,' — a discourse the main features of which have already been published in the *American naturalist.* On Feb. 23, Mr. John Murdock, late of the signal-service party at the Oglaamie station, North Alaska, gave a very vivid account of 'Eskimo life at Point Barrow.'

— Mr. E. R. Quick has presented to the Brookville (Ind.) society of natural history his entire collection of birds, numbering several hundred specimens, mostly North American. This is one of the largest and best-arranged collections in the state. The society is this year providing a course of free lectures upon popular scientific subjects for the benefit of the citizens of its town. Five of the lectures have been given, and three more are to follow at intervals of three weeks. The last was given by Prof. Jos. F. James of Cincinnati, upon 'Flowers and insects.'

— The museum of comparative zoölogy has published another of its useful 'selections from embryological monographs,' intended to bring together illustrations from the most authentic sources of the early stages of development of various groups of animals. This one is concerned with the Echinodermata, and is compiled by Mr. Alexander Agassiz. It consists of fifteen excellently executed quarto plates, crowded with figures, and accompanied by very simple explanatory text, the bibliography of the subject having already appeared in an octavo form. The protozoa, acalephs, polyps, fishes, and reptiles are announced as in course of preparation.

— All students interested in the study of the brachiopods will be pleased to learn that the last parts of the series of superb monographs of Thomas Davidson, on British fossil Brachiopoda, are completed by the author, and are now in the printer's hands. In a letter received by a correspondent a few days since, from Mr. Davidson, he says that "after thirty-three years of hard labor, in connection with British recent and fossil species, I this year complete my large work; and, indeed, the whole remaining manuscript is in the printer's hands, and being printed. This last part includes, 1, an appendix to the supplements, with plates; 2, an elaborate general summary, with numerous illustrations of the progress of science in connection with the Brachiopoda from 1606 up to the end of 1883; 3, a catalogue of all the British species of the class, some eight hundred and sixty in number, with geologic distribution in time, and full references; 4, a brachiopod bibliography, which I have been compiling during the last forty years. I have some four thousand entries; and it will, I feel sure, prove to be very useful for references. I began it at 1606, and continued it up to the end of 1883." Of the value and character of this great work, this is not the place to speak; but we cannot refrain from expressing feelings of gratitude, respect, and honor to the man who has given his time and means to prepare for publication a work that reflects so much credit on modern science, especially the division of invertebrate paleontology. Mr. Davidson is now in the sixty-seventh year of his age; and we trust that many useful years still remain to him, in which he may contribute information from his studies upon the Brachiopoda of other countries than Great Britain.

— According to the San Diego papers, a large stone lance-head of Eskimo fashion was found deeply embedded in the tissues of a whale taken at the whaling-station on Ballast Point, near the harbor. The species is not named, but the creature was probably Megaptera versabilis. The migrations of the California gray whale, Rhachianectes glaucus, are well known, though it is not hunted by the Eskimo; but those of the other species have been less clearly made out, and facts of this sort are worth putting on record.

— Charles Ashford continues his investigations of the Spicula amoris in British Helicidae. He examined Zonites excavatus and Z. nitidus. Until recently the latter was supposed to be the sole member of its genus which possessed a dart: now the former keeps it company. The arrangement of the secreting-organs is remarkably like that of Zonitès intertextus and suppressus, as figured by Leidy. The dart is found in a very small percentage of the total number of adults examined. On the other hand, in Helix virgata ninety-five per cent of the adults examined have furnished darts.

— Dr. Benjamin Sharp, the professor of invertebrate zoölogy in the Academy of natural sciences of Philadelphia, will be inaugurated on Tuesday evening, March 18, on which occasion he will deliver a lecture on 'Methods of biological investigation in Europe.' Professor Sharp's course on biology will begin on Thursday, March 20, at 4.15 P.M.

— Dr. D. G. Brinton, the newly elected professor of ethnology and archeology, will deliver a course of lectures in April, introductory to an extended and thorough course to begin next autumn. The subjects of the spring series are as follows: 'Prehistoric man in the new world,' 'Origin of the Aryan races,' 'The study of ethnology in the United States,' and 'The civilized races of America.'

— Two of the naval ensigns pursuing a scientific course at the National museum, Mr. Harlow and Mr. Dresel, have been ordered to the Greely relief expedition.

SCIENCE.

FRIDAY, MARCH 21, 1884.

COMMENT AND CRITICISM.

THE work of the census has again, and for the third time, come to a stop for lack of money. This time the suspension is more serious than ever, the working-force being reduced to the chief clerk, who is also acting superintendent, and an assistant. The public printer has been notified to stop printing the reports; and, unless some extraordinary step is taken, the whole work of the bureau for four months to come will be confined to opening the daily mail. Several volumes of the final report have been published, and have been received with unqualified satisfaction, both here and in Europe; demonstrating, as they do, that this census is the most complete and the best organized ever yet attempted by any nation. The remaining fifteen or twenty volumes are understood to be ready for printing. The causes of delay are two, — the modesty of the superintendent in his requests to Congress for money, and the overcrowded state of the government printing-office. Surely Congress will not refuse to make apropriations of the most liberal dimensions to carry on this work, and to secure the printing of the reports before they have lost part of their interest through age. Let the demand be for a quarter of a million, if necessary; and let the office staff be increased in efficiency by the appointment of a special staff of experienced editors, who shall aid the superintendent in bringing the publication to an early termination.

THE fourth number, for March, of the pilot chart of the North Atlantic Ocean, issued by the Hydrographic office, differs from the earlier sheets of the series, notably in the number of icebergs reported for February south-east of Newfoundland. An aberrant berg appears about three hundred miles west-south-west of Ireland, in latitude 51°, longitude 18° west. In the legend concerning the weather reported for February, we are glad to see the term 'straight-line gale' of the previous charts reduced to the more non-committal 'gale;' but the absence of 'cyclones' is still insisted upon. Whatever be the meaning attached to this word by mariners, its ordinary use to include all large rotary storms, whether from within the tropics or not, is now so general and so proper, that the repeated statement, 'no cyclones are reported' for the winter months of the stormy North Atlantic, surely needs qualification. The intention is, no doubt, to state that no *tropical* cyclones have come up along our coast from the West Indies: if so, it should be more explicitly worded.

The compilation of observations on wrecks and abandoned vessels promises valuable results for the determination of currents. In only four months' records, over sixty examples are given, in many cases identified by name, and in a few cases reported by two or more observers on different dates. When the wrecks are floating almost awash, presenting little surface for the wind to blow upon, they will move only with the surface-drift, and, as noted in sucessive positions, will give excellent data for measuring the direction and velocity of currents. By thus keeping track of their movements, it will be possible to avoid the error of the old-fashioned bottle-experiments, in which only the beginning and end of the course were determinable, and time of passage was unknown. At the end of the year we shall hope to present a *résumé* of the results thus attained.

THE various local sub-committees of the British association at Montreal seem to be pushing the work in their special subjects with an energy which promises much for a successful meeting in August. In the section of economics especially, the committee is taking advantage of the opportunity presented, by bringing

forward papers which will give a comprehensive survey of the various important economical questions which are just now exciting so much discussion with reference to the future growth and prosperity of the colony. Among these, agriculture necessarily occupies a prominent position; but it is gratifying to see that general and technical education is also to receive important consideration.

Our leading article mentions at its close the brief life and sudden death of a society formed for home study for young men, modelled upon the older society, still vigorously flourishing, restricted to young women. Why there need be distinct organizations of that sort for the two sexes, it is a little difficult to see; but it is a little curious to find, that, hard upon the death of the 'Young men's society for home study,' a new organization has sprung up for the same purpose, but without limitation as to sex, bearing the somewhat pompous title of the 'Correspondence university.' It announces forty-one instructors (two of whom are women), resident in eight states of the Union, besides one each in Germany and Scotland. Sixteen of these are assigned to different departments of science, eleven to mathematics, and six to modern languages; so that the scientific leaning of our new 'university' is very marked. We shall look with much interest at the result of this experiment; for the promoters of the enterprise have certainly secured the services of many most excellent teachers, and they aim at a higher grade of instruction than has been attempted by the earlier organizations. A large proportion of the teachers are connected with Cornell university, which may be considered the headquarters. Unfortunately, as far as published, the plan appears to lack that unity and proper co-ordination which would at once command respect and confidence; and its higher grade of charges, though still very small, may prove an obstacle to its popularity.

We are glad to see a change in the wording of the 'indications' issued by the signal-service. Heretofore, variations of pressure have been indicated by 'rising' or 'falling barometer;' although change in the warmth of the air has always properly been mentioned as 'higher' or 'lower temperature,' and not 'thermometer.' Now the wording is made uniform, and observations of the barometer are recorded as implying 'increasing' or 'diminishing pressure.'

The late issue of *Copernicus* (a double number, 33–34) will be received with no little regret by many astronomers, as it contains the unwelcome announcement that this periodical will be discontinued after the publication of No. 36. We understand that this action on the part of the editors is due chiefly to the insufficient list of subscribers; and it is much to be regretted, as *Copernicus* is the only astronomical magazine, printed in quarto form, in which excellence of typography and general attractiveness in appearance seem to be thought desirable. Its style has been rather that of book than of magazine printing, and its papers on mathematical astronomy have had as fine a setting as the average article in the purely mathematical quartos.

The periodical began in January, 1881, under the editorship and management of Dr. Ralph Copeland, astronomer to the Earl of Crawford and Balcarres, and Dr. J. L. E. Dreyer, then of the Royal observatory, Dublin, and now director of the observatory at Armagh. The first six numbers were issued under the name *Urania*, for which *Copernicus* was then substituted, the editors having become aware of the previous existence of an astrological journal called *Urania*. Its many pages, devoted to the reviews of current astronomical literature, have formed a very valuable feature; and arrangements were, from the beginning, concluded with the Earl of Crawford and Balcarres whereby all the subscribers to this journal have received at the earliest moment the 'DunEcht circulars,' forwarded directly from Aberdeen. The new magazine has fairly established its claim to be 'an international journal of astronomy;' the chief astronomers abroad who have contributed to its support being the Earl

of Rosse, the Earl of Crawford and Balcarres, Drs. Wagner, Schjellerup, Ball, and Backlund, and Professors Klinkerfues and Bredicton. American astronomers have also done their full share; papers having been contributed by Dr. Peters, and Professors Pickering, Holden, Todd, Wright, and Stone. We express the hope that *Copernicus*, as a high-class journal for the publication of astronomical papers, may at some future time be re-issued under the same management as before.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

'Illusive memory.'

THE subject presented in *Science* for March 7 (p. 274) under the above heading, by Mr. Osborn, if an obscure, is certainly an interesting problem in psychology. Its scientific treatment, however, will probably require a much wider range of investigation than that proposed by the writer. He has indicated 'two widely different theories' in explanation of the mental phenomenon: a third hypothesis appears to have escaped him.

Plato, as is well known, recognized this peculiar condition of the mind, and made use of it as an evidence of pre-existence, — a fancy embodied in the familiar lines of the poet: —

> "Our birth is but a sleep and a forgetting:
> The soul that rises with us, our life's Star,
> Hath had elsewhere its setting,
> And cometh from afar:
> Not in entire forgetfulness,
> And not in utter nakedness,
> But trailing clouds of glory, do we come."

If, now, we substitute for Plato's conception of an individual personal experience the more prosaic one of ancestral experience, we shall have, in brief, the third hypothesis, — the partial continuity of consciousness through genetic descent, instead of through metempsychosis or transmigration. From this aspect, the problem of the irreferable impressions of vague reminiscence would not fall under the class of *erinnerungs-täuschung*, or '*illusive memory*,' at all.

The modern reference of all the varied 'instincts' of animal life to the simple physiological datum of the heredity of a limited experience and memory, would naturally lead us to anticipate some such exhibition in the human race; nay, rather to wonder why we do not find such experiences much more pronounced and abundant. Notwithstanding the enormously greater expansiveness of cerebral action in man than in his lower fellow-creatures, the long-continued or reiterated impressions of a far-reaching ancestry would seem to justify the induction that 'intuitions' (so precious to the metaphysician) should be manifested in particular channels in a much stronger and more decisive form than we actually observe. Here, then, is a negative psychologic problem calling for explanation, and well deserving a careful comparative investigation.

To satisfactorily test this 'third hypothesis' is undoubtedly an extremely difficult undertaking, both by reason of the usual 'haziness' of these Platonic reminiscences, and of the rare opportunities of authentic verification of special parental or aval recollections. The question, however, is one of such biologic importance, that it merits an even laborious research; and, if in only one or two instances a clear evidence of such transmitted memory in man could be established, it would justify the inference that many similar cases are referable to the same principle.

The inquiry should include the antecedent experiences of grand-parents as well as of parents: since there is reason to believe that aval heredity is *relatively* more frequent than direct parental heredity; or, in other words, that there is a tendency to 'alternate generation' running through the animal kingdom.

W. B. T.

Washington, March 13.

'The oldest living type of Vertebrata,' Chlamydoselachus.

In *Science*, No. 57, p. 275, my friend, Professor Cope, falls into the error of placing among the species of the genus Diplodus Ag. (re-named Didymodus by Cope) the 'peculiar selachian' recently discovered, and described by me in these columns. With the specimen before him, he would be the last man to make such a mistake. And no doubt he will thank you for giving the space necessary to a correction.

The most important of the characters on which the genus Diplodus was founded by Agassiz (1843, Poissons fossiles, iii., pp. 204, 209), that by which it is separated from Hybodus, Sphenonchus, and Cladodus, is a greater development of the secondary cones of the teeth, while the median cone remains rudimentary or comparatively undeveloped. This is not the case with Chlamydoselachus: it is not the secondary, but the median, cone in which is found the greatest development; agreeing in this respect with Agassiz' genera Hybodus, Sphenonchus, and Cladodus, in which "le cône médian l'emporte sensiblement sur les cônes latéraux, et se développe en quelque sorte à leur détriment." In the teeth of Chlamydoselachus, the cone at either side of the median is a mere rudiment. If the new selachian was to have been placed in either of the fossil genera mentioned, it should have been Cladodus. Mr. Cope says of Didymodus, 'The species possess two, three, or four denticles.' Of course, a second thought will increase the number so as to include Chlamydoselachus, which has more than four.

The propriety of placing living species in fossil genera of so long ago on account of resemblances in a single organ, such as a tooth only of a selachian, is to be questioned. The teeth do not give satisfactory clews to structure and shape of other organs, or of the body itself, in the majority of the sharks and skates. This is evident enough on comparison of the teeth of Carcharias, Alopias, Zygaena, Squatina, Torpedo, Scyllium, Raja, Triakis, Disceus, Mustelus, Trygon, Pristis, Potamotrygon, Rhinobatus, Dicerobatus, and others. It would be hardly worth the while to separate recent genera by the number and position of fins, or shape of body, and then make them equal to the same fossil genus on account of some similarity in teeth. Material in my possession will enable me, as soon as the necessary drawings can be made, to prove conclusively that Chlamydoselachus does not belong to the genus Didymodus of Cope (=Diplodus Ag.), and that it was hardly safe to announce Didymodus as the 'oldest living type of Vertebrata' until more was known about Chlamydoselachus.

S. GARMAN.

Cambridge, March 17.

The 'shark recently discovered in Japanese waters,' described by Mr. Garman as Chlamydoselachus anguineus (in *Science* for Feb. 1, vol. iii. pp. 116, 117; *Bull. Essex inst.*, vol. xvi.), as its describer has remarked, "is a form of more than ordinary interest on account of the respects in which it differs from the majority of its kindred." It not only appears as a new element in selachology, and becomes the representative of a hitherto unknown type, but it throws light on the ancestry and some of the extinct forms of the class; and, still further, it may serve as a guide for the interpretation of certain of the tales of the sea-serpent.

In respect to its place in the system, I perfectly agree with Mr. Garman, that it is the representative of a very distinct family (Chlamydoselachidae): I am also of the opinion that it may be regarded as the type of a distinct sub-order at least. Mr. Garman, in *Science*, was "inclined to consider this the type of a new *order*, to which the name Selachophichthyoidi might be given;" but in his article in the Essex bulletin he is entirely silent on the subject of the major relations of the new type. The name, having been thus never defined, and being objectionable on account of its length and cacophony, might be replaced by a shorter one, like Pternodonta; but on this I shall not insist. A more important question is, What is the status of the selachian in classification? Mr. Garman thinks that 'it stands nearer the true fishes than do the sharks proper.' I do not know how he would express this idea in a linear arrangement, but most would do so by placing it immediately between the selachians and fishes. I am also disposed to consider Chlamydoselachus to stand 'nearer the true fishes than do the sharks proper,' not because it appears to be in the line of descent *between* the two, but because it is nearer the primitive line from which both types have diverged. Judging from Mr. Garman's remarks in the two articles referred to, I presume there would be essential concordance between us as to this point.

As to the relations of Chlamydoselachus to extinct types, however, I must dissent from Mr. Garman. Fortunately, an article throwing light on the affinity of Cladodus has been published recently, — probably too recently to be available to Mr. Garman. I refer to Dr. R. H. Traquair's communication 'on a new fossil shark,' in the *Geological magazine* for January, 1884 (decade 3, vol. i. pp. 3-8, pl. 2). Dr. Traquair has therein made known the form of the cladodont selachians, and proved beyond doubt that the cladodont dentition and ctenacanthoid spines co-existed in the same fish. The 'new shark' in which these parts were coincident has been named Ctenacanthus costellatus. In the words of Dr. Traquair, "accepting the fish just described as a new species of Ctenacanthus, it yields us the following important facts regarding the genus: —

"1. The shape of the animal was moderately elongated, with blunt snout and heterocercal tail. 2. The skin was covered with shagreen granules, mostly of an ornate, ridged, pectinate character. 3. There were two dorsal fins, each with a spine, that of the first being the longer. There were no paired spines, and the ventral fin was opposite the second dorsal. The presence of an anal fin is doubtful. 4. The dentition was cladodont. 5. The vertebral axis was unsegmented, but there were extensive calcifications in connection with other parts of the skeleton."

It is obvious from this summary, that Cladodus was not at all related to Chlamydoselachus; and I may add, that it did not have the essential dentition of Chlamydoselachus, so well indicated by Mr. Garman in the statement that "each tooth has three slender, curved, inward-directed cusps, and *a broad base . . . preventing reversion.*"

But, as Professor Cope has claimed (*Science*, vol. iii. p. 275), Chlamydoselachus did have a representative in the carboniferous genus Diplodus, or Didymodus; although I do not think that the two can be congeneric. In fine, the recent discoveries by Messrs. Garman and Traquair enable us to co-ordinate a number of extinct types, and compel us, I think, to add two sub-orders or orders to the list of those necessary for the long-known living forms. The living sharks I have proposed (in Jordan and Gilbert's Synopsis of the fishes of North America, p. 967) to distribute among four sub-orders; of which the Opistharthri or Notidanidae are the most generalized, and the Rhinae or Squatinidae the most specialized. The two additional sub-orders appear to be still more generalized than the Notidanidae, and the sequence would therefore be as follows: —

1. Lipospondyli, including selachians without developed vertebrae, but with a persistent notochord, and comprising the family Hybodontidae (Hybodus, Cladodus, Ctenacanthus, etc.).
2. Pternodonta or Selachophichthyoidi, including Squali with vertebral condition unknown, and with teeth having fixed bases, comprising the family Chlamydoselachidae (Chlamydoselachus and Didymodus).
3. Opistharthri or Cyclospondyli.
4. Proarthri (Heterodontidae).
5. Anarthri (most living sharks).
6. Rhinae.

It is by no means certain that the hybodontids are Squali at all, and they may prove to be more nearly related to the Holocephali. The plate of Dr. Traquair's memoir delineates very plainly one external branchial aperture, and one only; and the condition of the vertebral column and dorsal spines are features in which there is greater resemblance to the Holocephali than to the Plagiostomes. The primitive form from which the two diverged must theoretically have been not unlike the new Ctenacanthus, and it is quite possible that in the hybodonts we may have one of the 'missing links' between the two groups.

I had intended to refer to certain of the 'sea-serpents' which might be correlated with Chlamydoselachus; such as the Maine animal noted recently in the *Proc. U. S. nat. mus.*, the animal seen by Capt. Hope about 1848, and the selachian found in 1808, and partially described by Dr. Barclay, but must defer a notice to a future time. THEO. GILL.

Evidence of unrecorded tornadoes.

There is evidence in the forests of Pennsylvania that many localities have been visited by tornadoes of which no accounts have ever been recorded. The places referred to are called 'windfalls;' the timber having been prostrated apparently by violent storms of wind, while the trees immediately adjoining remain erect and undisturbed. Sometimes, instead of forming a path through the forest, the tornado has descended, and quickly ascended into the air, leaving its marks on a small area. Judging by the remains of the timber-trees thrown down, these events were of all ages, and of various degrees of violence. Sometimes the fallen timber was found sufficiently sound, after the first settlement of the country, to be worth manufacturing into lumber; in other cases, being older or more shattered, it was worthless; while in others it has entirely decayed and disappeared, the ground being covered with a later growth of a smaller and different kind, and the sur-

face dotted with hillocks, like rifle-pits, caused by the up-turned roots of large trees, of which no other vestige remains. In the eastern part of Bradford county were extensive ancient windfalls, still recollected by the older inhabitants, where now is a fine, well-cultivated farming-country; and in the southwestern part of the same county a tornado of a later date left a long, straight path through the pine timber, which was known as the 'Devil's Lane.' I have seen the track of an extensive tornado in the forest of one of the Alleghany Mountain counties of this state. I have reports of others in West Virginia and in Indiana, and of very numerous ones in the vast forests of Lower Canada, in New Brunswick, and Nova Scotia. Every hunter and lumberman who has travelled through the forests is familiar with these evidences of more or less ancient tornadoes, and of a few in later times. From their occurring in uninhabited regions, and from their not being attended with loss of life or improvements, no accounts of them are to be found, and the traditions of them are soon forgotten. In the further study of this interesting subject, these fossilized tornadoes, so to speak, should not be overlooked. The tornadoes of Kansas, Missouri, Illinois, Minnesota, and Georgia, are probably only repetitions of what has at long intervals occurred fortuitously in all parts of our country.

James Macfarlane.

Towanda, Penn., March 11.

[Windfalls are the subject of Tornado circular No. 12, which may be obtained on application to the chief signal-officer, U. S. Army, Washington. Information concerning the location, direction, length and width, and, if possible, also the date, of these old tornado-tracks, is much desired.]

Remains of a prehistoric tree.

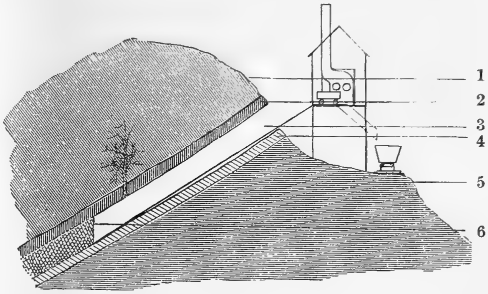
While making some assays for the Oregon iron and steel company, during the past summer, I was often in the mines of the company at Oswego, eight miles south from Portland, Ore.

Being on one occasion about five hundred feet down the main gangway, my attention was called to a curious 'hole in the roof.' On examination, I found it to be a perpendicular cylindrical cavity in the roof-rock, in diameter about ten inches. Upon feeling the walls of the cavity, I found the surface somewhat rough, like the bark of a tree. Introducing a lamp, I could discern small indentations corresponding to the knots and twigs upon the trunks of trees. I was convinced that the hole had once been occupied by a tree, and, procuring a jointed pole, probed the cavity to a height of twenty-two feet. Toward the top the indentations became more numerous; and, by replacing the stiff pole by a flexible bamboo, the side orifices could be probed to a depth of two or three feet, and seemed to have a slight inclination (see figure).

Examining the ore on roof and sides, I was rewarded by finding a network of roots, which retained their original forms perfectly, although petrified. I procured one specimen an inch and a half in diameter. An analysis of it showed the material occupying the position of the original bark to be kaoline; it being perfectly white, and about a quarter of an inch in thickness. Inside this ring of kaoline the wood had been replaced by iron ore, not differing from that of the surrounding vein.

Above and below the ore I found no roots; the tree having grown in the space now occupied by the ore-vein, and at an inclination to it. The strata dip to the north at an angle of 35° to the horizon.

Immediately under the ore is a stratum of scoriae one to three feet in thickness. Below this is hard, compact basalt. The roof of the mine is 'greenstone,' decomposed by heat to coarse sand-rock immediately over the ore. The ore-vein averages five feet and a half in thickness.



Section in mine at Oswego, Ore.

1, 'greenstone;' 2, sand-rock; 3, gangway; 4, scoriae; 5, basalt; 6, ore-vein.

At six hundred feet I found pieces of wood not petrified, and in a good state of preservation, some parts showing a charred surface. I found afterwards, in other parts of the mine, several smaller orifices in the roof-rock, and similar to that described above.

Harold B. Nye.

Congenital deafness in animals.

Mr. Lawson Tait, quoted by Professor Bell in *Science*, No. 54, says that 'congenital deafness is not known to occur in any animal but the cat.' In contradiction to this statement, Dr. Burnett has reported to you (No. 57) the cases of two deaf dogs; and I now refer you to the mention of *a deaf-mute cow* in Dr. Haubner's 'Bericht über veterinärwesen,' quoted in the 'Organ der taubstummen- und blinden-anstalten in Deutschland,' vol. xxv. p. 176. This cow was twelve years old, and had been in the possession of the same owner since she was three weeks old. She was perfectly deaf to all sounds. At feeding-time, or when a calf was taken away from her, she made the same demonstrations that other cows do, stretching out her head and neck, and opening her mouth wide as if to bellow, but only making a short, deep, gurgling sound, very different from the ordinary lowing of cattle. Her sight was good, and she was an intelligent animal. Nothing abnormal could be discovered in her ears or throat. Her color is not mentioned. She had had eight calves: but whether these inherited their parent's deafness is not known; for in this case the danger, if such a danger existed, of 'the formation of a deaf variety' of the bovine race was effectually prevented by the early butchering of the calves.

Edward Allen Fay.

National deaf-mute college, Washington, D.C., March 14.

Muraenopsis.

Is it not by mistake that you state, in the review of 'Yarrow's check-list' (*Science*, No. 56, p. 264), that the generic name 'Muraenopsis' must be suppressed because 'pre-occupied among the eels'? The name was first applied to eels by Kaup (1856, 'Catalogue of apodal fish,' p. 11), though credited by him to Le Sueur. The latter, however, did not use it. His name was 'Muraenophis' (1825, *Journ. Philad. acad.*, v. p. 107), or 'Muronaephis' (l.c., pl. iv.), or 'Muroenophis' (l.c., index). Kaup's error was copied by

Günther (1870, 'Catalogue of fishes,' viii. p. 68). It is probable that by one or the other of these authorities you have been misled. 'Muraenopsis' was given to the batrachian by Fitzinger (1843, 'Systema reptilium,' p. 34) as a substitute for Amphiuma Garden, 1821. Subsequent writers have limited the genus Muraenopsis to the species with three toes, retaining in Amphiuma that with two. Examination of a considerable number of specimens shows that about one of every five individuals of tridactyla, from the same locality, has less than the normal number of three toes to each foot. For this reason it seems as if the species is not sufficiently distinct from the two-toed, Amphiuma means, to be entitled to rank in a different genus. In this view the genus Muraenopsis should be suppressed, and the name placed as a synonyme for Amphiuma.

S. GARMAN.

Mus. comp. zoöl.

[The writer of the review above mentioned must confess to a blunder. Not having a copy of Le Sueur's paper at hand, he trusted to the quotations made by Kaup and Günther. The former writer, as above stated, expressly adopts the genus Muraenopsis from Le Sueur.]

STUDY AT HOME.

IN discussing the value of a new plan for making men wiser and better, the thing to do is not to compare it with other plans in successful operation, with which it does not propose to interfere, but simply with the state of things in which it is absent. No one pretends that personal instruction is not of value, or that the urgent stimulus and vivid directness of a living teacher and a *viva voce* explanation can ever be replaced by the slow medium of letters. When an organized effort was made to introduce home study on a large scale, it was on account of the patent fact that there are many young people, and many people no longer young, who are not in a condition to go to school, and to whom, nevertheless, the systematic study of some subject in which they take an interest would be a benefit and a delight. The difference between a sporadic effort to do a little solid reading by one's self, constantly interrupted by flagging interest and by difficulties too hard to overcome, and a regular correspondence with some one who is able and willing to lend encouragement and aid, is very great. If the enthusiasm for this sort of work should become so wide-spread as to keep large numbers of students from giving themselves a regular course of instruction in school and college, it would be time to consider the evils of the plan; but of this there is little danger at present.

Ten years ago some reports of an English organization, called the 'Society for the encouragement of home study,' fell into the hands of a group of missionaries in Boston; and they were immediately inspired with a desire to work out the idea suggested by the title. An exchange of letters with the English secretary was of very little assistance in the development of the American plan. The English society offered no correspondence, but simply sketched out courses of reading, and plans for botanical and art work, to be carried on without assistance for a year, after which the students were expected to go to London for a competitive examination with prizes. In the autumn of 1873, the 'Society to encourage studies at home' was established by a committee of ten persons, six of whom carried on the correspondence with the forty-five students who offered themselves for instruction in the course of the year. Only two points of method were settled at the beginning; namely, that there should be a regular correspondence, and that there should not be competitive examinations. Later the plan was developed of making the students take notes from memory, at the beginning of each day's work, of the reading of the day before, and send to the appointed teacher at the end of each month a few sample pages of their daily notes, and a full abstract, written from memory, of their month's work. There are also frequent examinations; and by this means the students are divided, at the end of the year, into a first, second, and third rank. The plan of giving certificates, based upon the results of an annual examination, was abandoned after two years' trial. The annual fee charged is merely a nominal one, — two dollars at first, and afterwards three, — but it has been sufficient from the beginning to cover all the expenses of paper, postage, the printing of the necessary circulars, the salaries of the assistants to the secretary and the librarian, and for the last two years the rent of the rooms on Park Street, Boston, where the society has its headquarters.

The work of the teachers is, of course, a labor of love. In numbers the society had a very rapid growth for the first four years of its existence, and since then it has remained nearly stationary. In 1880 over eleven hundred students entered, of whom seventy-one per cent persevered throughout the year, and twenty-six per cent were excused for sufficient reasons. The number of teachers is about two hundred. History, science, and art, French, German, and English literature, are the subjects taught; and the proportion of students in each subject remains almost constant year after year. More remarkable still, the subjects divide themselves into three groups of two subjects each, which keep nearly abreast

of each other. An average of the last four years shows, that, out of every hundred students who have persevered, thirty-four have taken English literature and thirty-three history, twelve have taken science and eleven art, five have taken German and four French. History is taught by topics, and there are circulars giving minute directions for critical study in the literatures of the different languages. The Shakspeare paper is particularly suggestive and valuable. Much thorough scientific work is done, if it is of an elementary character. Geology and mineralogy are taught by sending specimens and requiring observation and description, as in the class-room. Excellent work has been done in blowpipe analysis, and several students who live in fossiliferous regions have made discoveries in their own neighborhood. Botany has always been well taught: most of the teachers have been pupils of Gray, Goodale, and Farlow. Biological subjects have not been popular; possibly owing to the lingering survival of a lady-like repugnance to frogs, mussels, and moulds. Physics and chemistry have not been attempted. That the scientific department is thoroughly well conducted is assured by the fact that it is under the charge of the head of the woman's chemical laboratory of the Massachusetts institute of technology.

The society has a lending-library, which began with the purchase of twenty-nine books in 1874, and which has now about a thousand volumes, many of them valuable works in illustration of archeology and art. Out of the eight thousand issues which have been made to the most distant states and territories, through floods and railroad accidents, only twelve volumes have been lost in the mails, and five through the carelessness of students. A small pamphlet enforcing obedience to the rules of health has been prepared by the secretary, and is sent to every one who joins the society. The pupils are widely distributed, both socially and geographically. Massachusetts and New York have always furnished the largest number, but not so many as the remaining Middle States together. The extreme south and the remotest west, as well as the Canadian provinces, are well represented. Many industries and all grades of society, above absolute penury and ignorance, furnish students. There are girls in cities with large allowances, and married women far from any post-office, who do their own household work. A telegraph-operator, a compositor, a matron of a public institution, a railroad paymaster (acting also as treasurer, and going up and down her road in that capacity), a colored teacher at the south, another colored woman well married at the north, have taken advantage of the society's courses. Six deaf-mutes have been among the pupils; and one, after studying several years, has become an associate teacher, and takes charge of four of her companions in misfortune. Mothers study for the sake of teaching their children; and even grandmothers, not to be left too much alone, join the rest of the family group. In age, half the pupils are between twenty and thirty, and one-fourth between thirty and fifty. Many continue their studies for several years. Last year there were more old students than new. One has been eight years in the society, has taken a full course in many subjects, has read a small library of important works, and has taken, after the first two years, the first rank in every thing. "Now and then an enthusiastic student tells us that she hopes to continue with us all her life;" and one writes, "The very thought of leaving makes me homesick." Those who have only known the active life of cities can have no idea how great a boon to a country girl is a correspondence with an intelligent and sympathetic woman. The students' letters are full of appreciation and gratitude. One says, "I only regret that I did not know of the society at the beginning of its existence;" and another speaks of having derived "pleasure and incalculable benefit from the systematic course of study prescribed." After buying a science text-book, a student writes, "It has cost me my summer hat, but I do not regret it in the least;" and another, "I pin my lesson copied the night before, to the kitchen wall, and the drudgery of dish-washing is removed." With such eager material to work upon, it will be strange if the society does not find some mute, inglorious Herschel, or some village Somerville, upon whom it will act as an inspiration to great things. If Du Bois Reymond was able to become a great physiologist at a time when rubber tubing was not an article of commerce, a girl who has learned to use the blowpipe by teaching at a distance must blame herself, and not her circumstances, if she does not do good work as a mineralogist.

A society for home study for young men has had an existence for three years, and has come to an end. Longfellow, Howells, and Holmes, John Hay, Justin Winsor, and Charles Dudley Warner, are among the names on its committee, and the reports for the first two years were very enthusiastic. They state that the students are twice as many as in the young women's

society for the corresponding years, that the average time given to study is ten hours a week instead of eight, that there has been no difficulty in finding a large number of cultivated gentlemen who were willing to give their time and attention to the work, and that the wonderful success of the earlier society may be taken as an indication of what may be done for young men by the same means. The secretary says, "This year's work has convinced us that we have every promise of the society's becoming a successful and useful institution, and that it is meeting a great need in a practical way." A year later it is decided to give up the organization; and no more specific reason for this course is given than that the committee is satisfied, on the whole, that the good done is not enough to make worth while the labor required of officers and correspondents.

THE BIOLOGICAL LABORATORY OF THE JOHNS HOPKINS UNIVERSITY.

THE recently opened biological laboratory of the Johns Hopkins university is eighty-four by fifty-two feet in external measurement, and

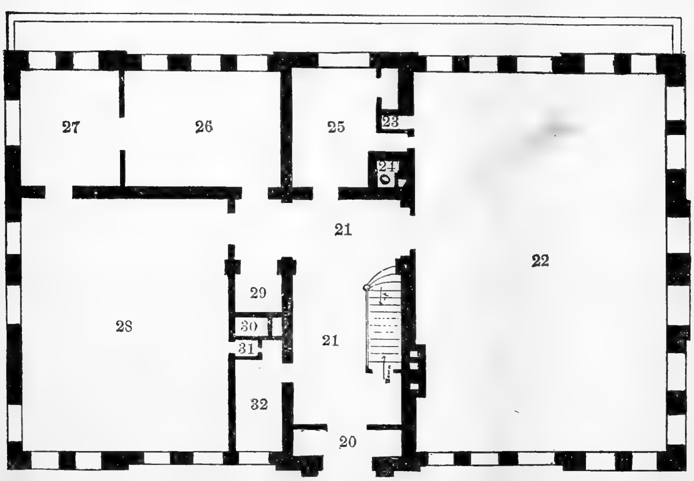


FIG. 1.—20, vestibule; 21, main hall; 22, work-room for practical instruction of less advanced students; 24, 30, ventilating-shafts; 25, storeroom of materials and reagents for general practical class-work; 26, chief assistant's room; 27, storeroom for diagrams and lecture-apparatus; 28, lecture-room; 29, elevator; 32, cloak-room.

consists of three stories and a basement. It is built of Baltimore pressed brick; with steps, entry, window-sills, and band-courses of Cheat-river bluestone. While free from any attempt at mere architectural display, the building is

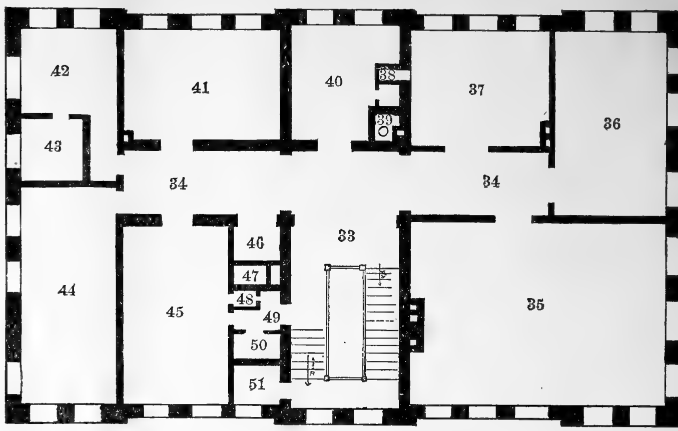

FIG. 2.—33, 34, hall and corridor; 35, museum; 36, advanced morphology; 37, preparation-room for museum; 40, assistant's room; 41, library; 42, 43, photography; 44, advanced botany; 45, lecture-room; 46, elevator; 47, 39, ventilating-shafts; 51, lavatory.

handsome, as will be seen on examination of fig. 5, which represents its north and west elevations. A fact that at once attracts attention is the number and large size of the windows: as the laboratory is free on all sides, it is therefore very well lighted.

On ascending the front steps, and passing through the door, the visitor enters the main hall, from which a wide staircase ascends to the third story, and on which most of the rooms of the first floor open. This floor is given up to the regular class-instruction of students not engaged in special work. It has on it (see plan, fig. 1) a lecture-room with seats for sixty; a storeroom connected with this, for the keeping of diagrams and lecture-apparatus; an administration-room, the headquarters of the chief assistant; a preparation-room containing a supply of the reagents, specimens for dissection, and histological material required for the daily practical class-work; and the large general laboratory, thirty-two by forty-eight feet.

The latter (fig. 6) has windows on three sides. Around these sides runs a work-table, supported, independently of the floor, on brackets attached to the walls, and affording ample space for thirty students. If necessary,

a second table can be set inside this, giving places for fifteen or twenty more. The centre of the room is in part occupied by a dissecting

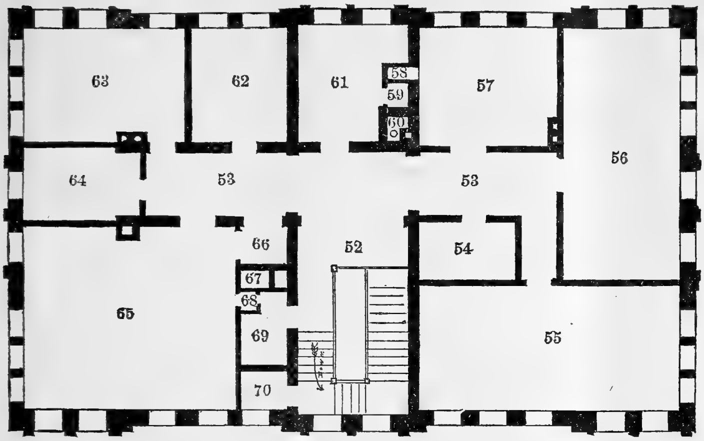

FIG. 3.—52, 53, hall and corridor; 55, experimental physiology of lower animals; 56, advanced histology; 57, workshop; 54, balance-room; 61, assistant's room; 62, myograph-room; 63, director's private room; 64, dark chamber; 65, experimental physiology of mammals; 66, elevator; 60, 67, ventilating-shafts; 69, closet; 70, lavatory.

and a chemical table. The latter is supplied with the reagents and appliances for practical work in elementary chemical physiology. The dissecting-table is for the dissection of animals, such as cats and dogs, which are of a size not to be conveniently handled at the regular work-places on the wall-tables: it has a slate top, and is provided with a sink and water-tap between every two students. The inner side of the room has, against the wall, tables for scales and the warm-water oven; a large hood for the performance of chemical operations calculated to give rise to noxious vapors; and a dumb-waiter leading to the basement, on which articles can be sent up from the store-rooms there when called for. Near the centre of the room is a chute, lined with plate-glass (so as to be readily kept clean), and passing direct to the furnace-room below. Through this chute all refuse is at once got rid of. The floor of the room, and of all others in the building in which messy work has to be done, is of asphalt, and the walls of hard cement to a height of two and a half feet. Thus no spilled blood or other offensive matter is absorbed; and the floor can be flooded with water, and thoroughly cleansed, whenever desirable.

The work to be done in this room annually is as follows: by first-year students, a thorough macroscopic and microscopic examination of about twenty-five selected vegetable and animal organisms illustrative of the course of lectures on general biology, and a study of the embryology of the chick; by second-year students, a course in practical animal physiology and histology a little more extended than that given in Foster and Langley's 'Practical physiology,' but essentially similar to it, and the thorough dissection of a dog or cat.

The second floor (see plan, fig. 2) contains the following rooms: a laboratory for research and advanced study in animal morphology, and a corresponding room for botanical work; a photographing-chamber, with heliostat and other appliances for micro-photography; a library of biological text-books, monographs, and journals; a small lecture-room (to be used for the present as the laboratory of psycho-physiology) capable of seating about thirty; an assistant's private room; a museum containing such typical osteological and other

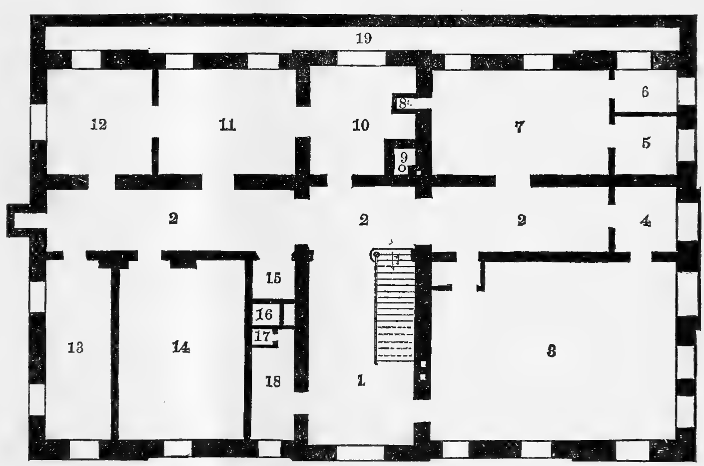

FIG. 4.—1, 2, entrance and corridor; 3, chemical physiology; 4, balance-room; 7, furnace-room; 10, 11, 12, janitor's store and battery rooms; 13, animal-room; 14, electro physiology; 15, elevator; 16, 9, ventilating-shafts; 18, lavatory.

specimens as are needed by students pursuing the regular courses of class-instruction, and the beginning of a collection of the local fauna

and flora, made by the members of the field-club; and a store and preparation room for the curator of the museum.

The third floor (see plan, fig. 3) contains three main work-rooms for advanced students, — one for animal histology, one for physiological experiment on invertebrates and the lower vertebrates, and one for experiments on warm-blooded animals. The room for the latter purpose communicates directly with the hydraulic elevator, which has also doors opening directly on the corridor of each floor, and runs to the basement: there is consequently no carrying of animals or their remains up or down the stairways. The other rooms on the third floor are, a dark chamber for spectroscopic work, for experiments in physiological optics, etc.; the director's private room; a room for the myograph; an assistant's private room; the mechanics' shop, for the construction and repair of instruments; and a small balance-room, containing also a case with a supply of chloral, curare, morphia, and other drugs frequently employed in physiological experiments.

The building being heated by steam supplied from a boiler in the neighboring chemical laboratory, the basement (see plan, fig. 4), which is well lighted, is left free for use. The scientific work-rooms in it are, a large, well-equipped room for advanced study in chemical physiology, a balance-room, and a room for the study of animal electricity. The basement also contains a suite of three rooms, which form the janitor's headquarters, where he has charge of the necessary stock of chemicals and glassware, and has also a carpenter's bench, at which he does any simple bit of carpentering required. From one of these rooms a shaft two feet square runs to the top of the building, communicating with each floor. Through this shaft it is intended to run wires to various work-rooms, transmitting electrical currents for the running of chronographs, and for similar purposes. The shaft was also planned in the hope that ultimately the clock-work of kymographs and such instruments will be replaced by electrical energy generated by an engine and dynamo in the basement, and distributed thence over the building.

FIG. 5.

The remaining rooms in the basement are, the 'animal-room,' fitted up with tanks for the keeping of frogs, terrapins, and so forth; and the furnace-room. The latter contains a cremation-furnace, in which all the combustible *débris* of the laboratory is disposed of, and a boiler and condenser for the preparation of distilled water: it has also in it a small steam-engine, designed to be used for running a centrifugal apparatus.

In the general internal fitting-up of the laboratory, the trustees of the university have acted upon the belief that it is, in the long-run, more economical to provide students with furniture which is good and attractive, and trust them to take care of it, than to supply cheap tables and cases, which the average undergraduate, at least, is apt to feel no hesitation in mutilating. The halls and lobbies are comfortably covered with cocoa matting; the tables, instrument cupboards, and cases of drawers are of polished cherry. But there has been no attempt at ostentation: the furniture is all simple, though handsome, and finished in every essential in the best manner. Every drawer runs as smoothly as in the best cabinet work; and each has its own lock, to be opened only by its own key, or the master-key for each floor kept in the administration-room.

The library is a little more luxuriously furnished than the other rooms. It is carpeted, and supplied with armchairs. So many students can only afford to hire rather uncomfortable lodgings, that it was believed desirable to provide in the library a really pleasant study, in which they might find at hand, not only the books they wanted, but writing-tables and other conveniences. None of the books are locked up. The student, on entering, finds before him a list of books which are not to be taken from the room, including text-books, monographs on the plants or animals which are used as types in the regular class-instruction, and the last-received numbers of periodicals: all other books may be taken (subject to call for immediate return at any time) on the student writing his name, and the title of the book he desires to take away, on a card provided for the purpose, and then slipping this through a slit in a locked drawer. The fellows and scholars in the biological department act in turn as librarians for the day, and are present

FIG. 6.

at a stated hour to receive books returned, and restore the receipts for them: until the card is returned to its signer, he is responsible for the book. This system of almost absolute freedom in taking books from the library is still on its trial: it has now been in practice for four months, and with the best results. Those who desire to take books home appreciate the trust reposed in them, and also the convenience to them of the present plan, and are anxious to secure its continuance.

The principle on which the library is managed, of inviting students to co-operate with the administrative officers in making it possible to allow the freest use of all books in it compatible with their safety, has been extended to the instruments in the various rooms for advanced work. On admission, each man has assigned to him a microscope, microtome, other histological appliances, and such chemical glassware as he is pretty certain to need. For these he signs a receipt, undertaking to restore the articles in good order on demand, or pay a specified sum for them. Glass slides and covers are purchased in quantity, and supplied by the janitor at cost. Other glassware, only occasionally needed, is supplied to any member of the laboratory on requisition, the recipient signing an agreement to return or pay for it. With these exceptions, free use of all instruments required for such work as he has been permitted to undertake is allowed to every student, on condition that upon removing any piece of apparatus from its drawer or cupboard he shall leave in its place a card bearing his name. The only alternative, of course, is to lock every case, and only issue apparatus on formal application to a special officer. The men are on their honor, and also know, that, if instruments cannot be traced, the present system must cease. Hitherto the endeavor to secure their aid in carrying out this plan of making all the apparatus accessible with the minimum of trouble or delay, has had most satisfactory results; largely, no doubt, owing to the fact that the majority of the students are graduates old enough to have a sense of responsibility, and to influence the younger men. Once a month one of the fellows, or graduate scholars, examines the instrument cupboards in each room, compares their contents with the inventory, notes what piece of apparatus has been taken and who has taken it. If any instrument is not accounted for, he posts a notice asking who has it. During the past four months the latter proceeding has been necessary only three or four times, when students had, in the hurry and excitement of an experiment, forgotten to write the required receipt: in every such case the delinquent has at once come to apologize and explain. What may be called the 'permanent' apparatus in the laboratory, as distinguished from glass tubing and other perishable 'current' apparatus renewed yearly, has cost more than ten thousand dollars: about fifteen hundred dollars are annually provided for repairing and adding to it. During the current year another five hundred dollars has been placed at the disposal of Dr. Stanley Hall for the purchase or construction of apparatus for psycho-physiological teaching and research. This stock of instruments is so valuable, and in many cases so easily injured, that a longer trial will, of course, be necessary, before it can be decided whether the present system of leaving every thing unlocked, and trusting students to leave an acknowledgment for such instruments as they take, can be continued without undue risk of loss or injury by carelessness for which no one can be found responsible.

The work for which the laboratory has been planned and built was stated in Professor Martin's lecture, published in our issues of Jan. 18 and 25. Briefly, it is the training of beginners in biology in the fundamental properties of living matter, and the structural and physiological characteristics of the chief groups of plants and animals; in co-operation with the seaside laboratory of the university, to afford opportunities for advanced study and research in animal morphology and embryology; and, ultimately, similar opportunities for advanced students of botany. In addition, very special attention has been given to providing facilities for class-instruction, advanced study and research in animal physiology and histology, and opportunity for such senior students as intend to become physicians to learn the methods of experimental pathological and therapeutical research, so far as they can be carried on in a laboratory. It is hoped that in this way the biological laboratory may prepare annually some students to enter special laboratories of pathological or pharmacological research more immediately connected with a medical school.

SOME PECULIARITIES OF PLANT-GROWTH.

THE following cases are here placed on record as affording interesting instances, not only of the ability of plant-tissues to repair injury, but of the enormous power exerted by vegetable structure during the process of development.

In the summer of 1873 I discovered a very interesting case of the lifting-power exerted by roots during growth, and in 1875 called the attention of my friend, Col. W. S. Clark, to the fact. He made measurements of the various parts, and noted the case in the *Scientific farmer* of Oct. 1, 1875. I cannot do better than reproduce his description, as follows: —

"On a ledge of coarse granite in the town of York, Me., stands a black birch (Betula lenta) which is about forty feet high, with a trunk two feet in diameter. The seed from which it sprang germinated in a narrow seam of the rock at a point eight feet from the ground in a perpendicular direction, and some fifteen feet along the line of the seam, which descended at an angle of forty-five degrees. The first rootlets of the young plant penetrated the seam until they reached the earth, from which supplies were to be drawn for the nourishment of the future tree. The mass of rock above the roots was more than fifteen feet long, from five to ten feet wide, and from one to three feet thick." Its weight was thus very nearly twenty tons. "Only two slender rootlets undertook the task of lifting and carrying this enormous load. One passed down nearly under the centre of the rock; and the other, two or three feet from the first, and so near the edge that at one point it has been forced out from under the rock, forming a sheet eighteen inches in width. The base of the trunk where it enters the seam now measures four feet in width and one foot in thickness. The mass of rock has been elevated twelve inches, and carried sideways eight inches by the expansive power of these two roots, which have not only borne this immense burden, but have supplied the crude sap for the development of the tree. It is but trifling to add the fact that they have not only raised the rock, but also the entire tree, from an eighth to a quarter of an inch every year."

The man on whose land this was found said he well remembered the time when it was impossible to insert his finger in the widest part of the seam. This is only one of the many similar cases which occur naturally, and is not more striking or suggestive than the force exerted by the mammoth squash in lifting a five-ton weight.[1]

In 1875, when carrying on some experiments with the squash-vine, it became necessary to remove the young squashes. This was accomplished by passing a knife through the stem of the squash, leaving the latter in position for future collection. One squash, though cut from the vine, was overlooked in the first collection; and, when the final harvest was made, it was discovered firmly united to the stem, and of a very good size. Upon careful examination, both outwardly and under the microscope, it appeared that (1) when the cut was made,

A BLAZE WHICH HAD BEEN COVERED BY MANY YEARS' GROWTH.

the squash was not displaced, and the cut surfaces immediately came together again; (2) as determined by a 'fault' in a crack of the epidermis, the squash rotated in position as the cut was made, thus accomplishing a displace-

[1] Clark, Phenomena of plant-life.

ment of nearly one-fourth of an inch on the surface of the stem; (3) the healing was complete in the interior, but the line of section was plainly visible under the microscope; (4) there was a displacement of the vascular bundles corresponding with the surface displacement; (5) the epidermis dried and shrank away before union could be completed, and there was thus left a V-shaped groove which extended completely round the stem, and demonstrated the completeness of the section in the first instance.

In the Redpath museum of McGill college there is a most interesting case of an old blaze on a beech-tree, which, in the course of a few years, came to be completely covered by the new growth. The specimen came originally from Belle Rivière, county of Two Mountains, and was discovered when cutting up the tree for firewood. It was exhibited before the Montreal natural history society, at its meeting in April, 1882; but no special description of it was published.[1] It is therefore thought desirable to figure and describe it here (see preceding page).

The figure, as blazed, is shown in the accompanying drawing; and its general character shows that it was probably made by one of the early Catholic missionaries, who little dreamed that it would be so effectually preserved. An examination of the stump showed by actual count at least one hundred and sixty rings of annual growth external to the blaze; and the size of the original tree is still clearly defined, showing that it was four inches and a half in diameter.

Two impressions are to be observed, — one representing the original marking; and the other, a cast from it, made by the overgrowing wood; both being very clearly defined. We have to note the following: —

1. That the figure was cut with a knife, as shown by occasional incised lines; though the outer cast, being in black, at first leads one to the belief that a hot iron was employed. Upon closer examination, however, it seems more probable that the black or carbonized portion was the result of slight decay, the decayed portion being subsequently covered up, and thus producing the appearance described.

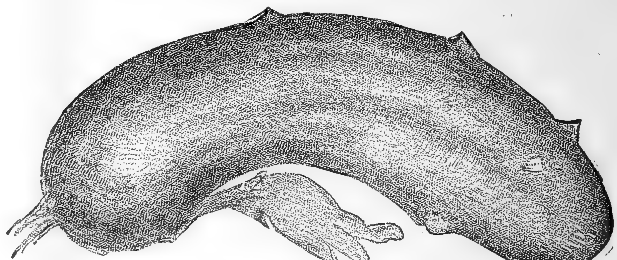
2. That the destruction of the bark and cambium was strictly confined to the lines of the figure, the intermediate portions still retaining their vitality and power of growth.

3. As now seen, the figures of the original blaze are defined by a stronger localization of coloring-matter in the wood, along the entire outlines, as shown in the drawing.

4. This offers a very good illustration of the tendency of active vegetable tissues to heal over abraded surfaces, and repair injury, the degree of reparation depending upon (*a*) the special vigor of the plant, and (*b*) upon the extent of the surface injured.

[1] Canadian nat., new ser., vol. x. no. 4, p. 238.

In 1879 I discovered a very interesting case of adhesion in a cucumber growing in the plant-house. My attention was not called to it until in an advanced stage of development,



FLOWER GROWING UPON A CUCUMBER.

as represented in the drawing, which is of full size. As is here seen, the monstrosity literally consisted of a flower growing upon a well-developed cucumber. As shown in the figure, the abortive flower was borne on a conspicuous peduncle, which became merged at its base with the base of the cucumber. The entire relation of parts would seem to indicate that there must have been two axillary flowers which became united in the early formation of the buds; one of them subsequently developing normally, while the growth of the other was largely arrested.

D. P. Penhallow.

McGill university, Montreal.

THE NATAL OBSERVATORY.

Mr. Edmund Neison, the government astronomer at Natal, submitted to the colonial secretary, in June last, his report on the Natal observatory, whose establishment has been mainly due to the active exertion of Mr. Escombe. It was decided to found the observatory in time to obtain observations of the then approaching transit of Venus of 1882; and, on being applied to, Mr. Gill, the astronomer royal at the Cape, furnished an estimate of the cost of a suitable establishment. A generous sum was secured at first by private subscription; and in June, 1882, the sum of three hundred and fifty pounds was voted by the corporation of Durban toward the expense of founding the observatory, and the next month this was supplemented by a special vote of

five hundred pounds by the legislative council. In all, a sum of about nineteen hundred pounds was contributed.

Under the superintendence of Mr. Robert Pett, of the Cape observatory, the new establishment was constructed, and the instruments erected. On the 1st of December, Mr. Neison took possession of the observatory as astronomer to the Natal government, and subsequently the observatory was taken over by the government of the colony. It lies on the south-west corner of the land originally granted for the use of the botanic gardens, and is a substantially built, rectangular red-brick building with cement facings, and carries a light wooden upper structure, forming equatorial and transit rooms. At present, there being no protection from the direct rays of the sun, the substantial walls of the observatory become so hot in the day, that it will be difficult to obtain proper observations until the building is completed by the erection of a veranda to shield the walls, and prevent their becoming so intensely heated. Having become thus raised in temperature during the day, the walls, owing to their massiveness, require the greater portion of the night in which to cool; and during this time they give rise to convection-currents of heated air, which render it difficult to secure satisfactory observations with any of the instruments.

At the time of Mr. Neison's report, the principal instruments of the observatory were: a fine eight-inch equatorial (by Grubb), the gift of Harry Escombe, Esq.; a high-class three-inch transit instrument, purchased by the government; an excellent sidereal clock, originally constructed for the Royal observatory, Greenwich, and at present lent by the Transit of Venus commission to the astronomer; and two chronometers, the one a sidereal, and the other a mean time. Mr. Neison describes these instruments, and reports their satisfactory performance. The observatory is at present without the usual equipment of meteorological instruments, but they will be obtained from England in the course of the spring.

Mr. Neison remarks upon the necessity of having proper steps taken for transferring in a regular manner to the Natal government the observatory and its site. It is built on ground originally assigned for a botanic garden, with the understanding that a sufficient space should be set aside for the purpose as might be deemed sufficient by the astronomer, though no written agreement to that effect was thought necessary. Owing to the nature of the ground, — a hillside covered with brush, — it is imperative that the astronomer (for the time in charge) should have every authority and complete control over the ground to the north and north-east of the observatory, which must be his chief observing-region; for otherwise he may be seriously hampered in carrying on his scientific work. The trees and other vegetation upon the surface of the ground have a far greater influence upon astronomical observations than in merely cutting off the view of a small portion of the heavens; this influence extending over the atmosphere for a considerable distance above them, owing to their liability to establish air-currents and tremors which are fatal to accurate observations. Experience has shown it to be not unfrequently necessary to clear the ground of particular kinds or groups of trees and shrubs, which establish such currents from being out of harmony in temperature and radiation-constants with the surrounding surface. Pines, laurels, and rhododendrons have had, on this account, to be removed from the environs of more than one observatory. Even the watering of the ground will give rise to most injurious convection-currents at times. When the moisture is general, as after a rain or heavy dew, it is of far less consequence; but when it is partial, as in watering plants, each plant sets up its own convection-current, and thus causes objects to appear most unsteady when seen through the air above, and so ruins accurate observation. Taking all things into consideration, Mr. Neison regards it as certainly most unwise to cramp the observatory and its future by confining the site set apart for its use to a smaller area than three hundred by seventy yards, both measured horizontally. A mere partial control or divided authority over this area, or any portion of it, would be unwise; for it would be sure to lead to complications and conflict of authority — if not in the immediate future, for a certainty at no long-distant date.

The Natal observatory has taken vigorous measures for the distribution of time-signals throughout the colony. At one o'clock every day a signal is sent to the central telegraph-office at Durban, from which it is distributed all over the colony, firing a time-gun and dropping a time-ball at Maritzburg, and also one at the Point, Durban. It is proposed to extend this system by the addition of a time-gun in the centre of Durban; to establish time-balls at Newcastle and Stanger; and, in connection with the Natal harbor board, to establish a system for properly regulating and rating ships' chronometers, similar to that already in existence at Liverpool and elsewhere.

In observing the transit of Venus the astronomers were moderately successful, no observations being undertaken outside of the usual optical ones. Copies of all the observations have been duly transmitted, through her Majesty's astronomer at the Cape, to the Transit of Venus committee at Burlington house, London.

With regard to tidal reductions, it has been arranged with the Natal harbor board that the tidal observations which are being made at Natal shall be reduced in the colony under the superintendence of the observatory, and proper tidal-tables constructed.

With reference to the future work of the observatory, it is proposed to take advantage of every opportunity for carrying out a series of observations of the moon, with a view of obtaining data for perfecting the tables of the motion of our satellite. The duty of making standard meridian observations of the moon is fully carried out at the Royal observatory, Greenwich, and partially at the Radcliffe observatory, Oxford, and at the U. S. naval observatory, Washington; but, for obtaining the full information necessary for properly discussing these observations so as to make them available for per-

fecting the theory of the motion of the moon, it is necessary that a considerable number of auxiliary observations should be made. These, it is proposed, should be made at the Natal observatory with the greater facility, as all the lengthy mathematical analysis necessary for their reduction has already been executed by Mr. Neison himself. The principal subjects already taken up at the observatory are the following: —

1°. The determination of the exact amount of the parallactic inequality in the motion of the moon by means of observations of the position of a crater near the centre of the lunar surface.

2°. The determination of the exact diameter of the moon by observations of pairs of points near the limb.

3°. The effect of irradiation and its variations upon the apparent semi-diameter of the moon.

4°. The systematic variation in the apparent place of the moon produced by the irregularities on its limb.

5°. The real libration of the moon by a method independent of the errors caused by abnormal variations in the apparent semi-diameter of the moon.

The first investigation is in continuation of the one already commenced at the Arkley observatory, England, and will be carried out with the additional co-operation of the observatory of Strasburg, Germany. Arrangements are being made to obtain the co-operation of the Cape and other observatories in the investigation of other of the above subjects.

ECONOMY OF FUEL IN IRON-MANUFACTURE.

As the price of iron falls, every item in the cost of its production is more and more carefully scrutinized, — the quality of the ore, the cost of transportation, the labor used at the various steps in the process, the accessories and mechanical appliances, the rapidity of working, the quantity of fuel to the ton of pig-iron produced, and the cost of the fuel. Of all these, the cost and quantity of fuel used are, perhaps, receiving the largest share of attention from the iron-men just at present.

One coal-saving device is the Gjers soaking-pit. Formerly the huge ingots of steel from the Bessemer converter were allowed to cool, and were again heated before rolling them into steel rails. The efforts to roll them while still hot failed, owing to the fact that the core might still remain fluid while the outside shell of the ingot was cooling even below the rolling-heat. The Gjers soaking-pit is a hole in the ground, walled with bricks, in which the ingot of steel is placed until it has uniformly cooled to the rolling-heat, thus saving the reheating-furnace. It is claimed that the Gjers soaking-pit saves sixty-seven tons of coal to a hundred tons of rails. Again: at the South Chicago works the pig-iron is run directly from the blast-furnace into the Bessemer converter; while the usual practice in most works has been, and still is, to allow the pig-iron to cool, and to melt it again in a special furnace for the Bessemer converter.

The above processes save in the *quantity* of fuel; while, on the other hand, a large saving in the cost of fuel is looked for in the improved methods of coking and in the recovery of the valuable by-products. It seems quite generally admitted, that a good system of coking, which will save the tar-oils and the ammonia, will pay all the coking-expenses.

The great national economy will be better understood from figures. In the year 1880, in the United States, 2,752,000 tons of coke were produced from 4,360,000 tons of coal by the old-fashioned beehive oven. Two years ago the figures for Great Britain were 7,000,000 to 8,000,000 tons of coke from nearly 13,000,000 tons of coal by beehive ovens. This quantity of coke could have been produced by the Simon-Carvès system of coke-ovens from 10,000,000 tons of coal; effecting a saving of 3,000,000 tons, and also a saving of the coal-tar and ammonia by-products.

The beehive oven, which takes its name from its form, is a low, square chamber with dome-shaped top; has an opening for escape of gases at the top, and a door in the side through which to admit the air, to charge the coal, and to discharge the coke. The burning is regulated by opening and closing the side-door, and all the gases go to waste at the top. The Simon-Carvès system of ovens consists of a row of chambers side by side, with combustion-flues in the parting-walls and under the floors. The waste-gases are burnt in these flues, and liberate heat enough to distil the gases of the coal. These gases, before entering the combustion-flues, are passed through condensing-apparatus, where the tar and ammonia by-products are saved. The two ovens, therefore, work upon totally different principles. The beehive cokes by slow combustion, sacrificing a portion of the coal by the door, as well as the by-products: the Carvès simply distils. The beehive saves 60% to 65% of the coal as coke: the Carvès saves 75%. The beehive oven produces a very fine coke, in long, columnar, hard, silvery, porous masses: the Carvès gives a dark, dense, heavy coke. And it is here that the iron-master hesitates; for he likes the silvery, porous beehive coke for making iron, and does not yet accept the dense, heavy coke of the Carvès oven.

Jameson has invented an oven which is known by his name, and which is essentially a beehive oven, with a suction-pipe entering at the bottom instead of the roof-outlet for gases. The products of combustion are drawn by an artificial draught through the pipe; and, after being carried through apparatus for the condensation of the by-products, this gas is available for any purpose. The actual yield from a ton of coal has been estimated to be: sulphate of ammonia, 10 pounds; oils, 8 gallons; gas, 12,000 cubic feet; coke, 67% to 69%. The tar from this oven is lighter than water (specific gravity, .960), and consists mostly of oils, boiling between 250° and 300° C., of little value as burning-oils, and of secondary value as lubricants. Paraffine is present, and both toluine and xyline in small quantities, but no benzine. A portion of the oils breaks up into phenols, which, so far as investigated, give colors of little stability. Neither naphthaline nor anthracine is present, both valuable as sources

of coal-tar colors; and, while this tar presents an attractive field for research, it is not of great value at present. On the other hand, the tar from the Simon-Carvès has a specific gravity of 1.20, is black and thick, rich in naphthaline and anthracine, contains benzine, toluine, xyline, and carbolic acid, and is free from paraffines. A good deal of benzol is supposed to be carried off and burned. Now, Mellor has recently patented a process for extracting benzol from gas by passing it up through an earthenware tower filled with broken glass moistened with nitric acid. Davis has also a process for refrigerating gases. Either of these processes, added to the present plant of the Simon-Carvès, would save valuable products for coal-tar colors.

It is generally the fate of new improvements, that some unforeseen difficulty stands in the way of immediate adoption. In this case the dilemma seems to be, that the iron-men say, give us beehive or Jameson coke and Simon-Carvès by-products, and we will embrace the improvement at once. But, while the Jameson coke is good, the by-products are not as yet of much value; and, while the Carvès by-products are valuable, the coke is not yet satisfactory. Improvements often are adopted partially, or in some modified form. So it appears to be in this case.

The furnaces at Gartscherrie, near Glasgow, Scotland, have for years been smelting with raw coal, allowing it to coke itself at the top of the furnace, thus losing all the by-products, and some of the coal itself. They have recently tried closing in the top of two of these furnaces, and conducting the furnace-gases through condensing-apparatus on the way to the boilers, hot-blast stoves, etc. They have been so much pleased with the result of the experiment, that they propose to apply the same improvement to the other eight furnaces. This arrangement will probably yield a much heavier oil than the Jameson oven, but perhaps not so heavy as the Simon-Carvès; and, as the coke is made within the furnace itself, it is hard to say just what its quality may be.

Report says that modified plans are being tried in still another way, and that the highly bituminous coals of Colorado are treated by a process of coking; and the derived gas is injected into the blast-furnace, and thus re-enforces the heat of the coke, which is mixed with the ore, as usual, and has thereby effected a reduction of 75% in the cost of the smelting.

R. H. Richards.

THE FLORA OF LABRADOR.

The list of the plants of Labrador published in the Proceedings of the U. S. national museum, vol. vi. pp. 126–137, is interesting as showing some facts of geographical distribution. Though the list makes no pretensions to being complete, still it may be considered that it represents the flora in a sufficiently complete form to allow inferences to be drawn from it.

There are enumerated, altogether, a hundred and sixty-one species and varieties. Of these, two, Ranunculus acris and Capsella bursa-pastoris, have been introduced from Europe. Of the hundred and fifty-nine left, a hundred, or nearly sixty-three per cent, are natives of Europe as well as of Labrador. Out of these hundred species, there are some having a more northern distribution than Labrador, and a few extend even to the Arctic circle. Many of them are marsh or swamp plants, or else live along the seacoast. The flora, as a whole, is most decidedly northern in its character.

Of the fifty-nine species not known to Europe, it is found that thirty-eight have a range to the northward of the 49th parallel, and that only about four (viz., Fragaria Virginiana, Kalmia latifolia, K. angustifolia, and Alnus serrulata) can be considered as southern forms. Of these, the first is 'rather rare,' the two Kalmias are found in 'ravines and near ponds in the interior,' while the last is found 'in ravines' and along the seacoast. The northern aspect of the flora is further illustrated by the following facts: —

The Ericaceae, an order most abundant in cold climates, has seventeen species; Rosaceae has eighteen species, ten of them belonging to the northern genera Potentilla and Rubus; Caryophyllaceae has eleven species and varieties; while the Labiatae has not a single one, the Borraginaceae has only one, Scropulariaceae but two, and Compositae is sparsely represented by four.

This last seems an especially striking fact, and is in accordance with what we might expect. We know that the order is largely a tropical one, and that probably the heat of the summer months in Labrador is not sufficient, and not long enough continued, to enable the plants to flower and fruit. Of the Leguminosae, there are only five species, four of them being European also; and this order may be regarded as being in the same category as the Compositae.

In a former article (Indigenous plants common to Europe and the United States, *Journ. Cinc. soc. nat. hist.*, iv. p. 51), I have endeavored to show that we must look to the north as the place of origin of many of our plants; and when we find that sixty-three per cent of Labrador plants are also European, and twenty-three per cent have a high northern range, some extending to Alaska and Greenland, we see further reason for the assertion. That many of these plants were at one time distributed all around the Arctic circle, there can be no doubt; and that they have been driven from their first homes by the excessive cold, and found suitable abiding-places at the south, must also be considered as an established fact. The agent in this pushing-southward of northern forms may be regarded as the glacial period, when the presence of the immense mass of ice on the continent caused the flora to continue to retire farther and farther south as the cold became more and more intense: when it mitigated, many of the plants returned north, and established themselves as near as they could to their original homes.

Jos. F. James.

THE HALL PHENOMENON IN LIQUIDS.

PROFESSOR ANTONIO ROITI publishes (Atti acc. lincei, xii. 397) under the above title the results of some experiments he has made. In preparing himself for his work, he repeated some of the ordinary experiments upon this phenomenon in metals: and the results, which contain nothing new, are shown in several diagrams. He devised one new experiment, however, which shows, as he thinks, that the effect he is investigating is not due to a direct action of the magnetic field upon the electric current *per se.* As the opinion thus reached by Professor Roiti must have been held two or three years by all who have given special attention to the matter, it is hardly worth while to inquire whether his new experiment is conclusive in itself.

In experimenting with liquids, Professor Roiti was unsuccessful in his main object, no effect similar to the well-known action in metals being detected.

It did appear, however, that the magnet, acting upon a solution of sulphate of zinc of given strength, was able to produce a change in the electric conductivity of the solution, the sign of which depended upon the direction of the magnetic force, the current in the liquid, and the degree of concentration of the solution. Thus, in a solution less concentrated than that which possesses the maximum electric conductivity, the effect was in a certain direction; while the opposite effect was produced, under the same conditions of current and magnetic force, in a solution having a concentration greater than that corresponding to this maximum. In a saturated solution no similar effect was observed.

Professor Roiti attributes this behavior of the non-saturated solutions to a want of homogeneity in the liquids, which become stirred up by the ponderomotive electromagnetic action. He makes several experiments tending to support this opinion. In a solution of ferric chloride (*cloruro ferrico*), of specific gravity 1.34, effects were obtained similar to those found with the dilute solution of sulphate of zinc. In a thin layer of mercury no similar effect was detected.

The examination of liquids with the view of detecting a 'rotational effect' similar to that observed in metals was probably first suggested in print by Ettingshausen.[1] The difficulties of the investigation were obviously great, however; and Professor Roiti appears to be the only experimenter who has yet undertaken it.

His account of his experiments is open to criticism in this respect: that it does not give sufficient data in regard to intensity of magnetic field, etc., to enable the reader to determine how severely the liquids were tested for the presence of the effect which gives the title to his article.

Moreover, he seems to have made a point of placing his side-connections unsymmetrically, so as to have, independently of the magnet's action, a considerable 'derived' current, — an arrangement which enabled him to discover the effect described above, but which, on that very account, should be studiously avoided in seeking for the phenomenon he was trying to detect.

[1] *Anz. akad. wissensch. Wien*, March, 1880.

Professor Roiti's ultimate object in beginning this investigation was to determine whether the transverse or 'rotational' effect would in liquids correspond to the magnetic rotation of the plane of polarization of light. Of course, no conclusion whatever upon this point can be drawn from the account given of his work and its results. And, even if his experiments had been entirely successful in revealing the effect looked for, it would be necessary to exercise caution in applying results so obtained to the case of the rotation of light. In the liquids, as here examined, the particles have time to fully adjust themselves, in position and motion, to the requirements of the magnetic force and the electric current to which they are subjected; while in the phenomenon of light, assumed to be electromagnetic in character, the mere inertia of the particles of the liquid must play an important part in the action of forces, which are reversed a countless number of times every second.

In the *Comptes rendus* of Sept. 17, 1883, Professor Righi states that he has found the Hall effect in bismuth to be of the same sense as in gold, but about five thousand times greater than in the latter metal. He obtains a very marked action in bismuth by use of an ordinary bar-magnet, and believes that he can produce a perceptible effect by the action of the earth's magnetism.

JANET'S THEORY OF MORALS.

The theory of morals. BY PAUL JANET. Translated from the latest French edition [by MARY CHAPMAN]. New York, *Charles Scribner's Sons*, 1883. 10 + 490 p. 8°.

IF books on ethics are to be noticed at all in a scientific journal, they might be, as a rule, safely classified under the head of fossils. No literature deals with a subject which would seem to be more living; yet no literature is, on the whole, more desiccated and dead. Human conduct, with all its infinite variety of standards and impulses, with all its marvellous interworking of passions and emotions, with all its pressing and personal problems, conflicts, and obligations — what subject would seem to stimulate students to greater vividness, picturesqueness, or incisiveness of treatment? Every man is in his own way an ethical philosopher. No one can escape thinking about the right principles of his conduct. Books on this subject address the largest possible audience on the one unavoidable subject of reflection. And yet there seems to be some subtile influence which dries up even literary instincts when they approach this theme and which makes even brilliant writers wearisome. There

is hardly any living English writer more abounding in vitality and wit than Mr. Leslie Stephen; but even he, when he enters this enchanted region, seems benumbed and drowsy, and is positively hard to read. There is said to be no American teacher who has imparted more moral force to his students than the venerable president of Williams college; but, the moment he arranges his instruction in a book, it is as if he gathered his living flowers from useful and from noxious plants, and laid away these virtues and vices, all pressed and juiceless, in successive drawers.

The last work of Janet, which he frankly describes as his *Magna moralia*, is certainly as little open to these criticisms as any book of its kind. It attracted much attention on its first appearance in 1874, and was for some years used as a text-book in Harvard college. It is now translated, and very well translated, for the use of President Porter's classes in Yale college. It has lucidity, as our last literary adviser would call it, and is full of learning. Its strength lies where the German masterpieces are weakest, — in force and variety of illustration. It is hardly extravagant to say that so clear and picturesque a treatise, in the hands of an alert teacher, might save the study of ethics from its almost inevitable fate of being very dull.

The stand-point of the author may be very briefly described. He is a conspicuous instance of the many minds who desire to be eclectics, but whose hearts will not permit them. He sees that the problem of ethics, like that of all present philosophy, is a problem of reconciliation. He sets himself to comprehend in his system the whole range of contributions to ethics made by modern utilitarianism, but he is none the less at heart a Kantian. The moral law of Kant appears to him too formal, too abstract, too empty, and he is repeatedly offering corrections and supplements; yet if Fichte is a disciple of Kant, so, in spite of frequent controversy with the master, is Janet. His first thrust is at the least-guarded part of the experiential method, — its incapacity to distinguish between quantity and quality in conduct. Here he discloses with ease the contribution which Mr. Mill has made to the view of conduct which he believed himself to be opposing; and we pass from the recognition of this distinction of quality in acts to the principle which alone can give quality to them. This principle he defines as their intrinsic excellence; and this excellence, in its turn, is to be judged by the contribution of acts to the unfolding of the best in man, — of his real personality, his reasonable will. Thus we find before us the moral dynamic of a completed life, the conception of an end in which happiness and excellence shall coincide, — in short, a moral ideal. This discussion occupies the first of three divisions in the treatise. The two remaining books unfold this fundamental conception in its relation to outward standards of duty and to inward laws of life. They proceed with great clearness and almost with vivacity of treatment, and invite us in somewhat fragmentary fashion to a great variety of problems, both of metaphysics and casuistry, which we cannot here consider.

Returning to the main contribution of the book to the theory of morals, the present reviewer has no controversy to undertake with its evident purpose. The ideal aim which it presents is not stated with the frankness of Grote, or with the fulness of Green; yet it is as plain with Janet as with Grote, that man is essentially 'an ideal-making animal,'[1] and as certain, though not so plain, with Janet as with Green, that the development of the moral ideal is a personal and inward, and not a social, evolution.[2] What we shall here with some diffidence suggest, however, is the highly technical character of all these treatises, and, indeed, of the whole range of ethical literature. We repeat the impression with which we began this notice. Here is a subject which deals more directly than any other with the real and daily relations of life; yet, as we have just now tried to describe the purport of a remarkably lucid book, we have found ourselves forced into the language of specialists, and away from the methods of practical affairs. It is quite possible for a man to be a highly trained moral philosopher, and yet be a powerless adviser concerning a specific moral problem, so far removed has been the science of right conduct from the subject with which it is supposed to deal. Now, we maintain that a science of life should frankly take its start from the data and the problems of life, and should proceed inductively to analyze and classify these data, and to discover what may be their law. The literature of moral conduct may be at present divided into two distinct classes, — the books which deal with theory, and the vast and rapidly growing literature which deals with the practical conduct of social life. This latter department is largely the growth of the last few years. It may be called ethical sociology. It describes the duties one owes to himself and to society, — the duties, or, in the case of Pro-

[1] Grote on moral ideals, p. 46, ff.
[2] T. H. Green, Prolegomena to ethics, 1883, pp. 189, 201.

fessor Sumner's little book, the absence of duties, between social classes; the problems of charity, temperance, and all the varied aspects of moral reform. Now, between these practical applications of ethics and the books on ethical theory there lies an unbridged chasm. The maxim of Kant gets ample illustration: "Ideas without content are empty; observation without ideas is blind." [1] When sociologists approach any theory of morals, they exhibit an almost ludicrous ignorance, as when Professor Sumner interprets sympathy in the spirit of unconscious Hobbism. When, on the other hand, a student of the metaphysics of morals approaches a problem of practical conduct, he is apt to find his law unmeaning. Here, then, it would seem, is an opportunity for what may be fairly called inductive ethics. It is not the method which commonly claims this name, and which simply means the exclusion of any evolution of personality; it is the construction of a theory of ethics from an examination of the facts of social life, the data of philanthropy, the testimony of ideal aims, the characteristics of moral personalities. This would be a method of ethics which would be constantly close to life, and which would gather up the real issues of conduct into their higher significance and tendency.

Francis G. Peabody.

BACTERIA.

Bacteria. By Dr. Antoine Magnin and George M. Sternberg, M.D., F.R.M.S. New York, *Wood*, 1883. 19+11+494 p., 12 pl., illustr. 8°.

This portly and handsome volume will be read with interest by all who have followed the painstaking and thorough work of Dr. Sternberg during the last three or four years. To him belongs the credit not only of having translated and published, in 1880, Magnin's useful book on the bacteria, but of having applied himself with tireless devotion and very considerable success to the actual work of laborious researches, often made under discouraging circumstances, and with little genuine sympathy from his fellow-countrymen. Dr. Sternberg is at the head of the American school of working bacteriologists, if, indeed, he is not its only member; so that any work coming from his practised hand should meet with a hearty welcome.

The present volume, which might well be called a handbook of bacteriology, is made up partly of Magnin's older treatise referred to above, and partly of new material supplied by Dr. Sternberg. Magnin's account of the morphology and the physiology of the bacteria, covering one hundred and fifty-two pages, is preserved intact. The rest of the older book is omitted; and in its place we have four 'parts' written by Dr. Sternberg, and discussing respectively, 'Technology,' 'Germicides and antiseptics,' 'Bacteria in infectious diseases,' and 'Bacteria in surgical lesions.' These, taken together, make up more than one-half the book.

Of Magnin's work it is not needful to speak. His book is familiar. We may turn, then, to the parts prepared expressly by the American author. Under 'Technology' we have a succinct but clear account of the various methods of collection, of cultivation, of staining and of photographing the bacteria, and of the attenuation of virus. Of most of them the author speaks from experience; and this chapter will be of the utmost value to the student and the investigator. Of course, in a subject like this, intricate and refined to the last degree, actual personal guidance is essential, or, at least, highly desirable; and we believe that Dr. Sternberg has given enough of the technology to help, but not enough to harm, the student.

Under the head of 'Photography' (p. 194) the author says,—

> "It is but fair to say that satisfactory results can only be obtained by the expenditure of a considerable amount of time and money, as the work must be done with high powers, and the technical difficulties to be overcome are by no means inconsiderable. The illustrations in the present volume may be taken as fair samples of what may be accomplished, and it will be found easier to criticise these than to improve upon them."

The plates are, indeed, of an unusually high order; the heliotypes of human (yellow-fever) blood being something remarkable, and not likely to be improved upon at present.

Under the head of 'Germicides and antiseptics' we observe at the outset (p. 210) the following conspicuous finger-post:—

> "If it were proven that the infectious character of every kind of infective material depended upon the presence of a specific living germ, as has been shown to be true in the case of certain kinds of infective material, *germicide* and *disinfectant* would be synonymous terms. Although this has not been proved, it is a significant fact that all of the disinfectants of established value have been shown by laboratory experiments to be potent germicides."

Numerous original experiments are here recorded; and the author agrees with the other authorities in giving little germicide value to most common disinfectants, and in pointing out the extraordinary efficacy of mercuric bichloride.

Besides a dozen or so of pages devoted to the *rôle* of the 'Bacteria in surgical lesions,' and having chiefly a medical interest, the rest of the book is devoted to a long and careful treatment of the 'Bacteria in infectious diseases,' and to the literature of bacteriology. These and the part on 'Technology' include the cream of the work.

At the start the author incidentally draws a subtle distinction, which may or may not be generally acceptable (p. 236), —

"The practical results of etiological studies, so far as the prevention and cure of disease are concerned, are likely to be much greater than those which have been gained by the pathologists;" —

adding directly in a tone of liberal conservatism, which no one can help admiring, especially as it comes from one who is in the advancing column, —

"and if the time ever comes, as now seems not improbable, when we can say with confidence, infectious diseases are parasitic diseases, medicine will have established itself upon a scientific foundation. But this generalization, which some physicians think is justified even now by the experimental evidence which has been so rapidly accumulating during the past decade, would, in the opinion of the writer, be premature in the present state of science. And for the present it seems wiser to encourage additional researches, rather than to attempt to generalize from the data at hand. . . . Those who have had the most experience in this difficult field of investigation are commonly the most critical and exacting with reference to the alleged discoveries of others."

Dr. Sternberg sees clearly enough that one of the most interesting theoretical questions in this whole subject which remains still unsolved is, how does inoculation or vaccination protect? or, in his own words, what is "the rationale of the immunity produced by protective inoculations? . . . Recovery, after inoculation with attenuated virus, is more easy to understand than is the subsequent protection" (p. 241).

Lecturers upon the subject often pass lightly over this point, and, by a comparison with a fermentation in a barrel of cider for example, say, "And just as a barrel of apple-juice can ferment but once under the same germ, so a man usually has the small-pox but once;" the idea being implied, that, as the alcoholic ferment has eaten up its food in the barrel, so the hypothetical small-pox plant has taken out all the available food-material from man, its living prey. Pasteur maintains a position like this; while Sternberg denies that it is a satisfactory explanation, and brings forward a lengthy argument in opposition, some of the points of which do not seem to us well taken. It is, however, the sufficient and fatal objection to the line of thought outlined above, that, while the barrel of apple-juice is a not-living medium, the living organism is undergoing constant repair, is even growing (in the technical sense) till death comes, and is therefore no fixed quantity, either in composition or condition. Dr. Sternberg would solve the problem by considering the acquired protection to be a 'tolerance,' a 'resistance' of the protoplasm to the new condition; e.g. (pp. 248–249), "during a non-fatal attack of one of the specific diseases, the cellular elements implicated, which do not succumb to the destructive influence of the poison, acquire a tolerance to this poison."

This would explain a temporary immunity, — would prevent a patient from 'giving' the disease to himself over and over again, — but would not explain a lifelong immunity, since new, and perhaps non-tolerating, non-resisting cells are being constantly produced from the old ones. The cells which actually suffered are therefore supposed by Dr. Sternberg to "acquire a tolerance to this poison, which is transmissible to their progeny and which is the reason of the exemption of the individual from future attacks of the same disease."

This hypothesis is certainly clear, and it is only befogged by the author's illustration (?) drawn from budding and grafting.

In view of the fact that bacteria are now believed to do their work largely by producing a genuine not-living poison which affects the living cells, the following is of interest: —

"The tolerance to narcotics — opium and tobacco — and to corrosive poisons — arsenic, which results from a gradual increase of dose, may be cited as an example of acquired tolerance by living protoplasm to poisons which at the outset would have been fatal in much smaller doses.

"The immunity which an individual enjoys from any particular disease must be looked upon as a power of resistance possessed by the cellular elements of those tissues of his body which would yield to the influence of the poison in the case of an unprotected person."

The reader must recollect, however, Huxley's discussion of 'aquosity' and 'horologity,' and remember that in such sentences as the following we are doing little more than formulating our ignorance: —

"The resistance of living matter . . . is a property depending upon vitality."

The question is often raised, Where do the pathogenic bacteria come from? Dr. Sternberg says in this connection, —

"If we suppose that under certain circumstances the conditions relating to environment approach those which would be found within the body of a living animal, we can easily understand how a micro-organism which has adapted itself to these conditions

may become a pathogenic organism when by any chance it is introduced into the circulation of such an animal. The culture fluid — blood — and temperature being favorable, it is only a question of superiority by vital resistance on the one hand, or by reproductive activity on the other.

"That harmless species of bacteria may develop pathogenic properties in the manner indicated seems extremely probable; and we should *a priori* expect that such a result would occur more frequently in the tropics, where the elevated temperature and abundance of organic pabulum furnish the favorable conditions required. In this way we may, perhaps, explain the origin of epidemics of pestilential diseases, such as yellow-fever and cholera. If these diseases do not at the present day originate in the manner indicated, they, at all events, have their permanent abiding-place in tropical countries."

Much space is properly devoted to the status of science regarding the individual diseases, and the treatment of them by the author is highly satisfactory. The volume closes with an admirable literature of the subject, for which all students will thank him. But in another edition he should add information as to where the papers of E. C. Hansen can be found. It would be better, also, to give the titles of German papers throughout in the German; and it surely is as needful to mention Schwann and Kützing as Cagniard de Latour, while the failure to record the translation of Schützenberger's work is a serious omission. Aside from these and other insignificant and pardonable errors, the bibliography is very satisfactory. The alphabetical arrangement which has been wisely adopted has one slight disadvantage: we miss the striking evidence of the growth of the subject, which a chronological arrangement such as was employed in the translation of Magnin's book in 1880, and which was in this respect impressive, gave.

On the whole, this book is the most practical, the most complete, and the most useful which we possess upon the subject. It is both a storehouse of principles and a handbook for the laboratory. If a physician or a student, a biologist or a pathologist, can have but one book, this one, because of its lucidity of style, its cool, cautious tone, its breadth and yet its comprehensiveness, and particularly because of its excellent illustrations, is emphatically the one to get. It is deeply to be regretted that Dr. Sternberg cannot be kept busily at work under every favorable condition at the expense of a country to whose service his life has been devoted, and that he is, on the contrary, obliged to write sentences so melancholy as these: —

"All this is admitted, and the experiment is introduced mainly to call attention to a method, which, carefully applied, should enable us to solve the question as to the pathogenic *rôle* of this micrococcus. The writer had mapped out for himself a series of experiments in this direction, and many others relating to etiological questions; but circumstances have not been favorable for the prosecution of experimental work, and he finds himself, somewhat reluctantly, engaged in a review of the field, when it would be far more to his taste to interrogate nature by the experimental method, and thus to aid directly in the solution of these interesting problems" (p. 447).

SCIENTIFIC LINGUISTICS.

Internationale zeitschrift für allgemeine sprachwissenschaft. Herausgegeben von F. TECHMER. Heft i. Leipzig, *Barth*, 1884. 16+256 p., 7 pl., illustr. 8°.

THIS new journal appears with an excellent though only partial list of contributors, representing various nations and languages. The articles may be in German, English, French, Italian, Latin, and, under exceptional circumstances, even in some other language; and the international character it is meant to have is perhaps the best justification for its existence. The editor, Dr. Techmer, *privatdocent* at Leipzig, has previously published a work on phonetics; and the most noteworthy article in this number is one by him on the same subject. Most, if not all, of the other articles might well enough have been published in already existing journals. They are all in German, except two in English (together occupying some twenty-two pages out of over two hundred and fifty) and one of about four pages in French. The writers are Pott (Einleitung in die allgemeine sprachwissenschaft), Techmer, G. Mallery (Sign-language, largely a reprint), Friedrich Müller, Max Müller (a short article in German on a Vedic name which he supposes to be identical with our word 'zephyr,' and to have been originally a name for the setting sun, zephyr meaning the west wind as coming from sunset), L. Adam (De la catégorie du genre), Sayce (The person-endings of the Indo-European verb), and Brugmann.

Techmer has two articles, — one devoted to the analysis and synthesis of audible speech; the other, to the transcription of sounds; both accompanied by illustrative figures and tables. The former is intended to give briefly what is known on the subject, and to add new contributions. The treatment of vowels is what is likely to interest phoneticians most in this latest work on the subject, especially its position with regard to the English school. It must occasion surprise, not that the English system is rejected, but that the arguments against it are so brief and insufficient; hardly any thing but Bell's work being considered, while

others, who have considerably modified Bell's system, are practically ignored. Sweet ought to have received careful attention; and Sievers surely deserved more than a curt footnote saying that the first edition of his book on phonetics had treated better than the second a certain class of vowels. The vowels meant have not yet been fully observed, but the Russian *jery* is one of them. Observations made several years ago in Leipzig, and renewed very recently in Boston by the writer of this notice, on the sound in question as pronounced by native Russians, are decidedly opposed to the theory accepted by Techmer; and Techmer's own hardly seem to favor it. That theory assumes that the sound is produced by *u*-position of the tongue, and *i*-position of the lips, while the English system makes it a vowel formed with the tongue in the 'mixed' position. In the present state of vowel-analysis, a correct account of this sound is of great importance, and vowels of the same class form one of the most marked features of the English scheme. Now, Techmer himself says he has only been able to observe a special form (*spielart*) of this class of vowels; namely, the Russian sound: and this he marks as formed with partially passive lips, like English vowels, and (sometimes only?) with an approach toward *mittlere zungenartikulation*. This comes very near the English description of the sound. The whole of Techmer's article is less clear and less interesting than Sievers's work, and makes the impression of resting more on theory than on unprejudiced observation of actual speech. To put, for example, *a* in the centre of the vowel-scheme must seem to many phoneticians a fundamental error. Still, the article contains much that is valuable, and is not to be neglected.

The second article, that on the graphic representation of speech-sounds, is open to objection for the same reasons. The account of English *e* in *err*, and *u* in *but*, certainly needed justification. They are represented as somewhat incomplete varieties of a sound to be classed with German *ö* and *ü*, — a statement which can only be accepted by one who agrees with Techmer as to the place of *a*, if, indeed, by any one. Also the English and American *r* sound ought to have been carefully distinguished from the rolled or trilled *r*'s, as Sievers has done.

If the journal lives, it will certainly contain much valuable matter. It is only to be feared that its rivalry will injure others already established, such as Kuhn's *Zeitschrift*.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Division of the Pacific. — This division includes those parts of California, Oregon, and Washington Territory the drainage of which flows to the Pacific Ocean. An exception is the Lewis Fork of the Columbia River, which rises within the limits of the Great Basin.

The work undertaken in this division is divided into two classes; viz., the investigation of the mining-industries, and the study of the volcanic rocks. As preliminary to the latter, topographic work has been carried on for two seasons in northern California. Some of the details of this work, in the vicinity of Mount Shasta, have already been published.

Examination of quicksilver deposits.— Mr. George F. Becker and his assistants have been engaged in an examination of the quicksilver deposits of California. During the season of 1883 Mr. Becker's personal attention has been devoted to investigations in the vicinity of Sulphur Bank. In August a trip was made to the North Fork of Cache Creek and to Lower Lake, the only localities in that section where fossiliferous strata occur. The latter part of August and early part of September were spent in this section in order to complete the map of the Clear-Lake region of California. Returning to Sulphur Bank, soundings of the lake were taken, and the final examinations of the mines made, after which the party returned to San Francisco to prepare for the winter's office-work.

In the New Idria district, topographic work in connection with Mr. Becker's work was carried on throughout the whole season by Mr. Hoffmann. The survey was made with the utmost care, and in great detail. Contour lines, eighty feet apart vertically, were run; and intermediate forty-foot contours were interpolated by means of slope-measurements in the steeper parts, and by running curves in the more level portions. The entire area surveyed includes twelve square miles, and the field-work for the map was completed early in 1884.

Geologic work. — Mr. Turner, under the direction of Mr. Becker, undertook an examination of the region in the vicinity of Knoxville, after a trip from Clear Lake to the latter point, during which, notes on the general geology of the line of travel were taken. His work was interfered with by sickness, which obliged him to enter the hospital at San Francisco for treatment. Later in the season, however, he returned to the field, and throughout January, 1884, was busy mapping the formations in the region about Knoxville.

L a b o r a t o r y w o r k. — Dr. Mellville, in the laboratory at San Francisco, has been busy with analyses of the minerals, rocks, and waters collected at Sulphur Bank, and with other analytic work in connection with the examinations of the quicksilver deposits. He and Mr. Becker have been investigating some of the chemical relations of quicksilver.

S t u d y o f t h e v o l c a n i c r o c k s. — Capt. C. E. Dutton has been placed in charge of the investigation and study of the volcanic rocks in this division, with Mr. J. S. Diller as assistant. Capt. Dutton, during most of the past season, was busy in the preparation of his memoir on the Hawaiian volcanoes, which will be completed in time for publication in the fourth annual report of the director. Owing to the as yet incomplete state of the topographic work (which is progressing satisfactorily under the charge of Mr. Gilbert Thompson) in northern California, the field geologic work has been confined mainly to preliminary reconnoissance work, which has been carried on by Mr. J. S. Diller. Mr. Diller and his assistants took the field at Red Bluff, Cal., early in July, and immediately began work in that vicinity. The plain east of Red Bluff is a volcanic conglomerate of andesitic basaltic fragments of tufa. This formation is apparently of great extent, and reaches to the eastward for twenty-five miles. Late in July the party left Red Bluff, after having made a trip of six days' duration to Lassen's Peak, and proceeded *viâ* Redding to Yreka. From this point the ascent of Mount Shasta was made, after which they went to Linkville, Ore., taking the valley of the Klamath River to cross the main platform of the Cascade Range. Mr. Diller spent some time in the region of Mount Scott and Crater Lake, the geological features of which he found especially interesting. A brief but careful examination was made of the valley which the Klamath River cuts across the Cascade Range, in order to ascertain the geologic structure of that mountain platform. Interesting studies were also made of the faults and dislocations on the eastern side of the range, near Klamath Lake. The work thus detailed kept the party busy during August; and during September the reconnoissance along the eastern side of the range was continued. Union Peak, Mount Thielson, Crescent and Summit lakes, and Diamond Peak were all visited. From the latter Mr. Diller proceeded to the group of volcanic cones known as the Three Sisters, where both Mr. Diller and his assistant, Mr. Hayden, met with the accident already noted, which obliged them to suspend work temporarily. Later on, however, the work was continued to the northward. An account of the return trip to Red Bluff, *viâ* the western side of the Cascade Range, has been already given in *Science*. The entire trip occupied a hundred and eleven days, and the distance travelled was twenty-five hundred miles. The work done will be of great service in the determination of many of the problems connected with the range, and will form an excellent basis for future field-work. Mr. Diller is of the opinion that a special study of Lassen's Peak, if made before the detailed examination of the Cascade Range is begun, will be of great service. He says, no other ancient volcano in the United States is known that has erupted such a variety of lavas, or placed them in so favorable a position for study of their succession, as has Lassen's Peak. The solfataric phenomena at 'Bumpass' Hill,' and other places in the vicinity of Lassen, are much more extensive than at any other point in the Cascade Range. The region is also readily accessible. To the northward and southward, there are good exposures of the rocks which form the foundation of the Cascade Range, whereas north of Mount Shasta the exposures of these rocks are limited.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Appalachian mountain-club, Boston.

March 12. — The following resolution was adopted by the club: holding in high esteem the geographical labors of the late Professor Arnold Guyot, be it resolved, that the Appalachian mountain club is impressed with the loss it is now called to sustain in the death of an honored and illustrious member, and that the club receives with gratitude that rich store of knowledge his researches have disclosed to those who seek the truths of nature among the Appalachian Mountains. —— A paper on mountain adventures by Mr. Alessandro di Placido, including a winter ascent of Fujiyama, Japan, and one by Dr. S. Kneeland on a visit to the crater of Vesuvius at night, in April, 1882, were read. —— Mr. C. H. Ames described the mountains around the Ktaadn iron-works in Maine. This group consists of thirty-one peaks, ranging in height from fifteen hundred to four thousand feet, the highest being White Cap. Mr. Ames exhibited a beaver-skin, moose-antlers, and a reindeer-head. —— Mr. W. M. Davis, representing the U. S. geological survey, explained the proposition which the survey has made to this state for the production of a map, and the following resolution was passed: resolved, that the Appalachian mountain club, in view of the great insufficiency of the existing maps of Massachusetts, recognizes, in the proposal recently made to the legislature by the U. S. geological survey, an opportunity to obtain a topographical map of the state which should not be lost, unless the legislature is prepared to inaugurate a more thorough and expensive plan.

Linnaean society, New York.

March 7. — The following officers were elected for the ensuing year: president, E. P. Bicknell; vice-president, Dr. A. K. Fisher; recording secretary, L. S. Foster; corresponding secretary and treasurer, N. T. Lawrence. —— Mr. E. P. Bicknell read the con-

tinuation of his paper, 'A study of the singing of our birds,' the first instalment of which has appeared in *The auk*. The portion of the paper read consisted of a consideration of the arrival, departure, and song periods, with their duration and lapse, of thirty-eight birds. His observations were made at Riverdale, N.Y. —— A paper was presented by Dr. C. Hart Merriam, giving a life-history of the woodchuck as he had found it in the Adirondack region; recording its change of abode from the meadows to the edges of the woods as the hibernating-time approached, its weak attempts at tree-climbing, its almost total abstinence from water, the rare exercise of its swimming-powers, its occasional evidence of carnivorous propensities; and closing with an extract from the laws of New Hampshire that offer a bounty of ten cents for each woodchuck destroyed in that state. Dr. E. A. Means stated that about two per cent of the Adirondack woodchucks were melanistic. —— Notes concerning a few early spring birds were given by Mr. N. T. Lawrence; and Mr. William Dutcher spoke of the recent capture of a fine female Archibuteo lagopus Sancti-Johannis in black plumage on Long Island. —— Mr. E. P. Bicknell mentioned the blooming of those early spring flowers, the skunk-cabbage and the golden saxifrage, at present at Riverdale, N.Y.

Cincinnati society of natural history.

March 4. — Mr. Charles Dury read a paper on North-American hares, with notes on the peculiarities and distribution of all the known species and varieties. He said that in Kansas and Colorado the common prairie hare, Lepus campestris, is commonly though erroneously called the jackass-rabbit. The true jack-rabbit, L. callotis, has a more southern range. A skin of a specimen shot by Mr. Dury in New Mexico was exhibited. He had measured tracks of this hare which were twelve feet apart. The flesh of L. callotis Mr. Dury found to be very coarse and unpalatable. Not so, however, that of the little sage hare, L. Nuttalli, which was very good, providing the animal be drawn immediately after being killed. If the intestines are allowed to remain for even half an hour, their contents give the flesh a sagy flavor. —— Prof. Joseph F. James read an abstract of notes on some plants of the vicinity of Cincinnati. He exhibited a series of specimens of Cardamine (Dentaria) laciniata and C. (Dentaria) multifida, which showed that the two species could not be separated, and should be included under one specific name. —— Mr. Davis L. James read a notice of Mr. Thomas W. Spurlock, a botanist of local reputation, — a sort of Tam Edwards, who followed botanical pursuits from a pure love of them, and who, by his liberal distribution of rare specimens, and by his simple and child-like love for flowers and plants, had laid collectors under many obligations, and made his memory dear to them.

Engineers' club, Philadelphia.

March 1. — Mr. William Ludlow described tests of the crushing-strength of ice which were made by him in order to learn approximately the strength required for an ice harbor of iron screw-piles, in mid-channel, at the head of Delaware Bay. Eighteen pieces were tried with government testing-machines at Frankford, Philadelphia, and at Fort Tompkins, Staten Island. The specimens were carefully prepared six-inch and twelve-inch cubes, and roughly cut slabs about three inches thick, of different qualities and from different localities. For pure Kennebec ice the lowest strength obtained was three hundred and twenty-seven pounds, and the highest a thousand pounds, per square inch. For inferior qualities the strengths varied from two hundred and thirty-five to nine hundred and seventeen pounds. The higher results were obtained generally when the air temperature in the testing-room was from 29° to 36° F., as against 55° to 68° F. for the lower results. The pieces generally compressed half an inch to an inch before crushing. —— The secretary exhibited for Mr. C. A. Ashburner a set of blue prints of some yet unpublished details of the Chicago cable railways. —— The secretary presented a note, by Prof. W. S. Chaplin, upon a prevalent error in data given for determining the true meridian, by observing the instant at which Polaris and Alioth come into the same vertical, and then following Polaris for a *certain time*, at the expiration of which it is said to be on the meridian. He gives as the true time the following: latitude 40°, 25 m. 36 s.; latitude 50°, 25 m. 24 s.; latitude 60°, 25 m. 5 s.; latitude 70°, 24 m. 29 s. —— Mr. C. J. Quetil exhibited models of the wire truss recently described by him. —— Professor Mansfield Merriman presented a statement of the progress of the triangulation carried on in Pennsylvania by the U. S. coast and geodetic survey.

Academy of natural sciences, Philadelphia.

Feb. 28. — Dr. Joseph Leidy directed attention to some parasitic worms, which included specimens of supposed leeches from the mouth of the Florida alligator. Herodotus states that the crocodile of the Nile had the inside of his mouth almost beset with leeches. The truth of this assertion has been confirmed by modern zoölogists, the species being the Bdella nilotica. The Florida specimens are, however, not leeches, but pertain to a species of Distoma or fluke, apparently not previously described, for which the name Distoma oricola was proposed. Of several Filariae, or thread-worms exhibited, two, a female and a male, belong to the species Filaria horrida. The former is twenty-eight, and the latter eleven, inches long. They were obtained from the thorax of the American ostrich. Other specimens were found in the abdomen of the marsh-owl. Two species of thread-worm have been previously observed in the bodies of owls, to neither of which the specimens under examination appear to belong. They so closely accord, however, with the descriptions of another species, Filaria labiata, infesting the black stork of Europe and northern Africa, that, notwithstanding the remote relationship in the host, the speaker believed them to belong to that species. —— Dr. N. A. Randolph spoke of the changes which occur in milk during boiling. Although but little difference can be detected by the unaided senses between raw and boiled milk, it was well

known, that, during the process of boiling, certain gases are given off; and the behavior of the fluid afterwards, under certain reagents, is different from that in its original state. If rennet be added to boiled milk at the temperature of the body, no change occurs for some hours; while, if added to raw milk, coagulation takes place rapidly. If diluted acid be added to boiled milk, it produces immediate coagulation; but, if mixed with the raw fluid, coagulation takes place much less rapidly. If alkali be added to the former, cream arises with rapidity and completeness, while no marked change occurs when it is added to the latter. Observations made, of forty-six specimens of gastric contents obtained from six men fed on milk, established the fact that unboiled milk had slightly the advantage as a nutrient, being somewhat more digestible than when boiled. Peptone was found to be present at all stages of digestion. His observations on the effect of rennet confirmed those of Schreiner, published some time ago in Munich. —— A communication was read from Miss S. G. Foulke on the structure and habits of Manayunkia speciosa, the fresh-water worm recently described by Professor Leidy. Miss Foulke has had an opportunity of studying mature specimens, and has consequently been able to make important additions to Dr. Leidy's account of the species, which was based on young specimens.

NOTES AND NEWS.

A GENERAL meeting of the American forestry congress will be held at Washington, D.C., on May 7. Time and place have been chosen contrary to precedent, in order to find an opportunity of calling attention to the society's active work, and impressing upon Congress, then assembled, the needs and requirements of forestry in this country. It is therefore desirable that such meeting should be well attended; and no individual efforts should be spared by the members and friends of this association to make the same particularly interesting and effective. The following subjects have been selected as leading topics of discussion, referees having been appointed to prepare papers in regard to them: Value of American timber-lands; Management of timber-lands and timber in Canada, and legislation thereon; Value and management of government timber-lands; Best method of planting trees on unoccupied government lands; Influence of forests on climate and health; Insects injurious to trees, causes and dangers of their excessive multiplication, and how to meet them in their wholesale ravages; Growing forests from seed by farmers; Preservation of forests on head waters of streams; Planting of trees by railroad companies; Irrigation in connection with tree-planting; Experiment-stations and forest-schools; How can we best promote the interest in, and knowledge of, forestry among all classes of this country?

— The yearly meeting of the Russian geographical society was, as usual, largely taken up by the report of the secretary about the yearly work. Nothing of special interest, not yet known, was included. In the yearly award of the medals which followed, the greatest gift of the society, the Constantine medal, was given to N. A. Sewertzow, the celebrated zoölogist and explorer of central Asia, for his lifelong work. The great gold medals of the sections of ethnography and statistics were not awarded this time. The Lütke medal was given to H. A. Wild for meteorological works. Four gold medals and a considerable number of silver and bronze ones were also awarded.

At the February meeting of the society a communication was received from Bukharow, Russian consul at Hammerfest, Norway, about his extensive travels in the Lapland peninsula in the fall of 1883. The fourth number of the society's *Izviestiya* has been issued. It contains, besides matter mentioned here, Konshin's account of the Kara-Kum sands in central Asia, and Vasenew's travels into western Mongolia.

— At a meeting of railroad engineers in Moscow in December, 1883, the establishment of meteorological stations at the railroad-stations, and of weather-telegrams sent by the railway-wires to Moscow, so as to be able to get information about the state of the weather, and predictions of events of interest to railroads (as snow-storms, heavy rains, and sudden thaws), was proposed. A meeting of the railroad boards, held soon after, agreed to this proposal; and so it is to be hoped Russia may soon have a system of observations by properly paid and controlled men, instead of relying entirely, as now, on unpaid and voluntary observers.

— A call has been issued for a meeting of inventors and persons interested in the perpetuation of the present system of U. S. patent-laws, to be held at Music Hall, Cincinnati, March 25, 26, and 27. The call is signed by gentlemen from twenty states, and delegates are expected from thirty-two states. Arrangements are being perfected for a probable attendance of three thousand.

The first object of this meeting is to effect a permanent organization for the purpose of protecting the rights of inventors and patentees. Over two hundred and fifty thousand patents have been issued by the United States, from which it is clear that very large interests are at stake in any changes of the patent-laws such as are now pending before Congress. Twenty-eight bills have been introduced in the present Congress, which interfere more or less directly with patents or their owners, and diminish in one way or another the protection afforded to inventors. One bill provides that no damages can be recovered for infringements prior to written notice served on the infringed by the patentee, thus rewarding the secret manufacture of patented articles. Another bill is to prevent the recovery of damages in cases where the amount involved is less than twenty dollars; and another bill fixes this amount at fifty dollars.

— On the 11th of February died John Hutton Balfour, for many years professor of botany in the University of Edinburgh, director of the Royal botanic garden, and Queen's botanist for Scotland. He was born in that city on the 15th of September, 1808, and

had therefore attained a good old age. About four years ago, in failing health, he resigned his official positions, but afterwards recovered his vigor, so that he might have been expected to see his university fairly entered upon its fourth century. The end of this excellent man came suddenly, — we believe, in the same week in which his son, Isaac Bayley Balfour, was elected professor of botany at Oxford. The elder Balfour was eminent only as a teacher of botany, in which he had great success, and in the development and administration of the admirable garden and arboretum of the Scottish capital.

— A "general geologic map of the area explored and mapped by Dr. F. V. Hayden, and the surveys under his charge, 1869 to 1880," forms No. 11. of the series accompanying the twelfth and final report of the geological survey of the territories. This map was not mentioned in our notice of the report (*Science*, No. 51), as it was omitted in the earlier distributed volumes; but it is of especial value in presenting a general review, that is nowhere given in the reports, of what has been accomplished by Dr. Hayden's parties. It includes all of Colorado and Wyoming, the greater part of Montana, and half of Dakota and Nebraska. It has unfortunately no topographic shading; and there is no distinction made in the coloring of those parts that have been examined with satisfactory detail, and others where information is derived from reconnoissance, or even from hearsay. Still, the more notable features of the region are well shown, — the broad monotony of the plains, the inconstant variety of the irregular mountain uplifts, the long-continued paleozoic and mesozoic conformity, and the absence or insignificant representation of the Devonian in the Rocky Mountains proper, and the unconformable overlap of the tertiary. Of more local peculiarity, there may be mentioned the isolated uplift of the Black Hills, here well shown in its relation to the ranges farther west; the abrupt change from a north and south to an east and west trend in the Laramie range; the appearance of narrow and parallel Great Basin ranges at the western margin of Wyoming; and the crescentic form of the Big Horn range. Concerning this last and the more northern part of the map, further exploration may require considerable changes.

— Mr. Paul Bert read to the Paris academy, at a recent meeting, the latest results of his researches into the effects of anaesthetics. He believes that the use of chloroform in surgical cases, where the patient suffers from weakness of the heart, may be made comparatively, if not entirely, safe. Mr. Bert is of opinion that the quantity of an anaesthetic is less important to observe than the tension of the vapor inhaled, and the proportion of air with which it is mixed. He has constructed an apparatus with which he administers a proportion of eight grams of chloroform to a hundred litres of air. Experiments which he has made with this have shown, that not only is a saving of chloroform effected, but the danger is considerably lessened. The pulse of the patient inhaling the mixture is calm, and the temperature of the body is not sensibly lowered; while in only four cases out of twenty-two was the slightest appearance of nausea produced.

To this proposition of Bert's, Gosselin objected that the use of a cumbersome piece of apparatus, in place of the convenient sponge or handkerchief, ought to be considered; and that by Bert's method a uniform amount of chloroform must needs be administered to all patients, regardless of their susceptibility to its effects.

Bert rejoined, that with the sponge there was great danger of exceeding the safe tension of the vapor. His experiments with dogs showed, that, with six grams of chloroform to a hundred litres of air, a dog could be rendered insensible; with ten grams, the insensibility comes on in a few minutes, and can be allowed to continue for an hour and a half with safety; while, with twenty-four grams, the dog was dead in forty-five minutes.

— The petroleum industry of Baku still continues, to attract attention. Messrs. Hobel, whose work there has been of such importance to the development of the trade, have published a pamphlet on the capabilities of the province, and the commerce of the Black Sea; while a book is announced in the literary journals, dealing with the working of petroleum since classical times. The title is 'Petrolia;' and it is by Mr. Charles Marvin, of Khiva fame.

— The *Centralblatt für textil industrie* recently published an article on the increase in manufacturing industry in Livonia, Esthonia, Courland, and the Polish provinces of Russia. The first three provinces contain 1,329 factories, the annual production of which now represents a total value of more than £12,000,000, this sum being nearly double the amount for 1873. In Courland the main industry is the distillation of spirits, which in 1882 attained a value of nearly £1,000,000. The development of Polish industry took place, for the most part, during the years 1877–80. In the year 1881 Poland contained 19,000 factories, which produced wares of the total value of about £30,000,000. The greatest progress has been in the textile industries. One factor in the industrial activity of Poland has been the steady demand for yarn from factories in the interior of Russia. The cotton industry is the most important: in 1881 it employed about 20,000 work-people, its out-turn representing a value of £5,000,000. Next comes the woollen industry, with 15,000 work-people, and a yearly production of £3,500,000 in value. In the linen branch 10,000 work-people are engaged, and the production represents about £1,000,000 per annum. The raw material is, for the most part, obtained from the interior of Russia, only a small quantity being imported. Moscow, Charkoff, and St. Petersburg are the principal markets.

— The *Engineer* states that the world's average product of sulphur is about 280,000 tons, of an average value of 109.20 lire per ton = 30,793,000 lire, or over £1,200,000 sterling. Of this total, Sicily produces 242,000 tons. There is an export duty of 11 lire per ton on sulphur, and the average export is 216,000 tons. The Sicilian sulphur is mostly exported raw,

as it comes from the kilns. It is of seven qualities, the values varying from 101 to 115 lire per ton. Except in the better-worked 'solfare,' the separation of the sulphur from the earths in which it is contained is still conducted in Sicily by means of kilns (calcuroni), which do not require any additional fuel, but which entail the consumption and loss of about one-third of the sulphur itself. About 18,000 hands are employed in the Sicilian 'solfare,' of whom about 14,000 work in the interior of the mines, including those employed in the transport of the ore to the surface. The sulphur in many mines is still carried to the surface on the backs of boys called 'carusi,' of whom there are about 3,500.

— Prof. F. H. Snow writes to the *Topeka daily capital* as follows: —

The climate of eastern Kansas is not the climate of western Kansas. Any discussion of this subject will be entirely inadequate which fails to recognize the fact that Kansas is meteorologically divided into two distinct regions, separated from each other by an intermediate area, whose climate exhibits a gradual transition between the eastern and the western sections. The inclusion of two such widely differing regions in one civil commonwealth has its disadvantages as well as its advantages. The striking adaptability of western Kansas to sustain the immense cattle interests of that section adds an important element of prosperity to the state; but the fact that thousands of new-comers, from ignorance of the climate, have attempted to introduce ordinary agricultural operations upon the so-called 'plains,' and have disastrously failed in the attempt, has placed an undeserved stigma upon the good name of Kansas in many far distant communities, and has undoubtedly somewhat retarded immigration during the past few years. It is time for the general recognition of the fact, that, except in the exceedingly limited area where irrigation is possible, the western third of Kansas is beyond the limit of successful agriculture. Yet this portion of Kansas, upon the basis of one individual to each ten acres, has the capacity to continuously sustain an aggregate of nearly two million head of cattle. The last biennal report of the State board of agriculture represents the total number of cattle in the entire state as less than one and a half millions, which is considerably below the number which might be supported by the western third of the state alone.

The average direction of the winds in eastern Kansas is from the south-west. The average velocity of the wind at Lawrence is a little more than fifteen and a half miles an hour. This is sufficiently high to assist materially the proper ventilation of our houses and our clothing, but does not justify the common expression in other parts of the country, that the Kansan lives in a continual gale. For the sake of comparison, it may be mentioned that the average hourly velocity of the wind in Philadelphia is eleven, at Toronto nine miles, and at Liverpool thirteen miles. The greatest velocity recorded at Lawrence was at the rate of eighty miles per hour, from 3.35 to 3.45 A.M., April 18, 1880. The average annual distance travelled by the wind at Lawrence is a little more than a hundred and thirty-eight thousand miles. March and April are the two windiest months, the velocity rising to nearly twenty miles an hour. July and August are the two calmest months, the rate subsiding to less than twelve miles an hour.

— The *Canadian naturalist*, which was discontinued last June, has re-appeared as the *Canadian record of natural history and geology*, published by the natural history society of Montreal. The former journal was published for the society by Messrs. Dawson Brothers. We regret the unnecessary change of title, when the scope of the journal is precisely the same as before, and it remains the organ of the same society.

— The belief of the Hawaiians, that the Achatinellae emit musical sounds, is an old one; and these pretty little mollusks were sometimes called 'singing-snails.' The Rev. H. G. Barnacle, M.A., of the Transit of Venus expedition in 1874, heard the music, which he compares to the sound of many aeolian harps. Hitherto the native story has not found credence among conchologists; but this gentleman succeeded in determining that the sound was due to the friction of the shells upon the bark of the trees, over which they are dragged by their inhabitants. As most of the species are arboreal, and they exist in millions, it is conceivable that the sound should be distinctly audible; yet that it should be in any way musical is singular.

— Miss Fannie M. Hele has recently observed the effect of food on a lemon-colored variety of Helix aspersa. A diet of lettuce reduced them to a dirty-brown yellow; and the more lettuce given to them, the darker and dingier the color of the shell became. A reversed specimen was bred from, in the hope of securing additional specimens of this rare variety; but to no purpose: the eggs, when hatched, produced only normal individuals.

— During the past year, four new additions were made to the group of small planets between Mars and Jupiter, making the number two hundred and thirty-five in all. No. 232, named Russia, was discovered the 31st of January, 1883, by Palisa, at Vienna: its magnitude is the twelfth, and the elements of its orbit exhibit no peculiarities. No. 233, not yet named, was discovered by Borelly, at Marseilles: its magnitude is the eleventh, and the elements of its orbit are as yet undetermined. No. 234, named Barbara, was discovered the 12th of August, 1883, by Peters, at Clinton: its magnitude is the ninth, and the elements of its orbit exhibit no peculiarities. No. 235, named Carolina, was discovered the 21st of November, 1883, by Palisa, at Vienna: its magnitude is the twelfth, and the elements of its orbit are as yet undetermined. The twelve small planets immediately preceding the above have received names as follows: —

220, Stephania.	224, Oceana.	228, Agathe.
221, Eos.	225, Henrietta.	229, Adelinda.
222, Lucia.	226, Weringia.	230, Athamantis.
223, Rosa.	227, Philosophia.	231, Vindobona.

SCIENCE.

FRIDAY, MARCH 28, 1884.

COMMENT AND CRITICISM.

The University of Edinburgh is making arrangements to celebrate, on the seventeenth day of April next, the three hundredth anniversary of its foundation, by an academic assembly, to which the chief institutions of learning throughout the world are invited. Several American colleges are to be represented. With reference to this tercentenary, Sir Alexander Grant, the principal, has just published two stout octavo volumes, in which 'The story of the University of Edinburgh' is elaborately told. The volumes are rich in illustrations of all the concurrent influences which have given renown to the youngest and strongest of the Scotch institutions. The rise of each important department of instruction is told, and the lives of all the more distinguished professors are briefly given.

Among the natural sciences, medicine has been the one most encouraged in Edinburgh, although it must be remembered that much of the medical reputation of the city is due to the peculiar arrangements by which medical men not connected with the university give instruction, and prepare young men for medical graduation. 'Extra-mural' instruction is the term employed. Nevertheless, the roll of university professors includes the name of Charles Bell, of whom the story is told, that, when he visited the class-room of Roux in Paris, Roux dismissed the class, saying, 'Sufficient, gentlemen: you have seen Charles Bell.' Another university professor was Sir James Y. Simpson, whose bold introduction of chloroform as an anaesthetic is world-renowned. When a Scotchman was presented at the court of Denmark, the king said, 'You come from Edinburgh? Ah! Sir Simpson was of Edinburgh.' Simpson himself said he was more interested in having delivered a woman without pain than in having been made physician to the queen. At an earlier date the fame of William Cullen was wide-spread. Among the teachers of non-medical sciences, the names of Black, John Playfair, Robert Jameson, David Brewster, Edward Forbes, James D. Forbes, and Wyville Thomson are those which come first to mind; while in mental and moral science the Scotch philosophers, Dugald Stewart, Thomas Brown, and Sir William Hamilton, are not likely to be forgotten. It sounds strange enough in these days to read that Thomas Carlyle thought himself ill-used because he could not get the appointment of practical astronomy and astronomer royal in 1834. Instead came Thomas Henderson, who won renown as 'the first discoverer of our distance from a fixed star.' We do not name any of the living professors, and we pass without mention many famous men who are gone; but what we have said suggests the doctrine, which cannot too often be repeated in this country, that the standing of a university depends upon illustrious teachers. The world of scholars, no longer united under the sovereignty of the pope, but loyal to the higher sovereignty of truth, will with one accord extend its congratulations to the great modern foundation of Scotch learning, and will rejoice that in its three-hundredth year it has reached its greatest numerical expansion, with increasing devotion to all that is noble in science and education.

The reports of the U. S. signal-office show that there were at Cincinnati, during last February, four clear days, three fair days, one cloudy, and *twenty-one* on which rain or snow fell; and that the total precipitation was 8.87 inches. The following figures give the precipitation in inches during February of each year since 1870: 1871, 2.27; 1872, 1.67; 1873, 3.76; 1874, 5.91; 1875, 1.83; 1876, 2.92;

1877, .67; 1878, 2.33; 1879, 2.22; 1880, 4.50; 1881, 4.95; 1882, 7.04; 1883, 8.22; 1884, 8.87. We hazard nothing in asserting, that it does not lie within human ability to arrest such mighty storms as occurred in 1883 and 1884: and it may fairly be questioned whether the ingenuity of man can devise means to prevent the wide-spread and destructive floods which must follow such a volume of water as then fell; whether any extension of forests, or system of catch-basins or reservoirs, could possibly retain or mitigate to any considerable extent such general and overwhelming floods. A system of artificial lakes might indeed be at such times a serious element of danger; for, if one of them should break its restraining banks, its accumulated waters would be likely to carry away others, and then the waters, suddenly let loose, would do damage of which we have had a few frightful examples on a small scale.

THE demands of progressive agriculture for a more substantial scientific basis are just now beginning to find definite expression in the Dominion of Canada. From the known attitude of certain members of the government, from the recent examination of experts before a special House committee at Ottawa, and from the general expressions of those who have a direct interest in the question, it is apparent that a keen sense of the utility of experiment-stations is now developing a movement, which, it is to be hoped, will secure for the Dominion one or more much-needed stations, founded upon the European idea of their utility from a scientific stand-point, and from that of the practical application of acquired results.

THIS season promises to be one of unusual activity in the observation and study of tornadoes. In response to an invitation from the signal-service, a considerable number of tornado reporters is secured; and the first fruit of their labors has just appeared with most praiseworthy promptness in the form of a set of four preliminary charts illustrating the recent numerous and destructive tornadoes in the southern states on Feb. 19. Further investigation is needed before a final account of these terrible storms is prepared; but it is shown by these charts, that over fifty tracks of tornado-action have been reported for Feb. 19, between seven in the morning and midnight, all occurring within a cyclonic area, and from three to seven hundred miles south-south-east of the centre of low pressure. As the broad cyclone moved forward, its centre passing from Illinois to Lake Huron, the tornado district on its southern edge had a similar advance across the southern states. The cyclone was peculiar in showing a long, trough-like barometric depression, and in presenting notably strong contrasts of temperature between its south-eastern and north-western sides. The tornadoes were all developed within the district occupied by warm southerly winds, somewhat in advance of the cold north-westerly winds; but they moved, without exception, in a north-easterly direction. Their destructive action was most severe in eastern Alabama, northern Georgia, and centrally across the Carolinas. Rough estimates place the value of property destroyed at between three and four million dollars; the loss of life, at about one thousand; the wounded, at more than double that number; while the homeless and destitute people are reported to count from fifteen to twenty thousand, many of whom are in a starving condition. About ten thousand buildings are said to be destroyed, and domestic animals were killed in great numbers. It hardly need be urged, that the possibility of giving some warning of immediate danger before such storms warrants the fullest and most careful investigation of all their attendant conditions.

In preparation for this work, the 'tornado circulars,' issued by the signal-service to promote the accumulation of record and statistics of these destructive storms, have now reached the number of twenty. The most considerable of the later ones is No. 16, which contains, in all, two hundred and three questions or directions designed to aid in the precise description of tornadoes and the conditions of their formation: these are arranged under several head-

ings, addressed to observers on the immediate track, or more than ten miles from it; and, if carefully read, they will serve as good training for those who desire to take part in the investigation of these most disastrous upsettings of the atmosphere. Circular 18 relates to observations to be made 'concerning the presence of electricity in tornadoes,' and asks thirty-two questions to this end. It is to be hoped that all persons living in the tornado districts of the country, and desiring to take part in the work as volunteer observers, will apply to the chief signal-officer for circulars of instructions.

It is worth mentioning, that the single waterspout recorded in the supplement to the pilot-chart of the North Atlantic for March occurred on Feb. 19, eighty miles east of Charleston, where it struck the schooner Three sisters, "carrying away main gaff, mainsail and foresail, and flattening in the after-hatches." This is evidently connected with the group of tornadoes above described.

LETTERS TO THE EDITOR.

*** *Correspondents are requested to be as brief as possible.*

Law connecting physical constants.

IT may be of interest to some of your readers to know how the two formulae published in the advertising columns of Science, No. 54, can be derived from the magnetic theory of molecular cohesion.

The work necessary to separate completely the particles of a body occupying the unit of volume can easily be calculated if we know the original attraction between every two particles, and its rate of change during expansion. For small magnetized spheres, this work is equal to the resultant attraction across the unit of surface. The latter, moreover, is necessarily equal to the pressure which the particles keep up by their incessant motion; which, again, is shown, by a well-known dynamical theorem, to be equal to the continued product of the coefficients of expansion and of resilience and the absolute temperature. This product is therefore finally the mechanical equivalent of the internal latent heat of the unit of volume of a liquid.

The theory does not apply to such liquids as water, in which, at low temperatures, a molecular re-arrangement is evidently going on; but in general, the higher the temperature, the more closely is the law fulfilled. The grouping of the atoms, and their vibration within the molecule, recently treated by Professor Eddy of Cincinnati, produce in the most unfavorable cases a variation of about thirty per cent from the theory: nevertheless, the general agreement is too great to attribute to chance, and becomes almost perfect when the causes alluded to are considered. The average value of the latent heat for ordinary liquids may be shown to be about 1.2 times greater than for simple substances.

The molecules of all liquids appear to be very close together, notwithstanding the common prejudice that they are far apart; and, taking into account the comparative shortness of their free path, the coefficients alluded to may be obtained approximately by processes of ordinary differentiation, while their rate of change as the temperature increases can be determined as accurately as by actual observation.

The latent heat is found to vary inversely, the coefficient of expansion almost directly, as the free path of the molecule; and their continued product with the molecular weight is therefore nearly, but not quite, constant. The average value is about eight and a half; and any slight variations from this average are accounted for by the complete formula.

With these hints, and remembering that the inductive attraction between two small magnets varies as the seventh power of the distance inversely, while their normal attraction is inversely as the fourth, any mathematician familiar with the principles of physics may verify the laws already enunciated, and deduce others of equal importance in the same way.

The difference, for instance, between the specific heats in the state of liquid and vapor, is evidently the derivative of any true expression for the latent heat; and the critical temperature is found by supposing the latent heat equal to zero. The relations between all these quantities are represented with a remarkable degree of approximation.

The magnetic theory of cohesion promises to be, in molecular physics, what the law of universal gravitation has proved to be in astronomy. While carrying on the development as rapidly as possible myself, I would urge others, independently, to do the same, in the belief that this theory affords a most magnificent field, both for work and for discovery.

HAROLD WHITING.

Cambridge, March 17.

Relics in Ventura county, Cal.

Rincon Creek, fourteen miles west of San Buenaventura, is the dividing-line between Ventura and Santa Barbara counties. Where this creek flows into the ocean, at least a hundred acres are covered with shells, bones, fish-scales, and other kitchen *débris* of the Indians, who have lived here from time immemorial. The creek, which is fed by mountain springs, afforded good water; the ocean yielded fish and mollusks; while the foot-hills and mountains furnished wild game. A large variety of mollusks are still found at this point, and the shell-heaps indicate their great abundance in past time. Edible clams especially abounded; as Pachydesma crassatelloides, Tapes staminea, T. diversa, also Mytilus californianus.

Rincon Point was doubtless long a favorite resort for the early race that inhabited this coast. In one spot I found human bones, a few years since, which were in a semi-fossil state. They had been buried on the brow of a high bluff overlooking the sea, and were about four feet below the surface. One skull, that of an aged person, was perforated at the apex. The perforation seems to have been made by a sharp instrument, and some time before death, but for what purpose it is difficult to say. In another spot on the mesa, and three hundred yards from the ocean, occurred a burial-place in which the skeletons were reduced to an impalpable dust. In this dry soil and climate it must have required centuries for them to decay. In this place I found many 'sinkers' from three to twelve inches long, carved from sandstone, limestone, etc. They were from three-fourths of an

inch to an inch and a half in diameter in the middle, gradually sloping toward each end. There were also tubes of serpentine six or eight inches long, large chert knives, spear-points, and other things, all buried about four feet deep. Between this spot and the ocean was another burial-place, where, on the side of a declivity, many skeletons were found but eighteen inches to two feet below the surface, mingled with broken sandstone mortars and pestles, spear-points, arrow-heads, etc.

On the east side of the creek, between a high precipitous bluff and the ocean, is a three-cornered tract containing about ten acres, which is the site of an old rancheria or village. In the midst of this old town site I found a burial-place that indicated a somewhat more recent race than the first two mentioned. Here I exhumed a hundred or more skeletons, and at least a ton of relics: consisting of mortars and pestles of sandstone, ollas and tortilla stones of crystallized talc, pipes and bowls of serpentine, spear-points and arrow-heads of chert; also beads and 'charms,' and innumerable shell ornaments.

Last month I again visited this place, and exhumed a few more relics. In a spot about four by eight feet, and in the shape of a parallelogram, I found fifteen skeletons. With one of these were three tubes about three inches in length. In shape they were similar to the 'sinkers' already described, but with raised beads in the middle and at each end. These and some round beads were manufactured from serpentine. Beside the specimens mentioned, were many small shell disks made from Olivella biplicata. An arrow-head was found with another skeleton. About three feet from the excavation described, I found three more skeletons, one of which was that of a child; and with it occurred two stone tubes similar to those above mentioned, also three round beads about one inch in diameter. The beads and tubes were of serpentine, containing seams of chrysolite, and were finely polished. With another skeleton, were five arrow-heads finely chipped from chert. One was a beautiful specimen with serrated edges, and a portion of the asphaltum with which it was fastened into the arrow still remained. With another, occurred several ornaments manufactured from Lucapina crenulata, and also an arrow-head. In a spot occupying less than fifteen feet in diameter I exhumed forty skeletons, piled one upon another. They were buried face downward, and could be counted only by the skulls.

STEPHEN BOWERS.

San Buenaventura, Cal.

The spirifers of the upper Devonian.

In the prefatory letter of the Report of progress, G. 7, of the Second geological survey of Pennsylvania, certain statements are made respecting the association and order of some of the fossil species of the Devonian rocks of New York, calling for comment.

It is stated on p. xx., in regard to Spirifera disjuncta, S. mesocostalis, and S. mesostrialis, that, "outside of Pennsylvania, these three species have been found, (1) never in any but Chemung rocks; (2) confined each to its own horizon; and (3) always in a fixed order from above downwards;" and, on p. xxi., that "Professor Hall has never seen any two of the three species co-existing in the same stratum; . . . that he cannot comprehend how S. dj. and S. ms. should be found together" (as they are reported to occur on p. 65 of the report).

Again (p. xxii.) it is stated that "Orthis tulliensis, in bed 41, § 13, p. 70, has certainly never before been seen in the Chemung 200′ above the Genesee (i.e., 300′ above the Tully limestone), nor in company of S. mesocostalis."

The report of species in such 'uncanonical' positions in the strata is made a reason for concluding (p. xxvi.) that "the startling fossil species of this report will therefore be regarded by the palaeontological reader as only *provisionally verified.*"

While the statements cited may express the general rule as to the occurrence of species in New-York state, there are specimens in Cornell university museum which do not bear out the statements.

In the first place, the two species S. mesostrialis and S. mesocostalis are found associated in the same stratum at Ithaca, N.Y., both in the mesostrialis zone and in the mesocostalis zone. Several instances can be shown where they occur on the same slab.

From a higher horizon in New-York state, and from several localities, either of these species may be found associated with S. disjuncta; and I have obtained each of the three species from the original Chemung locality at Chemung Narrows.

In the museum collection, is a small slab from that locality, containing beautiful representatives of S. disjuncta and S. mesostrialis; the latter preserving 'the fine radiate striae, with delicate concentric cross-lines' all over the surface of the shell, and with 'the broad median fold without a depression,' which are described as distinctive characters of the species (Pal. N.Y., vol. 4, p. 243).

The other specimen, only a couple of inches distant, has the characteristic plications on the median fold, and, with a surface equally well preserved, shows not the least trace of radiate or concentric striae, unmistakably indicating S. disjuncta.

From the same locality, though not on this individual slab, are specimens of both varieties of the so-called S. mesocostalis, — the large, coarse form with angular plications and reduplicated fold, and the more finely plicated form with prolonged hinge-line, which is more characteristic of a lower horizon.

These higher representatives of S. mesocostalis are, however, generally distinguished from the earlier representatives by a well-developed median septum in the ventral valve, — a character of which only a trace is seen in specimens from the Ithaca beds, reminding us of the genus Spiriferina. The punctate shell-structure of that genus has not, however, been detected in any specimens thus far examined.

In regard to Orthis tulliensis, it may be said that the common Orthis, occurring at the base of the Ithaca fauna, within a few hundred feet of the Genesee shale (less than 500), at its first appearance resembles O. tulliensis in form and general characters; though for distinction it may be appropriate to call it a variety of O. impressa, since a little higher, and in the same fauna, the typical O. impressa appears in abundance.

Still, there are specimens in the collection from the lowest zone which it would be difficult for any one to distinguish, by macroscopic or microscopic characters, from O. tulliensis, occurring, as they do, in a calcareous stratum.

I have no single slab containing this form with S. mesocostalis, but the latter is found both above and below the stratum containing the Orthis.

The record of an O. tulliensis at 200 feet above the Genesee shale in Pennsylvania seems, therefore, indicative of a careful identification of the species upon morphologic characters alone, without prejudice as to its supposed horizon or range.

In regard to the identification of these upper Devonian faunas of Columbia county, Penn., it may be said, that in the association of species, and the

relative order of the sub-faunas, the record agrees, in general, with that of the series exposed along the same meridian, farther north, in New-York state. The principal difference which strikes one familiar with the New-York section is the appearance of S. disjuncta and O. Tioga lower down in the faunas in the southern sections.

But although heretofore S. disjuncta has been met with in America only in the middle and upper parts of the upper Devonian, in Devonshire we find it reported from the middle Devonian, with corals and trilobites in abundance; and in northern Europe it begins at least as early as the base of the upper Devonian.

While it is beyond doubt that even in New-York state the three spirifers mentioned appear mingled at various zones in the upper Devonian, we do not question the fact that the periods of abundance for each species are in separate zones, and assume a regular sequence relative to each other.

HENRY S. WILLIAMS.

Cornell university.

The use of the method of limits in mathematical teaching.

Rice and Johnson's 'Method of rates' is especially to be commended for the scholarly manner in which they developed the subject; but there is the same difficulty in the fundamental conception as in the infinitesimal method. One may assume to understand an expression with which he is familiar until closely questioned. A student learns to repeat with ease, 'Velocity is rate of motion,' and thinks he understands it; but I have had many such ask, 'In a mathematically perfect engine, does the piston stop at the end of the stroke?' 'Does it remain at rest at any time?' 'How can it reverse its motion, if it does not stop?' 'How can it cease going in one direction, and move in the opposite direction, without stopping between the two motions?' These are critical questions, lying at the very foundation of all change of motion. Does change in the rate of motion take place *at* an instant, or *during* an instant?

The method of limits leads the mind towards a result the conclusions of which it is impossible to escape: hence, as a system of philosophy, it retains its strong hold. DE VOLSON WOOD.

Hoboken, March 16.

Ropes of ice.

On Saturday, March 8, while traversing several counties of southern Ohio by railroad, I observed an illustration of the viscosity of ice, that seems deserving of mention.

For a number of hours, rain had been falling, much of it freezing as it fell; but through the day the temperature rose slightly, remaining, however, close to the freezing-point. All exposed objects were coated with ice. In particular, telegraph-wires and the strands of wire fences were heavily loaded. In the afternoon the ice broke loose from the wires at innumerable points, hanging from them in depending curves, the fixed points of which were sometimes as much as six or eight feet apart, and the lowest points of the curves from two to twelve inches below the wires. Occasionally the curves would break, and the ends of the ice rope, two or three feet in length, would project downwards from the wires at an angle of forty-five degrees or more.

The best examples were passed without opportunity to make examination, but all of the facts were illustrated at the stations where the train stopped.

E. O.

Illusive memory.

I merely intended, in my letter of March 7, to present two of the most prevalent theories which have been advanced for these illusions. The 'race memory' theory, kindly brought out by W. B. T., should perhaps have been mentioned, as well as the theory of Lewes and Ribot, that these deceptions arise from the retrojection or false location of a *present* mental image as a recollection. The inheritance of the actual *cerebral impressions* of a former generation rests upon no scientific basis. We do inherit the brain structure, and, in so far as brain functions are dependent upon structure, we may be said to inherit certain functional disposition and powers; but this structure, and the impressions made upon it by sense-perception, are essentially different facts.

The correspondence invited should be addressed to Princeton, *N.J.*, instead of Princeton, N.Y., as as wrongly given in *Science*, No. 57.

HENRY F. OSBORN.

Princeton, N.J., March 21.

Ripple-marks.

Professor Wooster's note in No. 57, on ripple-marked limestones in Kansas, recalls an observation of my own in Utah. In the south part of that territory the Jurassic formation includes a sectile limestone fifteen to twenty-five feet in thickness, containing remains of Camptonectes and Pentacrinus. Some of the surfaces of the layers exhibit coarse ripple-marks, the wave-lengths ranging from six inches to one foot. The associated fossils cannot be regarded in this case as indicative of quiet conditions, for in neighboring districts the same forms are found in argillaceous sandstones. In the sandstones the shells and crinoid segments exhibit wear from rolling, but in the limestone their angles are unimpaired. While, however, there is no evidence in the limestone of violence, there is evidence of motion. The crinoids have not been found entire, and all their segments are usually detached. Moreover, the structure of some of the limestone layers is oölitic.

I conceive that the association of ripple-marks with shallow water, while usual, is not invariable. The most important condition for the formation of ripple-marks is motion; and any thing competent to produce motion at the bottom of deep water may form them. Wind-waves on the Atlantic are said to have brought sand to the surface from a depth of five hundred feet, and they must be supposed to produce at a still greater depth the gentler agitation necessary for the formation of ripple-marks.

The association of the Kansas ripple-marks with fine argillaceous rocks is perhaps unprecedented, but there seems no theoretic reason to regard it with wonder. Fine sediment does not usually come to rest in spots where the water is subject to agitation, but exceptionally it does; and the centre of every shallow pond with a muddy bottom affords an illustration. Some years ago I observed ripple-marks on a surface of fine river-silt at the bottom of a pool which had communication with a rushing river. The pulsation of the torrent communicated agitation to the pool, but no current; and I inferred that the pulsatory agitation caused the rippling. The pool shared to some extent the muddiness of the river, and the silt on its bottom was evidently a forming deposit. Not far away the bank of the same river exhibited in section

a deposit which seemed identical with that forming in the pool, the ripple-marks being represented by undulations of the laminae. A remarkable feature of the section was the coincidence of the ripples through a vertical space of about eighteen inches. All the laminae were inflected in the same way, so that the corresponding parts of the undulations fell in the same verticals, as illustrated in fig. 1.

It occurred to me, that there might be in this feature something analogous to the assumption of stable

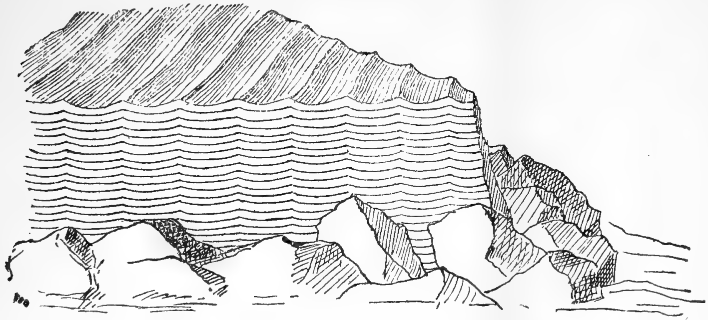

FIG. 1.

figures by free particles on the surface of a vibrating plate, and that the development of this idea might lead to a better theory of the origin of ripple-marks. The common theory, which makes the ripple-mark the homologue of the sand-dune, implies a forward movement of the ripple in the direction of the water-current, and is manifestly inapplicable to the phenomenon just described. I am disposed to doubt its applicability even to ripple-marks produced by currents; for there is a certain class of these, intimately related to small obstructions, which are certainly as stationary and constant as the water-waves on the rapid of a stream.

The analogy of ripple-marks to vibrations in elastic bodies is further illustrated by variations in the forms of the ripples, and by the combination of sets of ripples. The other figures show in profile four forms of ripple observed on upper surfaces of triassic sandstone in south-western Utah. They were carefully drawn from hand specimens. Figs. 2 and 3 are the prevalent forms. In fig. 3 the crest is acute, and the broadly curved trough is midway between the crests. In fig. 2 the crest and trough are moderately acute, and the trough is nearer to one crest than to the other. In fig. 4 the crest is broadly curved, and the trough is less so. In fig. 5 each ripple has a subsidiary crest upon one slope. The resemblance of this last to certain phonographic curves suggests itself at once. In other specimens two systems of ripples co-exist, intersecting at various angles; and the fact that this relation was observed repeatedly, leads me to think that the two sets were synchronously formed. If synchronously formed, there is something in their production analogous to the co-existence of independent and diverse vibrations in elastic bodies.

I do not venture to assert that the correspondences here pointed out are more than superficial analogies, but they suggest a line of investigation which should be fruitful. Such investigation I had intended to undertake, and the accompanying figures were engraved in pursuance of this intention; but, having found myself for some years unable to pursue the subject, I despair of commanding the necessary time and facilities, and avail myself of this opportunity to communicate my observations to the scientific public, in the hope that they may assist in the elucidation of the subject by another. The 'Batrachichthys.'

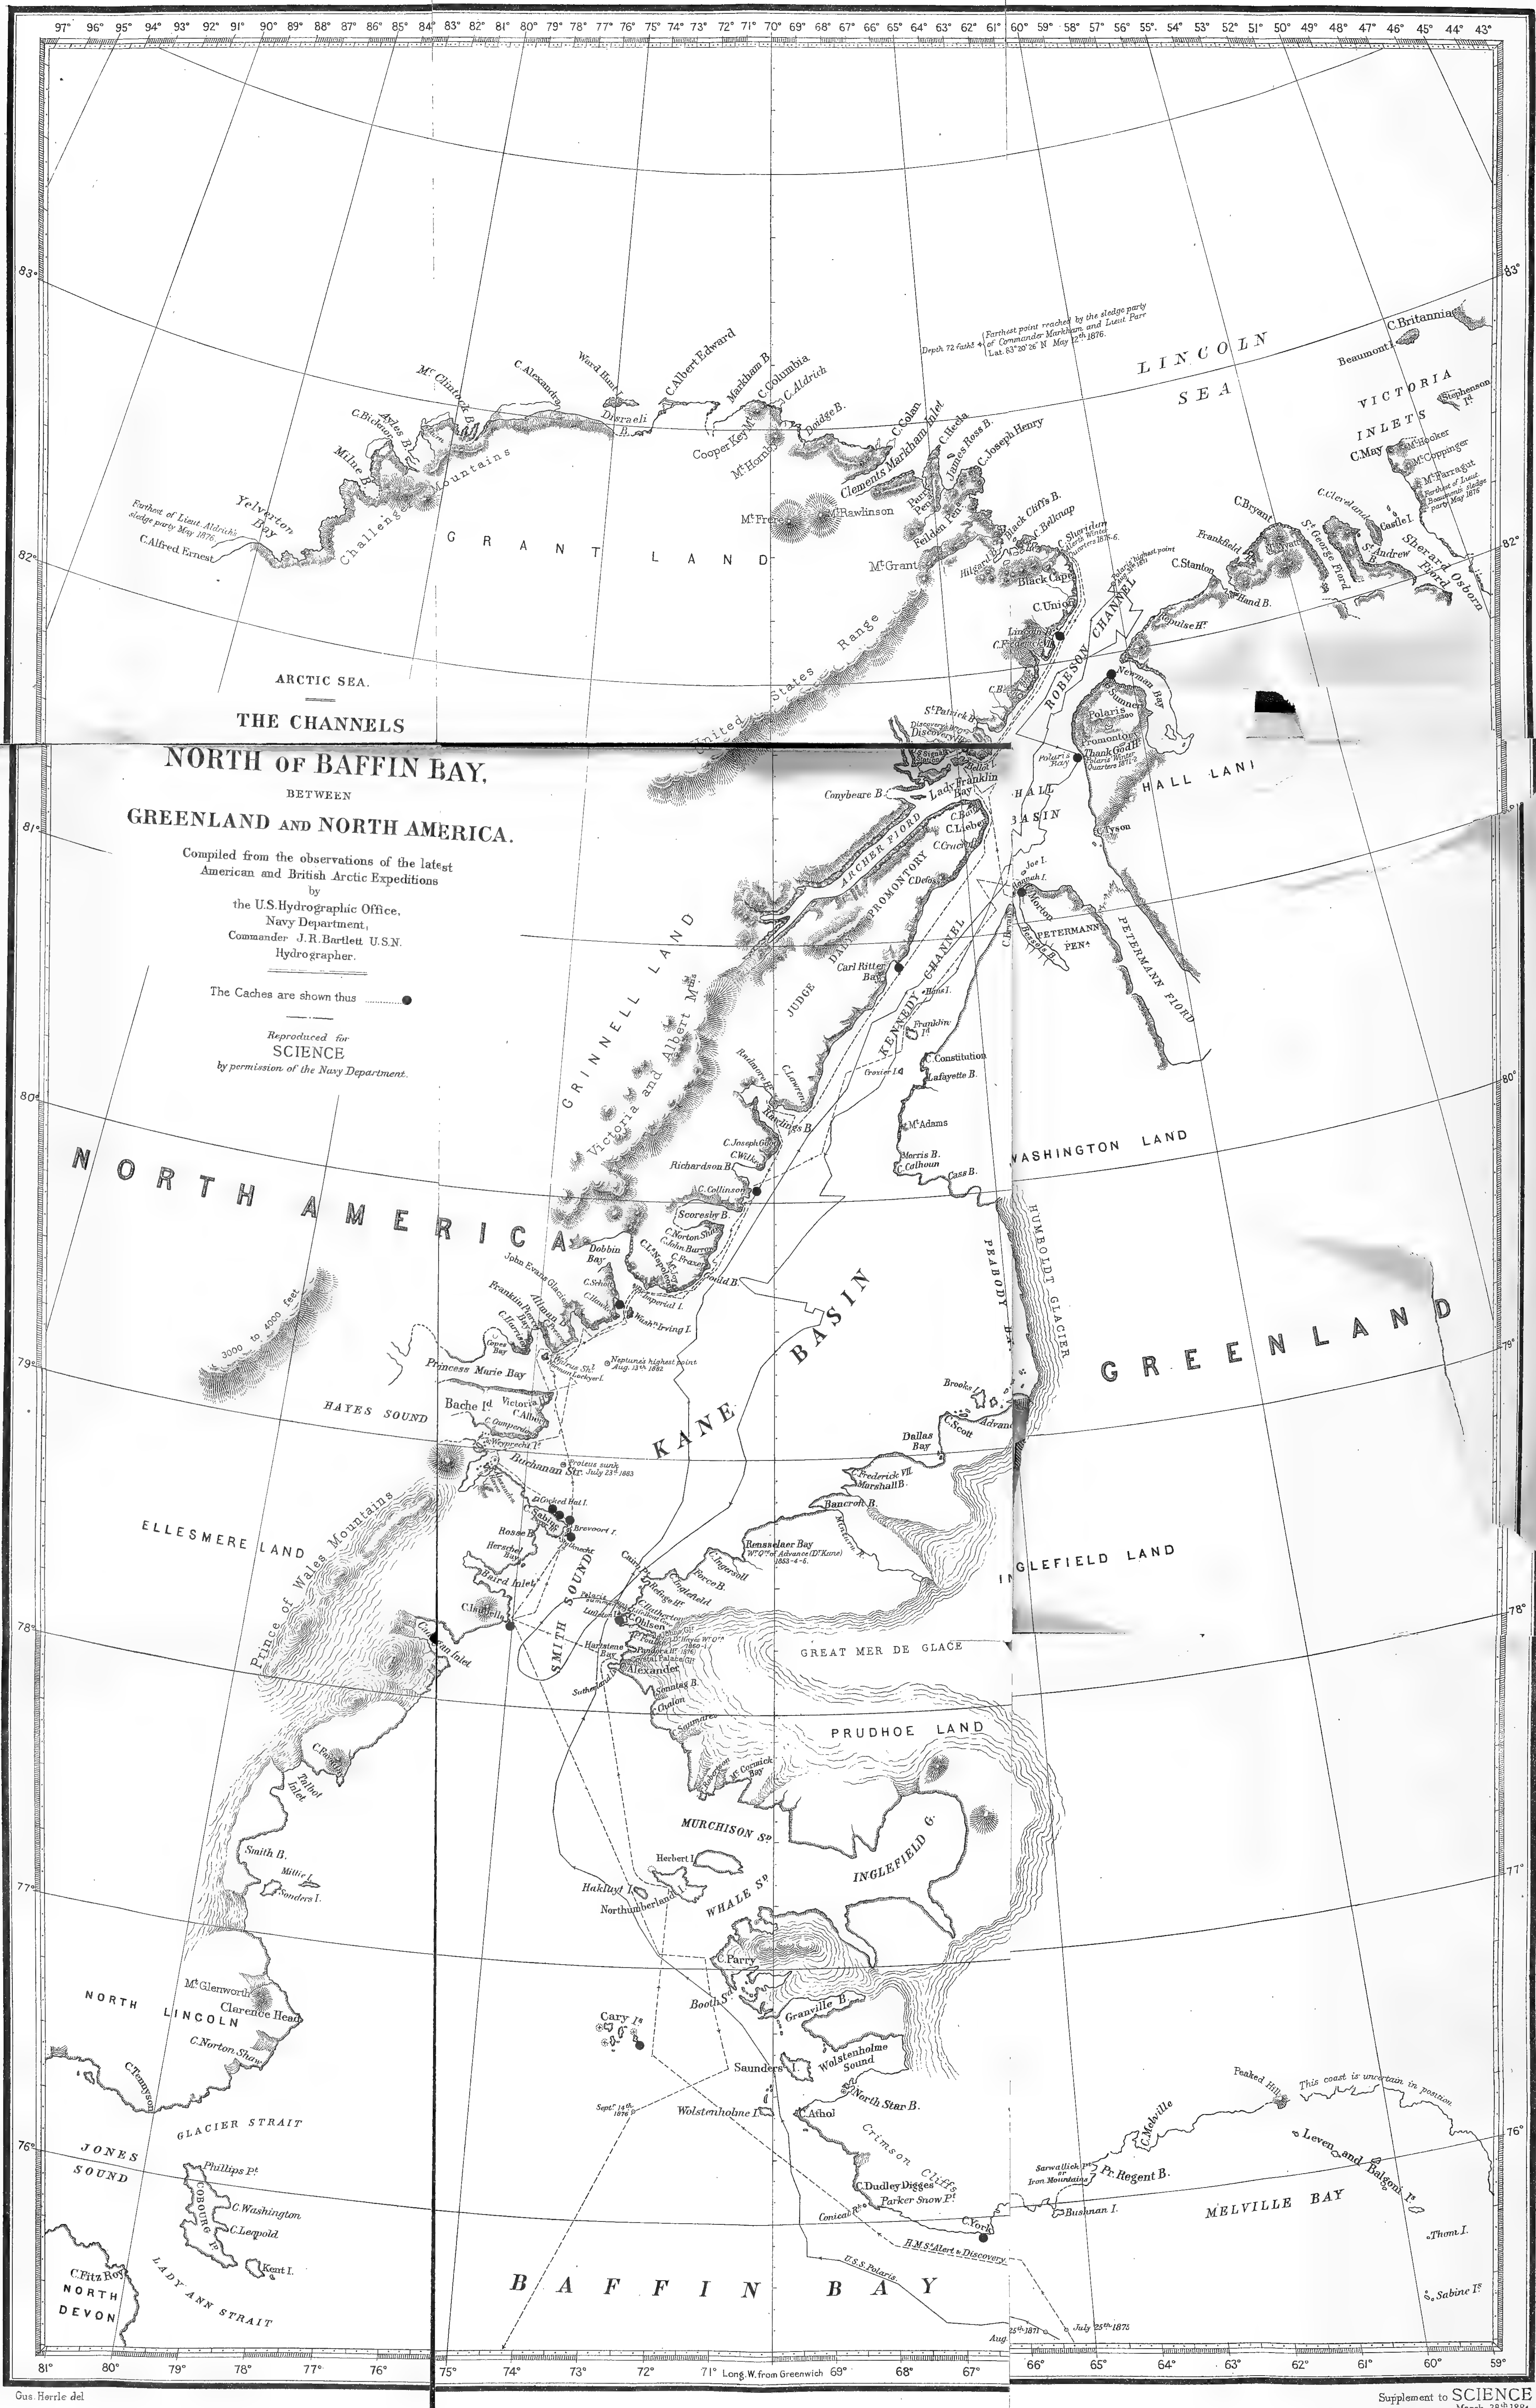
The publication of the *Archivos do museu nacional* of Brazil began in Rio de Janeiro in 1876. In the second issue, that for the second and third trimesters of 1876, the director of the section of zoölogy and comparative anatomy in the museum published a description of what he denominated 'an extremely curious little animal called Batrachichthys' The author evidently believed he had found a 'missing link,' and, as it were, he laid his prize at the feet of Darwin, Haeckel, and Martius with the greatest solemnity.



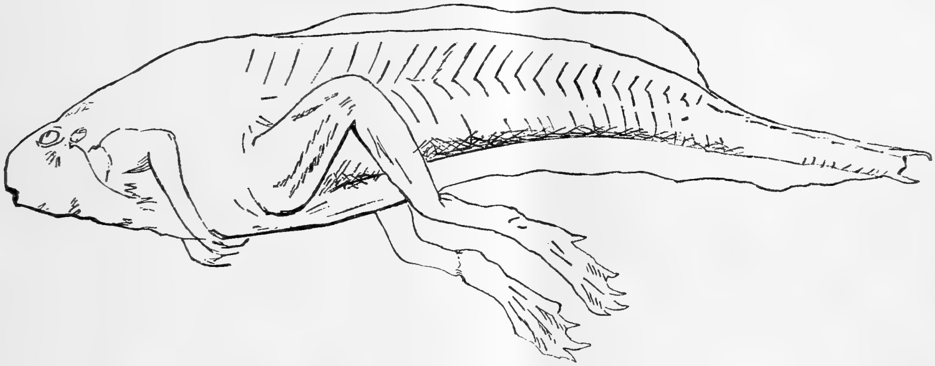
Gus. Horrle del

Supplement to SCIENCE
March 28th 1884.

Although the name of Prof. C. F. Hartt appears as that of one of the editors of the archivos at the time (he resigned shortly after the publication of this article), it is due his memory to say that he objected to the publication of the article referred to, and did all in his power to prevent it, well aware that it would bring ridicule upon the editors and upon the national Brazilian museum, of which he was a director. Notwithstanding Professor Hartt's protestations, the description appeared, accompanied by a plate, from which the accompanying figure is copied.

Mr. S. W. Garman afterwards called attention to the absurdity of making a new genus of this animal, which he shows to be an undeveloped form of a species of Pseudis (*American naturalist*, October, 1877).

More recently this 'extremely curious little animal' has come to the surface again, this time in the French academy. Especial attention was called, in that body, to the first volumes of the Brazilian archivos; and this description of 'a curious batrachian' was spoken of as 'a valuable essay' and 'particularly deserving attention' (*Pop. sc. monthly*, January, 1884, p. 428).



Agreeing with Professor Hartt in regard to its being nothing more than an unusual tadpole, I was anxious to obtain specimens of the animal in the various stages of its development, and thus make an ocular demonstration of the correctness of our opinions.

My work upon the Imperial geological survey, and later other duties, made it necessary for me to travel in almost every part of Brazil, and in some parts of the Argentine Republic and Paraguay; but nowhere could I find or hear of any such animal as that described in the archivos. Along the Paraguay River, which I traversed from its mouth to its source, I made especial effort to find it; for the specimen figured was said to have come from Paraguay. At length, during a trip made in 1882-83 to the interior of the province of Pernambuco in Brazil, I was so fortunate as to obtain a number of good living specimens; and it goes without saying, that they showed the Batrachichthys to be a mere tadpole. They were taken in an artificial pond near the village of Bonito, toward the end of January, 1883; being found in all stages of development from the tadpole to the full-grown frog, although the very young tadpole could not be had on account of the lateness of the season.

About Bonito these tadpoles are called *cacotes*. They are not uncommon in ditches and ponds, and sometimes occur in such numbers as to seriously interfere with fishing with the net. The full-grown frogs are called *sapos verdes* (green frogs). They are said to live in the weeds and rushes about the margins of the ponds; and, when disturbed, they jump into the water. In regard to these popular names, it should be remarked, however, that they are too general to lead one to suppose that they are applied to this species of frog alone throughout Brazil.

The specimens collected by me are now deposited with Professor Wilder at Cornell university.

JOHN C. BRANNER.

Geological survey of Pennsylvania,
Scranton, Penn.

THE GREELY SEARCH.

THE report of the board called to consider the plans of the relief expedition has been printed, and its principal features have been made public through the daily press. Two vessels have been purchased which there is every reason to believe are well suited for the work; and through the graceful courtesy and generosity of the British government, the Alert, well known as the advance ship of the Nares expedition of 1875-76, has been put at the disposition of the United States, without money and without price. A more timely and felicitous service could hardly be rendered; and the sentiment of the country in regard to it is well expressed in the communication of the 21st ultimo to congress from the president and secretary of state.

The position of affairs is about as follows: the Greely party were landed in August, 1881, at Discovery Harbor, with rations equivalent to supplies for three years on the basis used in the U. S. army; with beans, sugar, coffee, canned goods, and antiscorbutics, not embraced in the regular official ration, to the extent, as alleged, of about one year's additional provisions. Beside this, Lieut. Greely reported that about three months' supplies of fresh musk-ox meat had been killed before the departure of the returning vessel. It must be remembered, however, that the demand of human nature for food in these regions is greater than in more temperate climates; and the extra

supplies above mentioned would probably be consumed, together with the regular ration, instead of serving to extend it over a longer period. There is every reason for believing that the supply of fresh meat or game at the station is extremely precarious, accessible only during a few summer months, and perhaps practically absent in certain years. There is therefore reason to suppose that the supplies of the expedition will be entirely exhausted by the beginning of next winter.

On the failure to reach the party in 1882, it may be supposed that every care would be taken by its commander to economize supplies for the retreat last fall. This could not be carried very far; because the stamina of the men, already weakened by two years of arctic exposure, would not bear any great reduction of the ration. It is probable that Greely would have learned by the second summer, that delaying until September might prove fatal to his plan of retreat. He probably started south, if at all, in July or August, 1883. We assume that the party were living and in reasonably good health at that time.

The distance from Discovery Bay to Cape Sabine (see map) is about two hundred and fifty miles. The shore is bold and precipitous; the northern half compact, and almost without inlets or bays; and the usual ice-foot along the rocky walls of Kennedy Channel is, on this side, liable to be much broken by the grinding of floes against it. In this stretch of coast there are three caches of provisions. The first, at Carl Ritter Bay, seventy-five miles south from Lady Franklin Bay, contains two hundred and twenty-five rations, deposited by Greely himself in 1881, and sufficient to sustain his party for nine days. Sixty-two miles farther south, at Cape Collinson, are ten days' provisions, left by Nares in 1875. Fifty miles farther south, at Cape Hawkes, is a cache of unknown extent, but which Greely thought, in 1881, would subsist his party for two months. These, however, were partly in bad condition in 1881, and probably still worse in 1883.

Of the dogs taken by Greely, only eleven survived until the date of his last report, a number hardly more than sufficient to haul their own food from Lady Franklin Bay to Cape Sabine. It may be assumed that any attempt of the Greely party to retreat by means of sledges alone, would be unsuccessful and disastrous. If attempted, it probably would result in a return to their old quarters later in the season, as their only safety for the winter. Sledging over the hummocks of Kennedy Channel and Kane Basin is terrible work, and not to be compared with that done on open field-ice, like that of the sea north of Robeson Channel, or that crossed by Anjou, Wrangell, and De Long.

The practicability of a successful retreat to Cape Sabine, we believe, depended entirely upon whether the party were able to use their boats, and avail themselves occasionally of their sledges to make portages over ice isthmuses in their way. They were furnished with boats prepared especially for the purpose, besides a steam-launch, for which an abundant supply of coal might be procured from the coal strata near the station.

It is improbable, unless continuous water communication happened to favor them, that the party could transport their effects and records, together with a year's provisions for all hands. They could hardly take, in the four boats, more than eight tons besides themselves, and probably not more than six tons if any coal was carried in the launch. A year's provisions for all hands would weigh over fourteen tons. It would be necessary, therefore, for them to rely upon the stores they expected the relief-ship to cache on the east side of Grinnell Land in 1882, and upon the other caches already mentioned, to supply the deficiencies of their means of transportation.

It is highly probable, also, if the strength of the party had in any way become seriously impaired, that they would find it necessary (failing continuous land-water along the Grinnell Land coast) to abandon all but two of their boats, and as much of every thing else as they dared, to get through to the southern entrance of Kane Basin. Whether, if arrived at Cape Sabine, the caches there would suffice to pass them safely through the winter, does not seem to be certain from the rather confused statements in regard to it. It is also possible (as happened to the English on some occasions) that the condition of the ice alongshore might be such that the caches at Carl Ritter Bay or Cape Collinson, or both, might be inaccessible from the water.

We may conclude from the above facts and assumptions, that (1°) if the Greely party were able to use their boats, and reached Cape Sabine safely last fall, the probability of finding them there at open water is reasonably good; (2°) if they were not able to use their boats, they either wintered at the station (in which case they are probably in fair condition, but will be reached with difficulty, and must be reached within the year to save them), or they made an attempt to sledge southward to Cape Sabine, and can hardly have escaped serious disas-

ter; (3°) if they reached Cape Sabine, they are there at present, unless forced to attempt the transit of Smith Sound, — a task fraught with such difficulty that it may well be doubted if they could accomplish it. If accomplished, the absence of provisions expected to be found there would prove a grievous disappointment, and possibly the cause of disaster. But we think the prospect of the party, as a whole, reaching the eastern side of Smith Sound, to be almost unworthy of serious consideration, were it not that in matters like this nothing is unworthy of consideration.

The report of the board is sound and judicious, and was doubtless founded in great part upon the wise counsel of men like Nares and Schwatka, which is appended. It recommends a bounty to be offered for the recovery of the party, if north of Cape York, as urged in this journal and by various competent arctic experts among those consulted.

Since then the secretaries of the navy and war departments have united in a letter to Congress, which is too lamentably absurd to be any thing but comic. It has been well answered by Mr. George Kennan in the *New York herald* of March 19. That those poor, dear, stupid sealers and whalers might get themselves into trouble by rushing in where the navy is so much better fitted to tread, is essentially the reason offered by these landsmen as proof of the inadvisability of a reward. The common sense of mankind will put a right value on such a plea. The necessity for competent ice-navigators is sufficiently evident to any one, and is recognized by the board in its report. The necessity of leaving the ice navigation absolutely to their judgment is hinted at by Schwatka in his letter to the board, and much more fully developed by him in an interview published in the *San Francisco post* of March 1. Upon this much depends, as the experience of the Proteus in 1883 gives evidence.

The plans of the expedition are not yet fully matured, or at least not officially made public. It is stated that the Bear will sail, about April 25, to St. Johns, Newfoundland, to coal, take dogs on board, and proceed at the earliest possible moment to Disco and Upernavik, which it is hoped will be reached about the third week in May. The Thetis will follow from New York about May 1, coaling at St. Johns, and convoying a coal-steamer to Upernavik; when all three will proceed toward Cape York and Littleton Island, or Port Foulke, opening communication with the Eskimo at the earliest opportunity.

The Alert should arrive at Upernavik by June 1, and proceed during the month toward Littleton Island with the intention of providing a station to fall back upon for the crews of the two advance vessels, and later to send a sledge-party along the east coast of Smith Sound as far as the Humboldt glacier. This duty completed by Sept. 1, and the advance vessels not having been heard from, the Alert should return to St. Johns with her report.

The programme for the Alert is open to severe criticism. It cannot be too often repeated, that nearly all the chances are against any of the Greely party having reached the east side of Smith Sound, unless from Cape Isabella. The relief-vessels must follow the land-water on the Grinnell Land shore, to make northward progress. If they come to grief, they will have to retreat by that shore; and for them, as for the Greely party, a station on the Greenland side will be of no use, beside adding greatly to their perils — unless Smith Sound is navigable for small boats, which is hardly to be expected, late enough for a party wrecked north of latitude 79° 30′ to reach the Greenland side. The sledge-party along the Greenland shore will be useful only as a training in sledging for the youngsters. Here it may be observed that the report of the board contains a drawing of a new kind of sledge most ingeniously contrived to be worthless in the arctic regions. It weighs two hundred pounds, and contains bolts, bars, rivets, and varieties of metal, — enough to delight a locksmith, and, at arctic temperatures, keep him more than busy mending the breaks, and the surgeon as much so alleviating the blisters, which would rise wherever bare skin touched it.

It is understood that the expedition is to be commanded by Commander Winfield S. Schley, who will take charge of the Thetis, with Lieut. Uriel Sebree as executive officer, Lieuts. Emory Taunt and S. C. Lemlsy, Ensign Harlow, Chief-engineer Melville, and Passed assistant surgeon Green. The officers of the Bear will be Lieut. W. H. Emory (commander), Lieuts. Colwell and Reynolds, Ensign Usher, Engineer John Lowe, and Dr. Ames. The Alert will be commanded by Commander George W. Coffin, assisted by Lieut. Charles J. Badger and others not yet named. It is, of course, possible that changes in these details may occur at any time before the expedition departs. No opportunities are to be afforded for scientific observations not inevitable to the voyage — unless, perhaps, on the Alert, which returns to civilization.

That the expedition, in spite of crudities of

conception and inexperienced *personnel*, will do good work, we have no doubt; for it is the saving grace of our American navy, that its officers are apt in utilizing brief experience, fertile in expedients, and bold in execution of a task before them.

THE GREAT VIENNA TELESCOPE.[1]

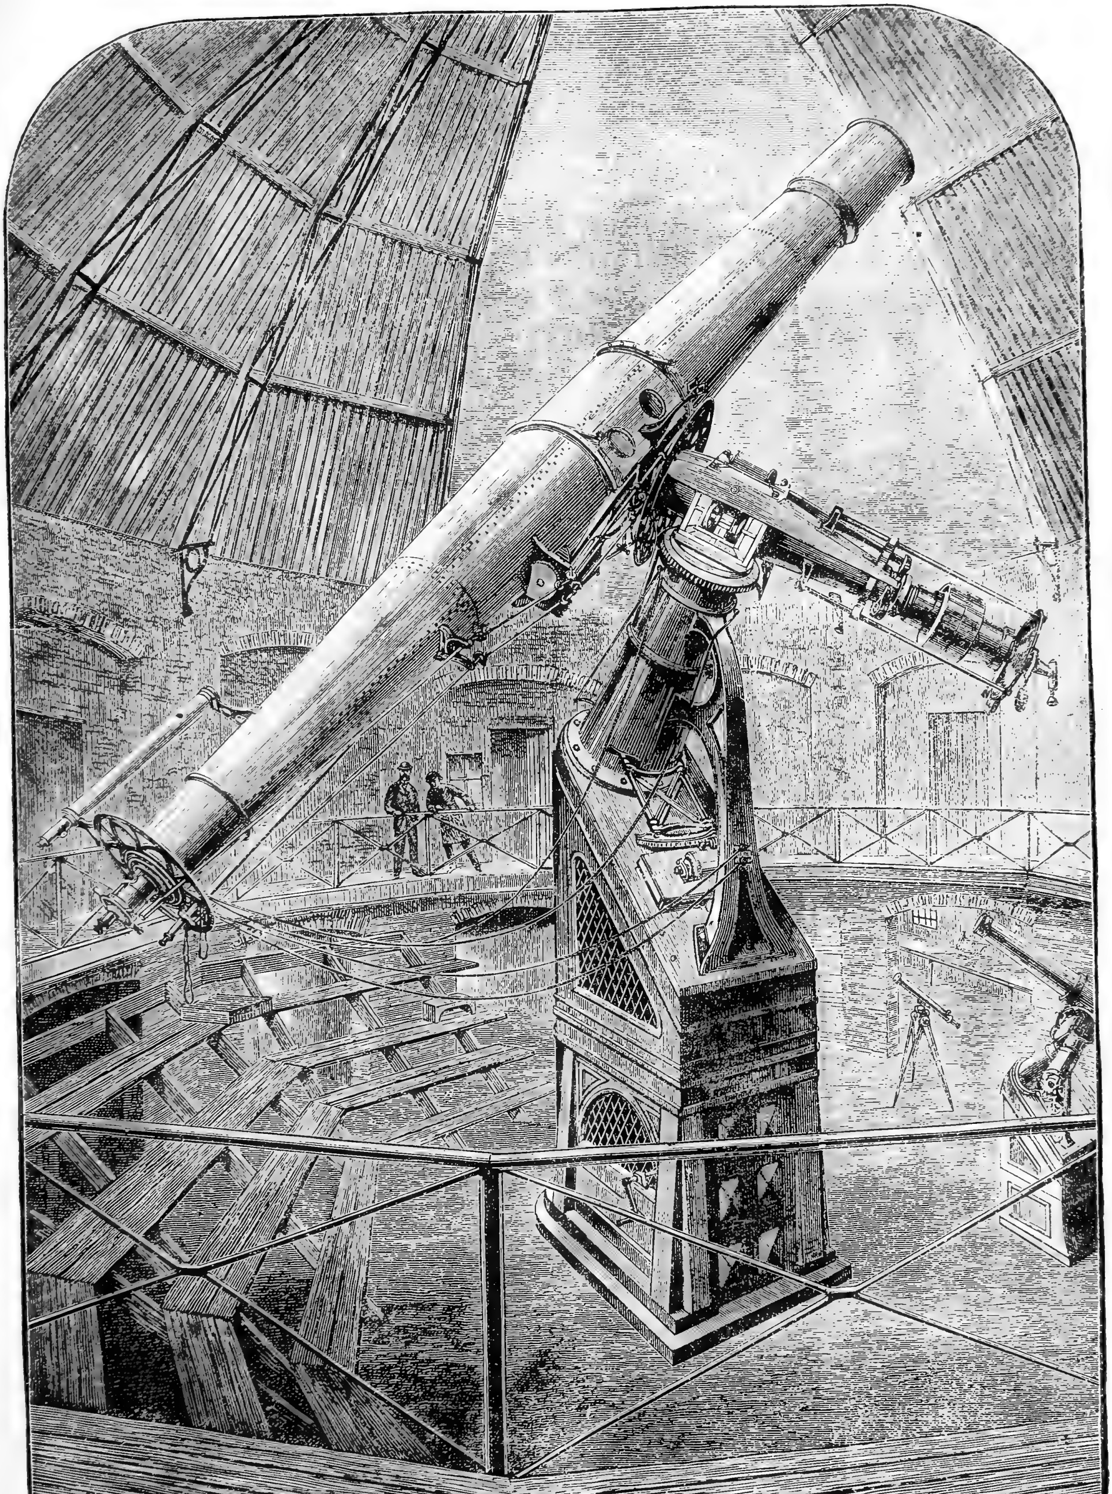
AMONG the instruments which I have examined, that to which most interest now attaches is the great telescope recently completed for the Imperial observatory at Vienna by Howard Grubb of Dublin. It is the largest refracting telescope in actual use at the present time, being of one inch greater aperture than that of the Naval observatory at Washington. The contract was made with Mr. Grubb in 1875; but, owing to difficulties in procuring glass disks of the necessary size and purity, it was not completed until 1881. Further delays occurred in mounting, so that it was scarcely ready for actual work at the time of my visit in April last. I made as critical and careful examination of its working as was possible during the unfavorable weather which prevailed at Vienna at that time. My examination was principally in the nature of a comparison of its working with that of the Washington telescope.

General character of mounting. — In its main features the telescope is mounted on the same general principle with that at Washington. Both of these instruments are counterpoised on the German plan. The tubes of both are of steel. The rapid motion in declination is by means of a rope attached to the two ends of the tube, and that in right ascension by a system of wheel-work. The clockwork is in the pier below the instrument. The leading points of difference are, that the mounting of the Vienna telescope is much larger, stronger, and heavier in all its parts; that the contrivances for making use of it are more numerous; that an elaborate system of friction-rollers in declination is provided, the Washington telescope having none; and that a more convenient system of illuminating the field and the divisions on the several circles has been adopted.

Ease of motion. — In moving the Vienna telescope, one is at first struck with the fact that mere weight is a serious drawback; but when the motion is once commenced, the movement in right ascension is almost as easy as in the Washington telescope. It is, however, very different in declination. For reasons which neither Dr. Weiss nor myself were able to perceive, the friction-rollers seemed to be of no benefit in easing the motion in declination, which was much more difficult than in the Washington telescope, and, in fact, quite a task upon the strength of the observer at the eye-piece. The quick motion for setting in right ascension is made below the end of the polar axis by turning a steel steering-wheel. This appliance is in every way inferior to the system at Washington, where the same motion is effected by an endless rope hung over a grooved wheel, which the observer turns hand over hand. By this motion the observer at the Washington telescope can make the required motion without taking his eyes from the telescope or the vernier, and without giving any thought to the motion of his hands. But the handles of the steering-wheel are much less convenient to take hold of than a rope; and, if the motion is at all rapid, the operator must be on the alert lest the steel handles strike his knuckles in the attempt to take hold of them without looking. The necessity of care in this respect makes the motion slow and laborious.

Clock-motion. — On the system of the Messrs. Clark, applied in the Washington telescope, the screw which turns the sector does not take hold of the circumference of the latter directly, but gears into a complete wheel, the axis of which is connected with the arc of the sector by a pair of brass or steel bands. By this arrangement the toothed wheel makes a nearly complete revolution while the sector is moving through its arc; and the effect of the small unavoidable irregularities in the working of the screw is diminished in the ratio of the arc of the sector to the circumference of the wheel. Whatever advantages this arrangement may have in small instruments, I think that in large ones they are more than counterbalanced by the evils arising from the elasticity of the band, combined with the changes of friction, the action of the wind, and other forces acting to vary the uniform motion of the telescope. Owing to this elasticity, the effect of the wind or of any slight pressure by the observer on the eye-piece is many times greater in the Washington than in the Vienna instrument. But it did not appear to me that the firmness of the connection in the latter instrument between the support of the turning-screw and the tube of the telescope was as great as supposed by those who lay stress on large and stable mountings. I found that, by a simple pressure of the thumb-nail upon the eye-piece of the

[1] Extract from a report to the secretary of the navy on recent improvements in astronomical instruments, by SIMON NEWCOMB.



Vienna telescope, the pointing in right ascension could be changed by a number of seconds, so as to throw an object entirely away from the wire. The main question is, however, the steadiness of motion when no pressure whatever is applied by the observer or the wind; and, so far, I have found no large telescope which is entirely satisfactory. The Vienna telescope was not supplied with a micrometer at the time of my examination, so that I could not test its motion as thoroughly as I wished to; but, by bringing the planet Uranus in the edge of the field, I found that there was constantly an irregular movement in right ascension, the amount of which I estimated as between one and two seconds of arc. This movement had no regular period, and therefore did not seem to be connected with any defect in the figure or motion of the screw. Its irregular period, if I may use the term, varied from the smallest appreciable amount to two or three seconds of time. Its most probable cause seemed to be the irregular friction of the motion in right ascension, and especially of the friction-rollers, by which the polar axis is supported at its lower end. A similar irregularity is noticed in the Washington telescope; but I think it is decidedly less than in the Vienna one, provided that no strong wind is blowing on the instrument.

Arrangement of sector. — In Mr. Grubb's large telescope an attempt is made to give greater stability to the screw by having its axis immovably fixed to supports in the massive base of the telescope, which renders it incapable of any motion except that of turning. The screw cannot, therefore, be unlocked from the sector, as in the instruments by other makers. When the sector reaches the end of its motion, it is to be turned back by giving a rapid backward motion to the screw itself, for which special apparatus is provided. From what I have already said, I am of opinion that this arrangement offers no advantage to compensate for the trouble which it causes the observer.

Slow motion. — The slow motion in right ascension in the Vienna telescope is endless, instead of being confined between narrow limits, as in that at Washington. This is a decided improvement, saving the observer much loss of time from the motion running out.

Illumination. — The apparatus for illuminating the field of the micrometer was not in perfect order at the time of my visit, so that I need not report upon it in this connection. It is in its general character similar to the system adopted by the Messrs. Repsold, of which I shall speak hereafter. The illumination of the divisions of both circles leaves nothing to be desired.

Minor points. — In the preceding I have indicated what may be considered fundamental points affecting the use of the instrument. There are, however, several minor points which are of almost equal importance, so far as the practical use of the instrument is concerned. As the instrument now stands, the drawback which strikes me most was the absence of any rough setting, either in right ascension or declination, and the impossibility of seeing, even approximately, the pointing in declination, except when the observer is at the eye-piece. This, when combined with the great force necessary to move the telescope in declination, makes its pointing a difficult and troublesome operation. The observer must first set the telescope by pure guess-work. He has then to mount to the eye-piece, wherever it may be, look into the microscope, and note the reading of the circle. He has then to withdraw his eye, and, by considerable muscular exertion, to make another guess, which he can test by again reading the circle. Thus the pointing is to be made by a series of trials, which are so troublesome that I found the observers were in the habit of mounting to the top of the clyinder in the dome, and finding the pointing in declination by moving the telescope around the horizon.

I remark, in this connection, that the Washington telescope has a coarse setting, which the observer can read from any point below the telescope with the aid of an opera-glass.

Objective. — The proper figuring of a great objective so as to give the best possible image of a celestial object is justly considered the most difficult task in the construction of a large telescope: especial interest, therefore, attaches to Mr. Grubb's success with the objective. The atmospheric conditions were very unfavorable to the finest tests, but I succeeded in making such examination as the circumstances admitted on three evenings. On the first trial the image was found to be distorted, owing to want of adjustment of the glass itself. This was soon corrected by Director Weiss. On the second trial I found a well-marked spherical aberration, which seemed, however, to be very regular from centre to circumference. But there had been a fall of temperature, and the dome had been opened but a short time, — circumstances under which the Washington telescope always exhibited the same phenomenon. On the third evening the dome had been opened long enough to nearly equalize

the temperatures. So far as I could judge, the character of the image was perfect, there being no appearance of those rings of different focal lengths which are commonly seen in large objectives. As I had not used a large telescope for some eight years, I could not feel that my judgment was an entirely critical one; but I am persuaded, that, if any defects exist, they are so minute as not to interfere in the slightest with the finest performance of the instrument.

I have been led by the examination above described, combined with some experience in the use of the Washington telescope, to some conclusions respecting the most appropriate features in the mounting of an instrument of the largest size. They may here be enumerated for the consideration of those engaged in constructions of this kind.

1. I think, that, in order to secure the necessary stiffness with the least weight, the axes should be hollow. The material can then be made comparatively thin. It is true that the greater the friction, the larger the axis; but the mass of metal in the interior of the axis contributes so little to its stiffness that the external diameter will have to be increased very little to secure the same stiffness with the hollow axis as with the solid one.

2. It is not worth while to supply the declination-axis with friction-rollers, unless experiment and research shall show that they can be made more effective than they appear to be in the Vienna instrument.

3. The best quick motion in right ascension is that adopted in the Washington telescope, where the observer pulls an endless rope hand over hand, and can lock and unlock at pleasure the gearing which connects the turning-wheel with the telescope.

4. If, as is probable, the quick motion in declination by means of the loose rope attached to the two ends of the telescope requires too strong a pull, the best method of giving this motion is through a gearing turned by an axis passing centrally through the polar axis, on the Repsold plan; but it is desirable to have this motion made by turning a crank, or pulling a rope, rather than by taking hold of the wheel.

5. Coarse divided wheels should be supplied, so that the observer, while turning the instrument, can constantly see its approximate pointing. It is better if this coarse reading can be made with the naked eye, as is the case with the right-ascension movement in Washington. The declination-circle, being farther from the observer, has to be read with an opera-glass if more than a coarse fraction of a degree is required. By such an arrangement the telescope can always be set by the quick motion so nearly that any object sought shall be in the field of view of the finder. In nine cases out of ten this will be all that is required in practical use. It should never be forgotten that in all quick motions it is very desirable that the observer should be able to keep his eye upon the movements of the telescope itself, so to save him from even a groundless apprehension that something may be going wrong.

6. The slow motion should, if possible, be endless. There is no difficulty in making it so in right ascension: there may be, however, in declination.

7. When the instrument is so large that there is an interval of three feet or more between the centre of the polar axis and the side of the tube, the screw which communicates the clock-movement should be geared into a complete circle rather than into a sector. The use of a metal band to multiply the intervening radius of the wheel offers no advantage, in the case of large instruments, to compensate for the disadvantage of want of stability arising from elasticity of the band and its fastenings.

8. In this connection the question arises of applying the Greenwich system, which consists in setting the hour-wheel so that its position shall correspond to sidereal time, and clamping to it a second wheel corresponding to right ascension. Every practised astronomer is familiar with the trouble in setting an ordinary equatorial, arising from the necessity of having to calculate the constantly varying hour-angle of the object on which he points. With the Greenwich arrangement there is no such trouble. The worm-wheel being once set to sidereal time, the observer has only to set the other one to the constant right ascension of the object. It is true that practical difficulties arise in the usual construction, owing to the fact that the vernier on the gear-wheel will from time to time be on every point of the circle; but this difficulty can, I think, be obviated by appropriate arrangements.

9. A clock-motion which can be kept up by water or other power is greatly preferable to any system which requires an assistant to wind up a weight.

10. The entire practicability of illuminating the divisions of the circle by lamps, and of reading these divisions from the eye-end of the telescope, has been so completely demonstrated, that all large instruments should be supplied with this arrangement.

11. The system of illuminating wires, field-micrometer slit, etc., by a single lamp which

shall be vertical in all positions, has been so perfected by the Repsolds, that it leaves nothing to be desired.

12. The Washington plan of having the whole micrometer-plate, including both fixed and movable wires, moved by a fine screw, offers such a convenience in setting, that it should always be adopted.

13. The old system of having a single finder on that side of the telescope which is opposite the declination-axis becomes very inconvenient in a large instrument, owing to the necessity of setting the slit in the dome, not only to the telescope, but to the finder. The plan adopted in the Vienna telescope, of having two finders, — of which one shall be above, and the other below, the telescope when the latter is in the meridian, — obviates this difficulty, and should always be adopted.

THE AMERICAN AWARDS OF THE GEOLOGICAL SOCIETY OF LONDON.

We give below the text of the addresses on the occasion of the awards to Dr. Leidy and Mr. Lesquereux at the annual meeting of the Geological society of London in the middle of last month.

The president handed the Lyell medal to Prof. W. H. Flower, F.R.S., for transmission to Dr. Joseph Leidy, F.M.G.S., and addressed him as follows: —

Professor Flower, — The council has bestowed on Dr. J. Leidy the Lyell medal, with a sum of twenty-five pounds, in recognition of his valuable contributions to paleontology, especially as regards his investigations on the fossil Mammalia of Nebraska, and the Sauria of the United States of America. These vast, and, in comparison with our own country, but little explored, territories have for some years past yielded a harvest of fossil vertebrate remains of exceeding richness, of which we have no example here. How well this harvest is being garnered by our trans-Atlantic *confrères* the flood of memoirs published by them during the last quarter of a century bears witness. Amongst these scientific laborers in the paleontological harvest-field, Dr. J. Leidy has held a foremost place. Careful in observing, accurate in recording, cautious in inferring, his work has the high merit which trustworthiness always imparts. The well-nigh astounding number of papers written by him between 1845 and 1873 (amounting to a hundred and eighty-seven), his reports on the 'Extinct vertebrate fauna of the western territories,' his 'Synopsis of the extinct Mammalia of North America,' and his 'Cretaceous reptiles of the United States,' testify to the fertility of his pen.

Professor Flower, in reply, said: — Mr. President, as I have profited so deeply by Dr. Leidy's paleontological writings, and also have the pleasure of his personal friendship, I was much gratified by his request, communicated to me by telegraph a few days ago, that I would represent him on this occasion, and receive from your hands the award which the council has so worthily bestowed. By the same means of communication, he mentions the interesting incident, that it was by Sir Charles Lyell's advice, given to him in Philadelphia about thirty years ago, that he was induced to abandon the study of medicine and take up paleontology. A letter which I understand Dr. Leidy has written, in which he doubtless has expressed his own thanks to you, has not yet reached me; but I am quite sure that this recognition of his valuable labors in that marvellously fruitful field of discovery, the extinct vertebrate fauna of North America, will be greatly appreciated by him and by his fellow-countrymen, by whom he is so justly esteemed.

The following is the letter from Dr. Leidy, mentioned by Professor Flower: —

Philadelphia, Penn., 1302 Filbert Street,
Feb. 7, 1884.

My dear sir, — I have just this minute received your note of Jan. 25, and hasten to reply, that there may be no delay in my answer, for the anniversary meeting of Feb. 15. I was equally surprised and delighted at the action of the council of the Geological society in awarding to me the Lyell medal and its accompaniment. Such approbation of my services I regard as rich compensation, added to the pleasure derived from my labors. I must add that I feel as if Sir Charles Lyell himself was expressing satisfaction, in consideration of my having complied with his wish, when thirty years ago, in my own home here, he said he hoped I would devote my time to paleontology instead of medicine.

Please present to the Geological society my warmest thanks for the honor it has conferred upon me. I have written to Prof. W. H. Flower, asking him to receive the award on my account.

With sincere regard,
Joseph Leidy.

Mr. Warington W. Smyth,
For. sec. Geol. soc.

In handing to Professor Seeley, F.R.S., a second portion of the proceeds of the Barlow-Jameson fund for transmission to Professor Leo Lesquereux, F.C.G.S., the president spoke as follows: —

Professor Seeley, — The council has awarded to Professor Leo Lesquereux the sum of twenty pounds from the proceeds of the Barlow-Jameson fund, in recognition of the value of his researches into the paleobotany of North America, and to aid him in further investigations of a similar kind. Professor Lesquereux's 'Contributions to the fossil cretaceous and tertiary flora of the western territories,' published in the 'Reports of the U. S. geological survey,' are works which, for their matter, typography, and illustrations, leave nothing to desire. In transmitting this award to Professor Lesquereux, you will convey to him the hopes of the council that it may assist him in prosecuting further investigations in the difficult branch of research in which he has already accomplished so much.

Professor Seeley, in reply, said: — Mr. President, I

feel much honored in receiving this award on behalf of Professor Lesquereux. His valuable researches not only contribute systematic descriptions of the American secondary and tertiary floras, but furnish almost the only data for comparing those floras with the plant-life from similar strata on this side of the Atlantic. All Professor Lesquereux's work is marked by such exactness and care, that I am glad we are thus able to honor it, and offer assistance in its progress.

THE DIFFICULTY OF PREVENTING THE OHIO FLOODS.

WILLIAM E. MERRILL, lieutenant-colonel U. S. engineers, in charge of the government improvements in the Ohio River, has, at the request of the editor of the *Cincinnati commercial gazette*, made public his views respecting the causes of the Ohio floods, and discussed the possibility of their mitigation in a letter published in the issue of March 8 of that journal.

In attempting to estimate the influence of forests, he says, experience has proved that the clearing and cultivation of level land have comparatively small effect upon floods, and may be left out of account: disastrous effects follow only when the hill and mountain sides are put under cultivation. The evil results of denuding the hills of trees are then illustrated by references to Spain, Palestine, Greece, parts of Italy and France, and the good results of reforesting the slopes of the French Alps noted.

Above Cincinnati the watershed drained by the Ohio comprises the western third of Pennsylvania, the whole state of West Virginia excepting four counties, the eastern part of Kentucky, and nearly the entire state of Ohio. Now, leaving out of consideration the more level portions of this area, the question is, whether its hilly and mountainous parts have been cleared of forests to such an extent as to materially affect its capacity to retain the rainfall, and so to call for legislative action to prevent greater calamities in the future. Col. Merrill answers this question emphatically in the negative. Speaking from an extended personal knowledge of the states of Pennsylvania, West Virginia, and Kentucky, which comprise the hilly portion of the Ohio basin, he says we are very far from having attained that state of forest destruction which would require the intervention of the government for the protection of the river-valleys in this manner. Any one who travels on the railroads which cross the Alleghanies sees that the country is still heavily wooded, while away from the lines of the railroad it is still a wilderness, except in a few isolated valleys. Even the removal of the merchantable timber from the country would do no especial damage, provided the underbrush and smaller trees were left to protect the soil. We thus far have no sure ground, he remarks, for asserting that man's interference has had any marked influence upon the discharge of the Ohio.

In sharp contrast with these views of Col. Merrill is an article on forests and floods in the *New York independent* for March 6 (p. 30), by Mr. N. H. Egleston of Washington, D.C., in which the basis of argument seems to be furnished by the map prepared by Professor Sargent to illustrate the census returns in regard to the condition of the forests, and more particularly by a careful examination of the amount of woodland now existing in the state of Ohio as compared with that of twenty years ago.

As the state is not much of it hilly, the argument appears in so far to be inconclusive, although the author states and explains the popularly accepted theory of the controlling influence of forests with great skill, and without hesitation ascribes the Ohio floods to their destruction. But Col. Merrill very pertinently remarks that the traditions of the aborigines show that even the great flood of 1884 was equalled by floods which occurred before white man's axe felled a single tree in the valley of the Ohio.

Whatever may be thought of the relative value of opinion upon this question, there is no doubt that Col. Merrill speaks as an expert and an authority when he treats the problem of controlling the surplus waters of the Ohio by artificial means. He says, the idea that it is possible to build a number of reservoirs in the mountains to store up water during freshets, and let it out during the scarcity of summer, is an old one, and one which has been discussed and abandoned in case of various European rivers. It was, moreover, advocated by the able engineer, Charles Ellet, jun., and vigorously pressed upon the attention of Congress. When the improvement of the Ohio was taken in hand by the government, after the close of the civil war, this scheme was practically investigated by W. Milnor Roberts, whose long engineering experience in railroad and canal construction in western Pennsylvania, and consequent familiarity with its topography, peculiarly fitted him for this work. After an exhaustive examination of possible sites, and estimate of cost of retaining reservoirs, which will be found in detail in his report to the chief of engineers under the date of April 30, 1870, he concludes thus: "My own careful investigations of the subject of controlling the floods of the Ohio by means of artificial reservoirs, which were made in 1857, satisfied my mind conclusively that such control by human means, attainable within practicable limits of cost, is impossible."

Mr. Roberts then examined another question, which was the practicability, not of controlling the floods at all, but of simply storing sufficient water to provide a supply to supplement the scarcity of the summer to such an extent that the summer flow at Wheeling should not fall below six feet. The reservoirs required to accomplish this were estimated to have a capacity of not less then a hundred and fifty billion cubic feet, and they must store the drainage from a watershed of not less than thirty-six hundred square miles. The estimated cost of accomplishing this with thirty reservoirs was sixty million dollars, a sum out of all proportion to the advantage to be derived from the improvement. Moreover, the dangers attendant upon such reservoirs are too great to justify the construction of even the few reservoirs required to secure a navigable stage of water, to say nothing

of the vastly greater constructions which would be needed in any attempt to control floods. There is special insecurity necessarily inhering in the foundations of hydraulic work such as this, constructed in the bed and banks of running streams. Besides this, mention may be made of the interference which such reservoirs would cause in vested interests, such as mills, factories, railroads, canals, and rafting.

The latter portion of Col. Merrill's letter advises the city of Cincinnati to appoint a commission to define the lines of the river-front for high and low water, and to make it the duty of some public officer to prosecute in case of infringement on the free waterway, so that there may be no future obstruction of the river-channel. He shows that to the present time there has been no perceptible obstruction at this point. He further advises that the lower part of the city, next to the river, be filled by continuing the present slope of the river-banks upward to high-water mark; and then that those squares of the city which stand on the slope be devoted to business alone, and be so solidly built as not to be seriously damaged by an occasional flood, while the houses of the laboring population be removed to other parts of the city.

In conclusion, Col. Merrill says, in reply to the question which has frequently been put to him as to what the government is going to do to try to stop these floods, that, if the government be guided by his advice in this matter, it will do nothing, as the undoubted cause of the flood was the excessive fall of rain and snow; and no means of controlling this has yet been discovered.

AN EXPLANATION OF HALL'S PHENOMENON.[1]

MR. E. H. HALL's original experiment was as follows. A strip of gold-leaf was cemented to a plate of glass, and placed between the poles of an electro-magnet, the plane of the glass being perpendicular to the magnetic lines of force. The current derived from a Bunsen cell was passed longitudinally through the gold; and, before the electro-magnet was excited, two equipotential points were found by trial near opposite edges of the gold-leaf, and about midway between the ends. When these points were connected with a galvanometer, there was, of course, no deflection. A current from a powerful battery being passed through the coils of the magnet, it was found that a galvanometer-deflection occurred, indicating a difference of potential between the two points, the direction of the current across the gold-leaf being opposite to that in which the gold-leaf itself would have moved across the lines of force, had it been free to do so. On reversing the polarity of the magnet, the direction of the transverse electromotive force was reversed; and, when the magnet was demagnetized, the two points reverted to their original equipotential condition. Subsequent experiments showed that the direction of the effect differed according to the metal used. This effect was attributed by Mr. Hall to the direct action of the magnet on the current.

Mr. Bidwell claims that Hall's phenomenon might be completely explained by the joint action of mechanical strain and certain thermo-electric effects. The strain is produced by electro-magnetic action. It will be convenient to refer to the metallic plate or strip as if it were an ordinary map, the two shorter sides being called respectively west and east, and the two longer, north and south. Let the south pole of an electro-magnet be supposed to be beneath the strip, and let the strip be traversed by a current passing through it in a direction from west to east: then the strip will tend to move across the lines of force in the direction from south to north. Since, however, it is not free to move bodily from its position, it will be strained; and the nature of the strain will be somewhat similar to that undergone by a horizontal beam of wood which is rigidly fixed at its two ends, and supports a weight at the middle. Imagine the strip to be divided into two equal parts by a straight line joining the middle points of the west and east sides: then in the upper or northern division the middle district will be stretched, and the eastern and western districts will be compressed; while in the lower division the middle part will be compressed, and the two ends will be stretched. If, now, a current is passing through the plate from west to east, the portion of the current which traverses the northern division will cross first from a district which is compressed to one which is stretched, and then from a district which is stretched to one which is compressed; while in the southern division the converse will be the case. And here the thermo-electric effects above referred to come into play.

Sir William Thomson, in 1856, announced the fact that a stretched copper wire is thermo-electrically positive to an unstretched wire of the same metal, while a stretched iron wire is negative to an unstretched iron wire. From this it might be inferred, as Sir William Thomson remarks, that a free copper wire is positive to a longitudinally compressed copper wire, and that a free iron wire is negative to a longitudinally compressed iron wire; and experiment shows this to be the case. *A fortiori*, therefore, a stretched copper wire is thermo-electrically positive to a compressed copper wire, and a stretched iron wire is negative to a compressed iron wire. If, therefore, a current is passed from a stretched portion of a wire to a compressed portion, heat will (according to the laws of the Peltier effect) be absorbed at the junction if the metal is copper, and will be developed at the junction if the metal is iron. In passing from compressed to stretched portions, the converse effects will occur.

It follows from the above considerations, that, if the metal plate (which is subjected to a stress from south to north, and is traversed by a current from west to east) be of copper, heat will be developed in the western half of the northern division, and absorbed in the eastern half; while heat will be absorbed in the western half of the southern division, and developed in the eastern half. But the resistance of a metal increases

[1] Abstract of a paper read at the meeting of the Royal society, Feb. 21, 1884, by SHELFORD BIDWELL, M.A., LL.B.

with its temperature. The resistance of the north-western and south-eastern districts of the plate will therefore be greater, and that of the north-eastern and south-western districts smaller, than before it was subjected to the stress; and an equipotential line through the centre of the plate, which would originally have been parallel to the west and east sides, will now be inclined to them, being apparently rotated in a counter-clockwise direction.

If the plate were of iron instead of copper, the Peltier effects would clearly be reversed, and the equipotential line would be rotated in the opposite direction.

The peculiar thermo-electric effects of copper and iron, discovered by Thomson, are thus seen to be sufficient to account for Hall's phenomenon in the case of those metals. It became exceedingly interesting to ascertain whether the above explanation admitted of general application; and the author therefore proceeded to repeat Thomson's experiments upon all the metals mentioned by Hall. The results are given in the following table, where those metals which in Hall's experiments behave like gold are distinguished as negative, and those which behave like iron as positive.

Metals.	Forms used.	Direction of current.	Hall's effect.
Copper	Wire and foil, pure.	S. to U.	Negative.
Iron	Wire and sheet, annealed.	U. to S.	Positive.
Brass	Wire, commercial.	S. to U.	Negative.
Zinc	Wire and foil.	U. to S.	Positive.
Nickel	Wire.	S. to U.	Negative.
Platinum	Wire and foil.	S. to U.	Negative.
Gold	Foil, purity 99.9 %.	S. to U.	Negative.
	Wire, commerc. pure.	U. to S.	
	Jeweller's 18-ct. wire and sheet.	S. to U.	
	Jeweller's 15-ct. sheet.	S. to U.	
Silver	Wire and foil.	S. to U.	Negative.
Aluminium	Wire and foil, pure.	U. to S.	Negative?
Cobalt	Rod, 8 mm. diameter.	U. to S.	Positive.
Magnesium	Ribbon.	S. to U.	Negative.
Tin	Foil.	S. to U.	Negative.
Lead	Foil (assay).	No current.	Nil.

S. means stretched. U. means unstretched.

It will be seen that in every case excepting that of aluminium, and one out of five specimens of gold, there is perfect correspondence between the direction of the thermo-electric current and the sign of Hall's effect. With regard to the aluminium, a piece of the foil was mounted on glass, and Hall's experiment performed with it. As was anticipated, the sign of the 'rotational coefficient' was found to be positive, like that of iron, zinc, and cobalt. Either, therefore, Mr. Hall fell into some error, or the aluminium with which he worked differed in some respect from that used by the author. The anomalous specimen of gold, being in the form of wire, could not be submitted to the same test: it probably contained some disturbing impurity.

[To the foregoing article, Dr. Hall has favored the editor of *Science* with the following reply.]

Mr. Bidwell's table is certainly very suggestive, but his 'explanation of the Hall phenomenon' cannot stand.

He makes this phenomenon to be an incidental result of the manner in which the metal strip is attached to the plate of glass. It is, he says, like a beam rigidly fastened at both ends, and weighted in the middle. Without discussing the closeness of this analogy, one can see, that if we fasten the strip by its middle, and leave it free at both ends, the conditions upon which Mr. Bidwell supposes the phenomenon to depend are quite changed.

After reading Mr. Bidwell's paper, I took a strip of soft steel, about one-tenth of a millimetre thick, and made the usual connections, but, instead of fastening the strip to glass with cement, so arranged it that it could at will be clamped across its middle or across the ends to a sheet of hard rubber. The end-clamps were about three centimetres apart, and the width of the magnetic poles between which the strip was placed was considerably greater than three centimetres. Now, when the strip was clamped across its middle and left free at the ends, and was made to conduct a current of electricity across the magnetic field, it was like a beam supported at the middle, and with a load distributed from end to end; but when the strip was clamped at its ends and left free in the middle, it was like a beam supported at both ends, and with a load distributed from end to end. Experiment shows that the effect is positive, as I have always found it in iron and steel, whether the strip be clamped in the middle, or at the ends.

There is one other consideration to be urged. Mr. Bidwell would, I suppose, account for the fact that the observed effect is proportional to the magnetic force by saying that the strain would be proportional to this force. But how will he explain the fact that the effect is nearly or quite proportional to the current, as was shown in my first paper upon the subject? Let us see what his theory leads to. Doubling the current, the magnetic force remaining unchanged, would double the strain. But a doubled strain, with a doubled current, would make the heating and cooling from the Peltier effect four times as great as before. This would deflect the equipotential lines four times as much as before; and, as these lines are only half as far apart as before, the transverse current would be eight times as great as before the direct current was doubled. The transverse effect, then, would be proportional, not to the current, but to the cube of the current. EDWIN H. HALL.

Cambridge.

THE CREVAUX EXPEDITION.

E. MILHÔME writes from Corumba, Sept. 24, 1883, to the Société de géographie in regard to the possible survivors of the Crevaux expedition. He believes that several survived for a time, but were afterward put to death by the savages. Information of any sort could hardly be obtained; as the Tobas had made ready for war, and retired to the interior, holding no further communication with the neutral tribes from whom the previous vague news had been derived by the whites. The Indian survivors, from their terror and sufferings, can afford little help. It is known that Branco, one of the party, in his capacity of soldier, was preserved alive by the natives to instruct them in the use of the fire-arms which they captured; and it is possible he may be still living, but, if so, has

probably been carried far into the interior. It is certain that the Tobas who massacred Crevaux's party are now provided with hatchets, knives, and Remington guns, which they have captured, partly from Crevaux, and partly from the Bolivian expedition of Col. Rivas. They are not, however, so formidable as might be supposed; since it seems their captive instructed them to aim in such a way as to render it almost impossible that any thing of a man's height should be hit by the ball; so that the guns are more terrifying than dangerous to their enemies. The second expedition sent under orders of Col. Fontana accomplished nothing. The third, organized by Col. Sola, and since commanded by Col. Hazetta, is at present penetrating the Chaco region, toward the banks of the Pilcomayo. Another better prepared Bolivian expedition was in contemplation under Col. Campu; but the writer, broken down by fever, was obliged to return to Corumba on his way to Buenos Ayres. He fears that all traces of the expedition of Crevaux are lost; that even their remains cannot be recovered, since the Tobas are in the habit of utilizing the bones as trophies or for religious purposes, so that they would be widely separated and unrecognizable. The vertebrae of the hated Christians are in special demand among the Toba women for use as rattles or rattling pendants worn during their dances. Altogether, the savagery of these Tobas seems to be more energetic than that of any other American aborigines. Milhôme has sent to Paris a complete collection of their arms, tools, instruments, and clothing, with an explanatory catalogue.

On the other hand, M. Paul Armand, in the Bulletin of the Marseilles society for December, without mentioning any date (but published before Milhôme's letter), says that the Argentine expedition to the Pilcomayo arrived safely in the early part of August, at the Bolivian town of Caiza, without the loss of a man, although having fought three battles with the Tobas. They ascended the Pilcomayo sixty leagues beyond the place where the Crevaux party was assassinated. The Bolivian congress has resolved that a colony named after Crevaux shall be established at that point, and that it shall be marked by a monument to the sufferers. Thouar arrived at Caiza on the 12th of July; having heard from some neutral Indians that two survivors, Haurat and Branco, were prisoners with the Choroti Indians of the Rio Abajo. He had had some communication with the Tobas, and obtained some relics, among other things a barometer which had belonged to Crevaux. He intended to leave Teyo about Aug. 10, and pass completely round the north Chaco, on the left bank of the Pilcomayo. In January it was stated to the Société de géographie that Thouar had arrived safely at Assuncion, and was about to embark for France, where he was expected before this time. Nothing further is said in regard to his search for Crevaux; but it is stated that the most important result of his voyage will be the opening of a practicable commercial route between Bolivia and Paraguay, giving opportunities for a reciprocal commerce now valued at twenty million dollars.

A NEW THEORY OF HEREDITY.

The law of heredity: a study of the cause of variation, and the origin of living organisms. By W. K. BROOKS. Baltimore, *Murphy*, 1883. 12+336 p., illustr. 16°.

JAEGER is quoted by Semper as saying that there has been enough Darwinist philosophizing, and that it is now time to subject the numerous hypotheses to the test of investigation. While this is undoubtedly true, some hypotheses are necessary; and even incomplete and erroneous ones may be of great service by offering a series of definite problems for solution, instead of a chaos of facts. "An honest attempt to reason from the phenomena of nature can hardly fail to result in the discovery of some little truth." This is the keynote of the book before us, which is therefore worthy of very careful consideration, however unsatisfactory it may prove to be as an explanation of the great problem of heredity.

The theory proposed in this book is a modification of Darwin's hypothesis of pangenesis, reconstructed with a view of avoiding the many difficulties in the way of that hypothesis. Brooks's theory, very briefly stated, is as follows. 1. The union of two sexual elements gives variability. 2. In all multicellular organisms the ovum and the male cell have gradually become specialized in different directions. 3. The ovum has acquired a very complex organization, and contains material particles of some kind corresponding to each of the hereditary species characteristics. 4. The ovarian ova of the offspring are the direct and unmodified descendants of the parent ovum. 5. Each cell in the body has the power of throwing off minute germs. During the evolution of the species, these cells have acquired distinctive functions adapted to the conditions under which they are placed. When the function of a cell is disturbed through a change in its environment, it throws off small particles, which are the germs or 'gemmules' of this particular cell. 6. These germs may be carried to all parts of the body, and penetrate to an ovum or to a bud; but the male cell has acquired a peculiar power to gather and store up germs. 7. When impregnation occurs, each gemmule impregnates that particle of the ovum which will give rise in the offspring to the cell corresponding to the one which produced the gemmule; or else it unites with a closely related particle, destined to produce a closely related cell. 8. In the body of the offspring this cell will be a hybrid, and tend to vary. 9. The ovarian ova of the offspring inherit the properties of the fertilized

ovum directly, and the organisms to which they give rise will tend to vary in the same manner. 10. A cell which has varied will continue to throw off gemmules, and so cause variations in the corresponding parts of the bodies of descendants, until a favorable variation is seized upon by natural selection. 11. The ovarian ova will directly inherit the selected variation, and will transmit it as an hereditary race characteristic without the agency of gemmules. 12. The occurrence of a variation, but not its precise character, is due to the direct action of external conditions.

These positions Professor Brooks endeavors to establish by a great number of facts, taken almost exclusively from Darwin. He first combats the view that the sexual elements play similar parts in reproduction, and the objection seems to be well taken; though, when he says that it cannot be shown that either sex may transmit *any* characteristic whatever, he pushes his objection too far, as is demonstrated by a multitude of facts in the breeding of domestic animals.

Having stated the theory, the author devotes a large part of his book to the evidence in its favor. From the study of hybrids he concludes that hybrids and mongrels are highly variable; that the children of hybrids are more variable than the hybrids themselves; and that, from the evidence of reciprocal crossing in the case of hybrids, variation is caused by the influence of the male. The evidence from variation is then considered, showing that variation is more common in sexual than in asexual reproduction (in plants at least); that changed conditions cause variation, not directly, but in subsequent generations; that specific characters are more variable than generic; that parts excessively developed in males are more variable than parts especially developed in females. Professor Brooks next takes up the very complex subject of secondary sexual characters, and shows from various kinds of evidence that the male is more variable than the female; and that the male has led the way in evolution, while the female has followed. One of the most important aspects of the hypothesis, the author considers to be the manner in which it removes objections to the theory of natural selection, by showing that large numbers of animals vary similarly and simultaneously, and so give an opportunity for natural selection to come into play.

Now, how far can this ingenious and ably supported hypothesis be regarded as a permanently valuable contribution to science? One great objection is apparent at the very outset, — that the author has not gone to nature for his facts, but has taken them almost entirely from Darwin's works, as he candidly says. This must necessarily impair the value of his conclusions. The whole work bears the stamp of being merely an ingenious attempt to supplement Darwin's hypotheses, and re-arrange his facts, and might have been written by one whose knowledge of biology had been drawn almost entirely from Darwin's books. The objection which Mr. Lewes[1] made to pangenesis holds equally well against this hypothesis. "The hypothesis is thus seen to be one wholly constructed out of suppositions, each and all of which may be erroneous, every one of them being necessary to the integrity of the scheme." Thus, the existence of gemmules is a supposition; that cells throw them off when disturbed is a supposition; that the male cell has acquired a special power of gathering and storing these germs is a supposition. Scarcely a single proposition of the hypothesis can be regarded as in any way proved. Then, again, some of the apparently simple assumptions really involve a number of others, equally without evidence. Thus, when it is said that the ovarian ova, being the direct descendants of the fertilized egg, inherit its peculiarities, we have no explanation offered for what is perhaps as great a mystery as the main problem itself. The ovarian ova are derived from the fertilized ovum through an immense number of intermediate cells, most of which become indifferent epithelium. We must, then, assume that the gemmules are all segregated together, and transmitted unchanged from cell to cell till they finally reach the ovarian ovum, — surely a very forced supposition.

The evidence by which Professor Brooks endeavors to support his hypothesis is by no means convincing: usually all that can be said of it is, that it does not contradict the view. In spite of his evident candor, the author has not always resisted the temptation of straining his points to the uttermost limit, often preferring a far-fetched and doubtful explanation to an obvious one close at hand, as in the cases of the zebra and niata hybrids on p. 130. The statement that the peculiarities of the niata breed of Paraguay cattle are probably due to a *reversion* to the type of Sivatherium will be an amusing one to paleontologists.

Then it is not at all clear, from the evidence presented, that this hypothesis will account more satisfactorily for the greater development of the male in those species in which the sexes differ than does Darwin's theory of sexual

[1] *Fortnightly review*, new series, vol. iv., p. 508.

selection: for, admitting Professor Brooks's doctrine, that each individual inherits *all* the characteristics of the species, and that the female function prevents the development of the male characters (though they may appear when that function is destroyed), it is plain that those characters are either incompatible with the female function or useless to the female, and hence there is no reason why she should acquire them; while their presence in the male, to which they are of obvious advantage, is in most cases to be accounted for by sexual selection. On the other hand, it is obvious that all the complex apparatus of uterus, placenta, and similar organs, must have originated with the female. We cannot agree with Professor Brooks, that the presence of mammae in the male is an indication that the mammary function was originally a male characteristic, any more than that the presence of rudimentary stridulating organs in female Orthoptera shows that these were first acquired by the female. Why should Professor Brooks adopt exactly opposite explanations for precisely parallel cases?

The propagation of cells by means of gemmules is not only purely hypothetical, but, apparently at least, opposed to what we know of the mode of cell-formation. Cells arise only by division of some pre-existing cell, and never seem to arise spontaneously, as would very probably be the case if their propagation by gemmules were at all common. Nor does the process of impregnation, as actually observed, lend support to the new hypothesis; for the head of the spermatozoon coalesces with the nucleus of the ovum, apparently without loss of bulk, or in any way indicating an emission of gemmules. The influence of the male element seems rather to consist in modifying the action of the egg-nucleus.

Mr. Conn's very obvious objection (given on p. 294), that in many cases unfavorable conditions would not act upon certain cells, causing them to emit gemmules, but would result in the destruction of the animal, seems entitled to more weight than the author is inclined to give it. Any hypothesis that fails to account for so large and important a class of facts cannot be called complete.

Want of space compels the omission of many other objections, as well as the consideration of Professor Brooks's views on reversion, natural selection, and the intellectual differences between men and women.

But, in spite of all that has been said, Professor Brooks is entitled to the thanks of all students of biology for his clear statement of the problem, and the many suggestive fields for investigation here opened. The student of heredity will find in this book just what he needs to give him a clear conception of how the problem is to be attacked. The book is one of remarkable ability. The way in which apparently disconnected series of phenomena are brought together and shown to be special cases of one general principle, is indeed masterly. Even if every single proposition of the hypothesis should prove to be without foundation, and the hypothesis entirely untenable, Professor Brooks must always be credited with having made a most important step in advance. Assuming that the problem of heredity is at all capable of solution, some such preliminary clearing of the field is a necessity. If different observers will devote their energies to following up the various lines of inquiry which Professor Brooks has so ably suggested, we may be sure of most valuable and fruitful additions to our knowledge. To use Mr. Lewes's words, "even should the hypothesis prove a will-o'-wisp, it is worth following if we follow circumspectly, for it hovers over lands where we may find valuable material. As an hypothesis, it so links together wide classes of facts that it may be a clew to great discoveries."

WATTS'S MANUAL OF CHEMISTRY.

A manual of chemistry, physical and inorganic. By HENRY WATTS. Philadelphia, *Blakiston*, 1884. 16+595 p. 8°.

FEW text-books of chemistry have been more successful than the 'Manual of elementary chemistry' first published in 1845 by Professor George Fownes. Fownes, who was but thirty years of age at the time, held the chair of chemistry in University college, London. His work had marked success from the very beginning, and he was called upon to prepare three editions in the succeeding four years. The third, however, appeared posthumously; for Fownes died in January, 1849, at the early age of thirty-four. Under the editorship of the late Dr. H. Bence Jones, and afterwards of Dr. A. W. Hofmann, the work appeared at frequent intervals in six editions; and, notwithstanding the constant additions of large amounts of new and important matter, the familiar name 'Fownes's chemistry' was retained. The tenth edition was edited by Dr. Bence Jones and Henry Watts, and appeared in 1868; another edition, by Henry Watts, followed in 1872; and finally a twelfth, greatly increased in size, and issued in two volumes devoted to inorganic

and organic chemistry respectively, completed in 1877 the long and valuable series.

The honorable career of this standard work reminds us of that other remarkable handbook, the '*Cours de chymie*' of Nicolas Lemery, of which the first edition appeared in 1675, and the fourteenth, greatly enlarged by Baron, in 1756, eighty-one years after.

The new work by Henry Watts is confessedly "founded on the well-known manual of chemistry of the late Professor Fownes;" and, such being its origin, we are not surprised to find that it wears the garb of a familiar friend. The learned editor of 'A dictionary of chemistry' has in this manual dropped the name 'Fownes' from the titlepage, and given us a revised edition bearing his own name. And this he undoubtedly has a right to do, if one takes into consideration the great alterations and additions made in the preceding editions with which his name was associated, together with the improvements in the one before us.

The present volume commences with a short sketch of the more important elementary bodies, the principal laws of chemical combination, the principles of nomenclature, and the representation of the constitution and reactions of bodies by symbolic notation. In the preceding edition (twelfth) of Fownes the three topics last named were treated at p. 123 of the volume: here they appear at p. 7.

This introduction is followed by a section on chemical physics which has always occupied a prominent place in the several editions of Fownes. The next section contains a description of the non-metallic elements in the following order: hydrogen, chlorine and its analogues, oxygen, sulphur and its analogues, nitrogen, phosphorus, arsenic, boron, silicon, and carbon. This is succeeded by a fuller consideration of the general principles of chemical philosophy, embracing sections on quantivalence, the periodic law, crystallization, and chemical affinity. At this point is introduced the subjects of electro-chemical decomposition, or electrolysis, and the chemistry of the voltaic pile, which are thus divorced from their rational connection with the chemical physics in the earlier portion of the work. The latter half of the volume treats of the metals in their usual systematic order.

Watts's chemistry, on the whole, differs more from its predecessor in the arrangement of material than in the introduction of novelties; still, we find new paragraphs here and there, embodying late discoveries. The work shows evidences of having been rather hastily prepared. Thus, while the newly announced elements, scandium, decipium, ytterbium, and samarium, are briefly described in their proper connection (pp. 458 to 463), only two of them (Sc and Yb) obtain positions in the list of elementary bodies on p. 3. Again: under oxygen we find no mention of its liquefaction, though in the section on chemical physics the experiments of Cailletet and Pictet are, far too briefly, chronicled. Ozone fares very badly, obtaining no recognition whatever in the body of the work, and being relegated to a single page (584) at the very close of the appendix; and there it is very inadequately treated. Its liquefaction by Hautefeuille and Chappuis is not mentioned. The page is a simple condensation of the two pages given to the subject in the preceding edition of Fownes, without the addition of a single new fact. The atomic weight of antimony still appears as 122, notwithstanding the great weight of evidence in favor of 120. Meyer and Seubert make Sb = 119.6.

The well-worn woodcuts, too familiar and never very attractive, still do service in illustration. The volume contains thirty-four pages more than the English edition of the last issue of Fownes. In spite of some blemishes, however, Watts's Chemistry sustains the high reputation of its lineal ancestor, and well deserves a large patronage.

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Topographical work in North Carolina.—Party No. 1 of the Appalachian division was in charge of Mr. Charles M. Yeates, topographer, and, during the seasons of 1882 and 1883, surveyed the area lying between the Blue Ridge and the Tennessee line in North Carolina, with the exception of Watauga, Ashe, and Alleghany counties. This area lies between the 35th and 36th parallels, and extends from the 82d to the 84th degree of longitude, including the most mountainous portion of the state, and that which is usually designated as western North Carolina.

The state line separating North Carolina and Tennessee follows the summit of the Alleghany Range, which, in its different parts, has received various specific names; such as the 'Unaka,' the 'Bald,' and

the 'Smoky' Mountains. These names are applied to the portions that lie between terminal points where the rivers intersect it. Other local names have been applied to minor subdivisions and to summits; but the most prominent portions are known to the native population by names which agree with those used on the existing published maps of the region.

The Alleghany Range and the Blue Ridge are in general parallel to each other. The greatest distance between them is across Haywood and Transylvania counties, where they are fifty-five miles apart; while where they are closest they are only eight miles apart. They are also parallel with the coast-line; and a contour map of the state will show that it is crossed from south-west to north-east by a series of parallel ridges from a point within four miles of the coast to the Blue Ridge. The first of the ridges reaches an elevation of between seventy and eighty feet; and the succeeding ones increase in height, one after the other, until they culminate in the mountains of the western part of the state, where the general elevation is from 4,000 to 6,000 feet.

The Blue Ridge in this section is of peculiar interest, because in its details its course is very crooked. It is entirely unlike the long, straight ridges of eastern Tennessee. It enters the state from Virginia with an elevation of 4,000 feet above sea-level, and reaches its maximum height of about 6,000 feet at Grandfather Mountain, which is the highest summit in the ridge; although hitherto, High Pinnacle, near the Black Mountains, has enjoyed that reputation. The next highest point to the southward is Sugar Mountain, with an elevation of 5,200 feet. From the latter point the range drops to low summits, that do not usually exceed 3,600 feet above sea-level. These continue southward to Humpback Mountain, a distance of fifteen miles, when there is a rise to 4,800 feet; and from here to Bear Wallow Mountain the range is of a quite respectable elevation. At High Pinnacle, where the ridge joins the Black Mountains, the height is 5,600 feet. From Bear Wallow southward, the range is comparatively insignificant; but, as the state line is approached, it once more rises, and is of considerable importance as it passes from the state.

South and east of the Blue Ridge are the lowlands, while to the westward is the high plateau section. The difference in elevation between the two is generally about 1,000 feet in a distance of some two or three miles. The difference in seasons, between the two sections, is from two to three weeks. A view of the ridge from the west, at many points, would give an idea of insignificant elevation; whereas the same section, seen from the east, would be quite imposing. This peculiarity of the ridge is characteristic in North Carolina, with the exception of the section lying between Humpback Mountain and Sugar Mountain, in which the eastern and western descents are about equal.

North Carolina, west of the Blue Ridge, contains about 75,000 square miles, of which some 5,500 have already been surveyed, — 4,000 by Mr. Yeates's party, and 1,000 by Mr. Bien. The remaining portion will be surveyed by Mr. Yeates during the next season. The map will be on a scale of two miles to the inch, with contours two hundred feet apart vertically, which will show the country in considerable detail. The existing maps of the region have all been generalized, and are more or less indefinite.

The topographical features of the region are entirely dissimilar to those of the adjacent portions of Virginia and Tennessee. In the latter the strong orographical features of West Virginia and south-western Virginia gradually die out, while in North Carolina there appears to be no regular system when compared with the other states. The only resemblance is, that the Blue Ridge and the Alleghany Range are in general parallel with the ranges of East Tennessee. The distinctive topographical feature in North Carolina is the existence of cross-ranges which connect the Blue Ridge with the Alleghany Range, making immense drainage-basins, whose outlets are through the latter to the western river-systems. These cross-ranges, with the exception of the Great Smoky Mountains, are of more importance than the ranges which they connect; as they generally have a greater altitude, many of the summits reaching a height of more than 5,000 feet. The principal ones are the Rich Mountains, the Cockscomb Range, the Newfound Mountains, the Great Balsam Mountains, the Cowee Mountains, and the Nantehaleh Mountains. The Balsam Mountains share with the Smoky and Black Mountains of North Carolina, and the White Mountains of New Hampshire, the distinction of being the highest mountain masses in the eastern United States. The spurs of the cross-ranges form an intricate maze of drainage and topographical details.

The Black Mountains, a range ten miles in length, with seventeen summits, are neither one of the cross-ranges nor one of the transverse ranges, but a spur from the Blue Ridge, with which they are parallel. The highest point is Mitchell's High Peak, which is the highest summit east of the Rocky Mountains. Mr. Yeates, by barometrical measurement, obtained for it a height of 6,717 feet, which is six feet higher than any previous measurement. The coast and geodetic survey, by means of vertical angles, fixed its height at 6,688 feet above sea-level. The elevation given by Professor Guyot is 6,707 feet. Major James W. Wilson, chief engineer of the W. N. C. R.R., at the request of Gov. Swain of North Carolina, ascertained its height by means of levels, and fixed it at 6,711 feet.

The French Broad River is the principal stream of western North Carolina, and is a stream of much beauty, flowing through a valley of great fertility. Its course in the Transylvania valley is very sinuous, and its flow sluggish. The Indians designated this portion of its course 'sleeping serpent.' From Dunn's rock, a precipice that overlooks it, thirty-six bends can be counted as the river winds in its tortuous course through the farms in the valley below. Almost all the small streams, as well as the large rivers, of the section, have good water-powers, which must eventually be utilized for manufacturing purposes.

The timber-lands of the region form immense unbroken forests, exceptionally fine both as to density of growth and the character of the timber. Among the varieties of wood are maple, poplar, linden, balsam, cedar, hickory, ash, beech, birch, cherry, black walnut, and many varieties of oak. Some of the trees grow to an enormous size; and many men in this section, who a few years ago considered themselves poor because they possessed only a wilderness of forest, are beginning to realize that they are comparatively rich, the sale of a few individual trees frequently sufficing to give them an income for a considerable time. These trees are bought by speculators, who, in turn, sell them to other speculators, who may dispose of them to third parties, until finally a portable saw-mill is brought into the region, and the timber is prepared for market. A view from one of the cleared summits impresses one with the extent of the forests, which are, of course, broken here and there by many dots of cultivated land, both in the valleys and on the mountain sides. The country, however, is comparatively undeveloped. The soil is good, but farming is carried on in a primitive way and on a contracted scale. There is plenty of good grazing-land, and cattle are raised to a considerable extent. They are allowed to run wild among the mountain ridges; and the cost of keeping them is small, as they are allowed to find subsistence for themselves.

The mineral wealth of the region is well known. In fact, it has been said that almost every mineral or ore found within the limits of the United States can be found in North Carolina. The gold-mines east of the Blue Ridge have produced millions of dollars, notwithstanding the hinderances of swindlers and speculators. Mica-mining is one of the profitable industries of the region mapped by Mr. Yeates, and is carried on in nearly all of the counties west of the Blue Ridge. Kaoline and corundum mines are also worked, and a large deposit of talc is attracting considerable attention, while tin is the latest discovery.

PUBLIC AND PRIVATE INSTITUTIONS.

Peabody academy of science, Salem, Mass.

The director's trip to Japan. — Professor Morse left Salem early in the spring of 1882 for the purpose of visiting Japan and China, and reached Japan in May. On his arrival in that country he had several interviews with Mr. Kato, the director of the Imperial university, and told him that his time was to be divided between collecting ethnological material for the museum of the academy, and the study of ethnology and archeology, and specially the ceramic art. A suite of rooms in a little house near the astronomical observatory was fitted up for him by the university, and given to him free of cost during his entire stay. Rooms and closets in other college-buildings were given to him for storage purposes; and, indeed, every thing was done by the Japanese authorities to facilitate his work, without which assistance little progress could have been made in the task he had planned.

In return for the collections of corals sent out by the academy for the educational museum, the educational museum presented to the academy a large collection of tools illustrating the trades of Japan. Great credit is due Mr. Tejima, the director of the educational museum, for the thorough way in which this collection was brought together. Not only were the various implements collected; but in many cases partially completed specimens of the work, as well as colored sketches, accompanied the tools.

Through the influence of Dr. W. S. Bigelow, the academy is indebted for the remarkable collection of weapons which were presented by a famous sword-merchant, Mr. Machida Heikichi. Having explained to Mr. Machida the objects of the academy, and the nature of its museum, Mr. Machida, with great pains, and at his own expense, brought together the invaluable collection of swords, spears, bows and arrows, and other weapons which now enrich the academy's museum, and presented them outright, properly labelled and prepared for shipment.

Mr. Takanaka Hachitaro supplied the Japanese names for all the objects collected. He also presented many objects of household use, and clothing. Professor Mitsukuri, at great trouble, sought out the proper person to whom was intrusted the making of the large figures which now adorn the museum, and personally superintended their dressing and arrangement.

Korean collections. — Through Capt. Hammond Professor Morse was made acquainted with Count von Mollendorff, then on his way to Korea as special commissioner for China. He authorized him to spend a limited sum for purchases of ethnological materials in that country, and gave him a brief list of desirable objects. The results of his work, filling four cases, have already been received and unpacked. They arrived in fair condition; and as far as he knows, this is the first collection of Korean objects ever sent from that country. In this connection it is proper to mention, that members of the Korean embassy who visited this country last year presented a number of objects to the academy; and one of their suite, Mr. Yu Kil Chun, who remained in this country, and who is now living in Salem, presented his entire suit of clothing, and other objects, to the museum.

Accessions to the museum. — These have been more numerous and more valuable than during any year, perhaps, since the foundation of the East India marine collection in 1799. The principal ones are as follows: —

Morse collection, Japan, 680 numbers; Morse collection, elsewhere, 141; William Dolan, China, 50 specimens. Additions to county collections: plants, 54; mammals, 50; and archeology (85 lots), 322 specimens (this last includes about 15 lots, 50 specimens outside); botanical, 200; other accessions, 300; models of boats, 12.

Visitors to the museum. — Thirty-six thousand and fifty-six persons have visited the museum during the year. The greatest numbers on single days were: Feb. 22, 440; July 4, 182; April 5 (Fast), 346; Sept. 25 (first day of cattle-show), 384; Sept. 26 (second day of cattle-show), 936; Nov. 29 (Thanksgiving),

336. July 4 is mentioned to show how few persons are often at the museum on holidays now, as compared with the attendance on such days in former years, especially in summer, when 'attractions' are offered at the 'Willows,' 'Point of Pines,' and other popular resorts in the neighborhood.

The above figures are undoubtedly under the actual numbers. There is a steady increase, each year of late, in the regular daily attendance, and a corresponding decrease on popular holidays.

The specimens which seem to be of most interest to the general public are the life-size figures from China, Japan, India, and other countries; the general collection of mammals and birds; the Essex county animals and woods; and, perhaps more than any thing else, the human skeletons and crania. The carving 'Heaven and the day of judgment' of course holds the first place for the seeker after the curious and wonderful.

RECENT PROCEEDINGS OF SCIENTIFIC SOCIETIES.

Ottawa field-naturalists' club, Canada.

March 13. — Mr. W. P. Lett read a paper on the deer of the Ottawa valley. Of these, the most important as regards size is the moose, or American elk (Alce americanus), which unfortunately, owing to indiscriminate slaughter and illegal hunting, is rapidly becoming very rare, except in remote districts along the northern tributaries of the Ottawa. The woodland caribou, or reindeer (Rangifer caribou), formerly frequented the whole country on the north side of the river, but was only an occasional straggler on the opposite shore. Like the moose, it has been driven northward, and much diminished in numbers, although sometimes still found on the Des Licores River, fifty or sixty miles from its mouth, on the upper Gatineau, and to the north of Lake Nippissing. It is the swiftest and wildest of all deer; and the only successful method of capturing it is by still-hunting. The magnificent wapiti, or great stag (Cervus canadensis), falsely called the American elk, was, within the memory of persons still living, an inhabitant of the great hardwood forests along the Ottawa, and was seen within four miles of the spot where the city now is. Fragments of its enormous antlers are still turned up by the plough in various localities, but the stately monarch of the forest has retired to the far northwest territories. The common red or Virginian deer (Coriacus virginianus) is still found within a few miles of Ottawa, but owing to pot-hunting and slaughtering during the winter, when the snow is deep, is becoming annually less plentiful. Not many years ago immense yards, containing hundreds of deer, existed along the various tributaries; but, except in remote districts, the yards are now scattered and small, and the deer confined chiefly to the large swamps. Reference was made by the lecturer to the variety of this species known as the 'spikehorn,' and to interesting piebald and white specimens which had been observed by him. A fine collection of heads and antlers of the several species was shown, including some abnormal antlers from old red bucks.

Society of arts, Boston.

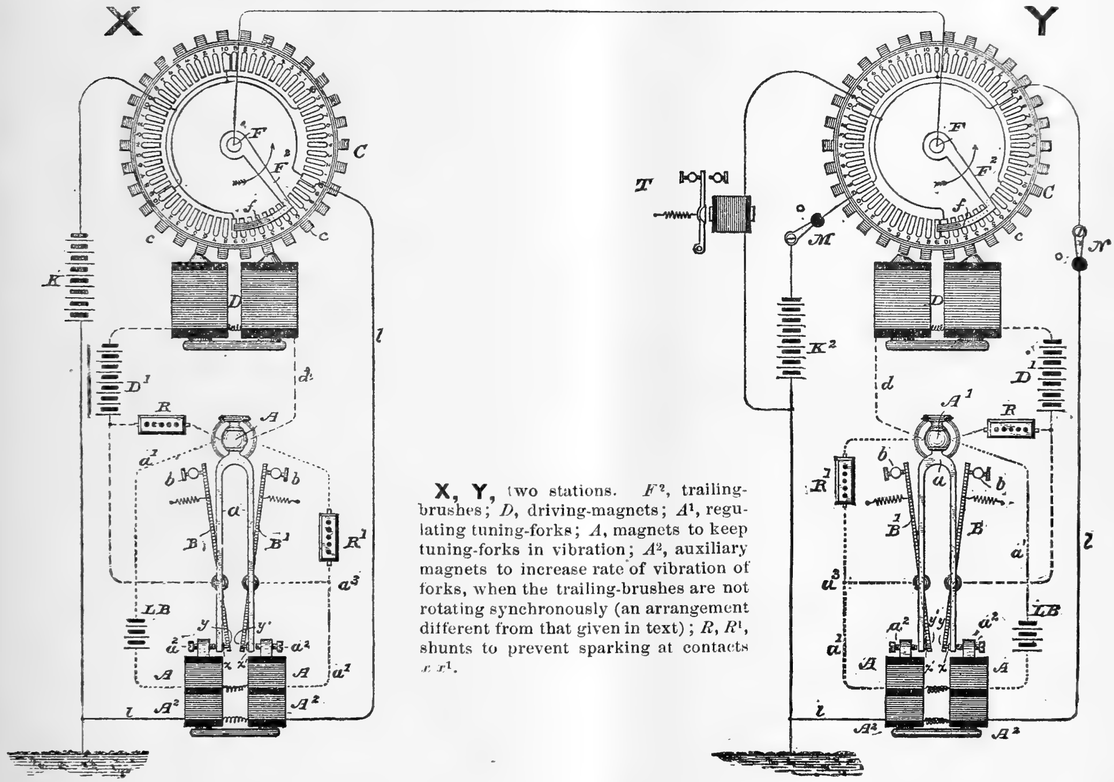
March 13. — Mr. P. B. Delany of New York gave the first public exhibition and description of his new system of synchronous, multiplex telegraphy, — the result of inventions by Mr. P. La Cour (1878), Mr. E. A. Callahan of New York, and himself (1883). By this system any number, up to twelve, of fast Morse circuits can be simultaneously worked over a single wire, the messages going in either direction on any circuit; also a greater number of slow Morse circuits, and as many as seventy-two printing-circuits.

At each end of the main line a drum, called a distributer, is maintained in uniform rotation about a vertical axis by the intermittent attraction of an electro-magnet on the toothed circumference of a horizontal circular plate carried by the drum. A tuning-fork, vibrated electrically (about eighty-five vibrations), opens the motor circuit at each vibration, and thus produces the intermittence in the motor magnet driving the distributer. If the forks at either end of the line were in absolute unison, and the toothed circumference had the same number of teeth each, the drums would rotate synchronously. The impossibility of absolute and continued unison is met by automatic regulation of the rate of the forks, the principle involved being an automatic shunting of a resistance-coil which is normally in the circuit driving the fork; thus increasing the current in that circuit, and hence amplifying the excursion of the prongs, intensifying the field of magnetic force in which this vibration occurs, and thus diminishing (by even five per cent) the rate of the fork. This slowing-down of the fork would immediately result in a corresponding lessening of the speed of rotation of the distributer at that end of the line.

The main principle of the multiplex use of the single line consists in giving the line synchronously, and in sufficiently rapid succession, to the corresponding instruments or circuits at the opposite ends of the line. In the apparatus shown, the rotating drum or distributer carried a brush which trailed over a circular series of eighty-four narrow, insulated, radial plates or segments of metal. Of these, twelve were utilized for the synchronizing arrangement, and the remaining seventy-two were divided among six circuits; the terminus of the same circuit being thus connected to twelve equi-distant segments, each circuit containing merely the ordinary polarized relay, reversing key and ground; the relay serving to close the local circuit through a sounder, as usual. Thus, when the brushes at both ends of the line make contact at the same instant with any one of the twelve segments of the same circuit, that circuit, and no

other, can be in operation. As the synchronous rotation continues, each circuit will be in turn closed through the single main-line wire in succession, and each twelve times in a rotation, and thirty-four times in a second. The frequency of successive closings of the same circuit is thus so great, that, in the fast-working Morse instrument, one closing at least will occur in even the shortest signal, so that no dot can be missed.

The automatic synchronizing device consists in having three equi-distant segments in each set about twice as broad as the others, the segment next preceding each of these being idle. The relative positions of these broad segments are not the same in the two sets; but, in the position corresponding to every broad segment of either set, there is, in the other set, an ordinary narrow segment connected with a grounded battery (the same battery serving, of course, for all three segments of each set). The broad segments are all grounded. The two distributers will be synchronous when the brush of one is on any one of its narrow-battery segments at the same instant that the brush of the other is on the idle segment next preceding the broad one. If the synchronism is perfect, both brushes will pass off these segments at the same instant. If, however, the brush on the idle segment is ahead of such a synchronous position, it will pass on to the broad segment while yet the other brush is on the narrow-battery segment: a current through the line and broad-segment contact to ground will ensue. This current excites a relay (located between the broad segment and the ground), which opens a local relay circuit (normally closed). As the armature of this second relay comes sharply to its back-stop, it short-circuits the resistance-coil previously alluded to as being in the circuit of the fork-driving battery, and thus effects a slowing-down of the fork and distributer, as before described. As there are three broad segments to be touched in each revolution, this synchronizing pulse may be sent thrice, twice, once, or not at all, as may be necessary, in either direction during each revolution. The two distributers may thus be kept within one-quarter of the width of the narrow segments of each other; this corresponding to a synchronism of about 0.001 of a second, or about 0.002 of a revolution.



X, Y, two stations. F^2, trailing-brushes; D, driving-magnets; A^1, regulating tuning-forks; A, magnets to keep tuning-forks in vibration; A^2, auxiliary magnets to increase rate of vibration of forks, when the trailing-brushes are not rotating synchronously (an arrangement different from that given in text); R, R^1, shunts to prevent sparking at contacts x x^1.

Trenton natural history society.

March 11. — W. S. Lee remarked on New Jersey as a paradise for the botanist, particularly commending the region about Trenton as one rich in rarities of plant-life. A certain hillside sloping to the south presents many spring flowers two weeks earlier than similar locations in even the same state; and several rare species grow there, among others Corydalis aurea and C. flavula. Other rare New-Jersey species mentioned as found near Trenton were Fedia olitoria, Ellisia nyctelea, Onopordon acanthium, Potentilla

argentea, Viola striata, and Cornus canadensis. —— Dr. T. S. Stevens exhibited a little garter-snake (Eutaenia sirtalis) preserved by nature in an interesting manner. It had been taken from beneath a wheat-stack in its present condition, the body thrown in graceful coils and curves, the head erect, the whole appearing like a snake on the alert, yet dead, perfectly dry and mummy-like, and presenting only the slightest changes externally. According to Dr. Stevens, it has remained in this condition, without any special attention, for ten years.

Academy of natural sciences, Philadelphia.

March 4. — Professor Joseph Leidy stated that he had recently been supplied with specimens of a wheel-less rotifer, attributed to Apsilus, which had been found abundantly last autumn, in a pond at Fairmount Park, attached to Anacharis, and in the Schuylkill River, near by, attached to Potamogeton. They were recognized as Dictyophora, first described in 1857; and as a result of the last examination, Professor Leidy was led to the opinion, that this form, the Apsilus lentiformis of Mecznichow, the Capelopagus lucinedax of Forbes, and the Apsilus bipera recently described by Miss Foulke, are all the same species. In the recent specimens, he had recognized the lateral antennae ending in exceedingly delicate and motionless cilia, as indicated by Mecznichow, and which previously, from the wrinkled condition of the specimens detached from hard objects, had escaped his attention. In all the forms described, the prehensile cup, in the same manner, is projected from, and withdrawn within, the mouth of a compressed oval or nearly spherical carapace, dotted with minute tubercles. This cup, substituting the usual rotary organs of rotifers, communicates with a capacious, variably sacculated, and dilatable stomach, followed by the ordinary gizzard with its mastax, and then a second sacculated stomach. The size of the European forms is fully thrice that of the one now described. —— Miss S. G. Foulke described a species of ciliated infusorian of the genus Trachelius, found in the form of a white speck in water from the Schuylkill River. —— Rev. Dr. H. C. McCook, referring to the spinning-work of spiders, stated that the orb-weavers have, as a rule, but one egg-nest; but this, in the different species, varies widely in form, size, position, etc. There are, however, four species which make several cocoons in connection with their webs. The labyrinth spider, Epeira labyrinthica, weaves a web of right lines crossing at all angles above the orb-web. In the midst of these right lines the spider lives, almost always under a dried leaf. Under the leaf is a little white silk tent or belt-shaped nest connected with the web by a trap-line. Hanging above the tent are nearly always five cocoons, braced above and below by a strong silken line. They consist of a lower cup portion, covered by a sort of lid, and each contains about twenty eggs. The tailed spider, Cyrtophora caudata, generally makes five nests, containing in the aggregate a hundred or a hundred and twenty-five eggs. These are strung along the median line of the orb-web. They are at first composed of a yellowish, slightly viscid plush, and are afterwards covered with fragments of captured insects. This may be an instance of protective mimicry, as the cocoons so covered closely resemble the spider itself; or it may be due to the maternal impulse to protect the repositories of the young as far as possible. Epeira basilica, which forms a beautiful dome-like web placed over a silken sheet, suspends its cocoons vertically in the centre of the snare. They consist of a dusky gray silken sac, within which is a hard ball like a cherry-stone. This ball is quite black, but proves, when placed under a microscope and illuminated, to be woven of a fine-textured yellow silk. It is filled with finely chopped silk, in which the young spiders are hatched. Uloborus riparia makes a horizontal web, the cocoons being strung horizontally from the centre. They are double cones, covered with little protective points.

Mathematical section, philosophical society, Washington.

Jan. 30. — Mr. G. K. Gilbert made a communication on the Knight's tour, on other fields than those of sixty-four squares. He showed that a complete tour was impossible if the number of squares was odd; that a tour having *bilateral* symmetry (latter half of the moves symmetrical with former half, with respect to a line through the centre of the field) was impossible if the number of squares was divisible by four, and hence altogether impossible on square fields; that a tour having *quadri-radial* symmetry (divisible into four parts, which exactly repeat themselves when the board is turned through a right angle about the centre of figure) was impossible if the number of squares was divisible by eight; that the only symmetry possible on the ordinary chess-board was therefore *bi-radial* (of two parts that coincide when the board is turned through two right angles). Upon a field of thirty-six squares, twenty tours with bi-radial symmetry are possible: of these, five have also quadri-radial symmetry.

NOTES AND NEWS.

THE following communication, kindly placed in our hands by the committee on invitations and receptions of the Philadelphia meeting of the American association, will interest the members of the association: —

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE,
22 ALBEMARLE STREET, LONDON, W.,
Feb. 27, 1884.

DEAR SIR, — The resolution of the American association, inviting members of our association to visit Philadelphia and take part in its meeting, was read to our general committee by Principal Dawson, and was received with enthusiasm. No definite resolution in reply was, however, proposed; because it was felt that the visit to Canada was only then assuming definiteness as to its outlines, and it was impossible to say what arrangements might be made in that country. But the members of the association were fully sensible of the courtesy and kindness of their American brethren; and the enclosed resolution, which was passed by the council at their last meeting,

and which I should have forwarded to the secretary of the American association as soon as the minutes had been confirmed, will, I hope, be regarded as a reply from our association.

The kind invitation repeated in your letter shall be embodied in a circular which we are about to issue to our members. I fear that at present it will be impossible for me to give you any idea of what number of our members will be able to avail themselves of the hospitality offered by your committee at Philadelphia, because at present only the bare outlines of the proposed proceedings at Montreal and in Canada are before them. When the immediate pressure of the issue of this circular is over, I will do my best to find out.

Very truly yours,
T. G. BONNEY, *secretary*.

Dr. P. FRAZER, *secretary*.

The resolution mentioned reads, —

"It was resolved to receive the standing committee and fellows of the American association on the footing of honorary members at the Montreal meeting, and the secretary was instructed to give intimation of this resolution, as far as possible, to the persons concerned."
